LOCKS SAFES AND SECURITY

The hardcover book, Locks Safes and Security by Marc Weber Tobias 2nd edition, was published in 2002. This work was followed by an electronic version called LSS+ CD a few years latter.

The LSS+ CD contains a lot more content than the book. Content has been updated as of 2004. It is released with 3 separate security levels, Public, Locksmith, and Government.

This document is a pdf version of the material extracted from LSS+. It contains material at Public, Locksmith and Government Levels

Locksmith vs Government Level Material:

Book 1 Chapters 1 thru 23 are identical
Book 2 Chapter 24 thru 30 are identical
Book 2 Chapter 31 is different (Decoding)
Book 2 Chapter 32 is identical
Book 3 Chapters 33 thru 36 are identical
Book 4 Chapters 37 thru 39 are identical
Book 4 Chapter 40 is different (Alarms)

LSS+ Electronic Infobase Edition of Locks, Safes, and Security

Version 5.0-04185

This infobase includes the revised editions of The Art of Manipulation;(1) A Treatise on Fire & Thief-Proof Depositories and Locks and Keys(2), originally published in London, in 1850; and Locks and Safes: The Construction of Locks(3), by A.C.Hobs. Locks, Safes, and Security(4) was first published in 1970 by Charles C. Thomas Publishers, Springfield, Illinois. The Second Edition was released in 2000. Supplementary materials can be found at the website www.security.org.(5)

Created by Marc Weber Tobias, B.S., J.D.

Member: ABA, ASIS, AFTE, IAI, ALOA, SAVTA, APA, AAFS, IAIL

The Books within the Infobase

LOCKS, SAFES, AND SECURITY

Electronic Infobase Version 5.0, based upon the Second Edition, published by Charles C. Thomas, Springfield Illinois, 2000. The original edition was published in 1970 and is no longer available.

Table of Contents

Master Exhibit Summary: Locks, Safes, and Security

Chapter 1 The Lock: Four Thousand Years of Technology

Chapter 2 The Last Twenty-Five Years

No Exhibits

Chapter 3 Definition of Terms

Chapter 4 Tools and Supplies

Chapter 5 Materials and Processes

Chapter 6 The Development of Keys

Chapter 7 Processes and Materials for Producing Blank Keys

utilized by Schlage.

Conversation with Chuck Murray, Kaba-Ilco, regarding keys and their production.

Chapter 8 Methods of Producing Cut Keys

Figure LSS+821 HPC 747xu tubular key duplicator
Figure LSS+822 HPC 1200 key duplicator
Figure LSS+823 HPC handheld key code computer (HP720)
Figure LSS+824 HPC KM-60 micrometer

LSS201: Procedure for making keys with a clay mold. Courtesy of MSC.

LSS201: Making keys by silicone impression, Courtesy of MSC

LSS202: The Ultracode key machine, Courtesy of Steve Fish.

LSS202: The Kaba-Ilco Triax key machine, Courtesy of Steve Fish.

LSS202: Kaba-Ilco RW2 Transponder system, Courtesy of Steve Fish.

LSS203: HPC BlueSHARK third generation key cutting machine.

Keys can be copied through the use of clay molds. Courtesy of Hans Mejlshede.

Keys can be produced from codes, courtesy of Harry Sher.

LSS203: Easy entrie key machine demonstration

LSS204: Demonstration of the Keyway King, by Greg Brandt

LSS205: Gale Johnson on key codes

Easy entrie Operating Instructions

Easy entrie PC Software operating instructions

Chapter 9 Producing Keys for Specific Locks

Forensic implications of using a shim to open a lock prior to analysis. Courtesy of Hans Mejlshede.

Chapter 10 High-Security Locks and Keys

No Exhibits

Chapter 11 Keying Systems

Chapter 12 Basic Lock Configurations: Hardware

Chapter 13 Warded Locks

Chapter 14 The Lever Tumbler Lock

LSS203: Rosengrens RKL10 assembly.

Chapter 15 Wafer Locks

Chapter 16 Pin Tumbler Locks

Chapter 17 Traditional Mechanical Locking Systems

Abloy master keying theory, Courtesy of Hans Mejlshede.

Forced entry of Abloy locks, and forensic indications, Courtesy of Hans Mejlshede.

The Peter Field (Medeco) patent for a security tumbler. Courtesy of Hans Mejlshede.

Forensic analysis of the Medeco cam lock. Courtesy of Hans Mejlshede.

Chapter 18 Electromechanical Locks

Chapter 19 Magnetic Locks

Chapter 20 Wireless Exchange of Code Information

Chapter 21 Intelligent Keys and Locks

Chapter 22 Programmable Locks and Keys

Chapter 23 Specialized Industry Applications

BOOK ONE: THE BASICS

The Fundamentals of Locks, Safes, and Security

PART A: General Principles

General Introduction To Locks and Keys

LOCKS, SAFES, AND SECURITY provides detailed information on the construction, theory, bypass, and analyses of modern locking mechanisms and security containers. The scope of this beginning chapter shall be to present a summary and chronology of major technical achievements of locking mechanisms during the past four thousand years. Particular emphasis will be placed upon developments since the beginning of the nineteenth century.

The historical development of **safes, combination locks, and lock picking** are topics presented elsewhere, but not covered in this chapter. Detailed relevant historical developments for each type of locking system are provided at the beginning of the chapter describing that mechanism.

Lock makers have demonstrated tremendous intellectual energy, cleverness, and skill for over forty centuries. These craftsmen would continually improve upon designs, playing a never-ending game of "security chess" with their opponents; the burglar. As each new feature was designed into a lock to frustrate methods of bypass, a resourceful locksmith, engineer, or criminal, in order to circumvent the last innovation, would develop new techniques.

It is difficult to fathom the problems presented by early security needs. Consider living thousands of years ago as a wealthy landholder, merchant, or banker. You have land holdings and have amassed many possessions of great value. Perhaps you are a merchant, jeweler, or moneylender. How do you protect your valuables, your castle, and your family from robbers and thieves? In the beginning, there were no vaults, electronic alarm systems, safe-deposit boxes, high-security locks, or other devices that could guarantee security. Extremely inefficient yet effective, the hired watchmen together with constant vigil provided the only real security to protect your possessions from the thieves and robbers of the day.

At some point, the local blacksmith is consulted, and asked if there is a way to provide better security through fortified enclosures and secret fasteners or locks. So, the blacksmith sets to work on the problem, apparently in many different parts of the world simultaneously. Such a demand for security was experienced that a special guild would emerge for those who dealt with such problems: locksmiths.

Remember, there is no machine shop, no security industry, nor any high-security locks or enclosures. The only materials are wood, brass, bronze, and iron. There are no factories, sophisticated metallurgy, or machinery to make the small and intricate components found in modern locks.

There was essentially nothing to draw from in the blacksmith's experience to solve the problem of protecting people and their assets. There is no history of technological developments. It is the beginning.

So how did we arrive at the end of the twentieth century with such an array of simple to highly sophisticated and secure locking devices and enclosures designed to protect people and their assets. Assets, as defined in our modern world, now include information, perhaps of such a sensitive and valuable nature that improper or unauthorized disclosure or acquisition could literally result in the destruction of the planet.

Chapter 1, then, traces the slow evolution of the lock through four thousand years to present state-of-the-art designs. The organization of the chapter attempts to present the logical steps that must have occurred in the development process.

LSS+ CD/ROM presents an in-depth overview of the history of locks, offering an extensive collection of photographs of both ancient and modern devices. In order to provide the reader with the rich history and perspective of the development of the modern lock, the author has revised two major works of the nineteenth century that are considered the source reference works on the subject of locks, safes, and security.

Fire and Thief-proof Depositories and Locks and Keys, was written by George Price in 1850. This is one of the most comprehensive and authoritative works on locks and safes, providing a chronicle of innovations and developments in locks and safes from their inception.

Locks and Safes: The Construction of Locks was written by Alfred C. Hobbs and edited by Charles Tomlinson in 1868. This book provides another chronicle of the technology of early locking devices, and traces the conceptual changes in design as relates to security. Interestingly, both of these individuals were American lawyers. Mr. Hobbs is credited with having been the first person to bypass the Bramah lock, produced in London. This feat, as will be described subsequently, set the stage for a race for higher security and new designs in locking mechanisms at the Great Exhibition of 1851 in London. That race continues today.

CHAPTER ONE: HISTORY

The Lock: Four Thousand Years of Technology

"And the key of the House of David will I lay upon His Shoulder."
-Isaiah, CH. XXII, V. 22

Master Exhibit Summary

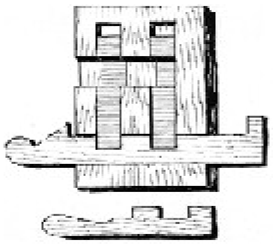
1_1.0 Introduction

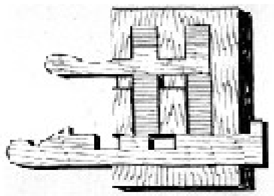
Apparently the need for greater security was felt in a number of societies at about the same time. Around 2000 B.C., evidence can be found that man began to construct the primitive locking devices that would lay the groundwork for forty centuries of development, culminating in today's sophisticated technology.

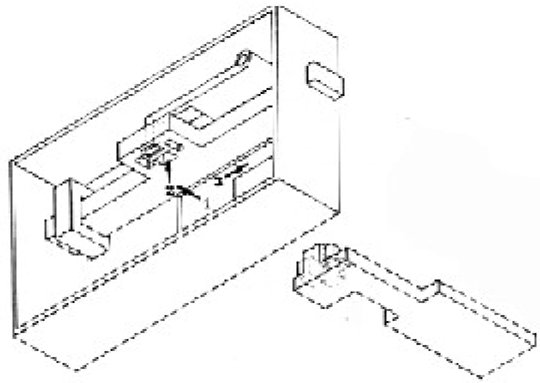
1_1.1 Original References to Locks and Keys

It is unknown when the original mechanism that could fairly be

described as a lock was really created. It appears that the first reference to locks was noted by **Joseph Bonomi(49)** in Ninevah and its Palaces. This described one of the frescos discovered in the ancient biblical city of Ninevah that showed a picture of a lock. The fresco was painted by an Egyptian artist, which provided evidence of dating to that era. The remains of an actual lock, corresponding to the fresco, were found in the ruins of a sumptuous palace near Ninevah. It is believed that this is the oldest lock in existence.





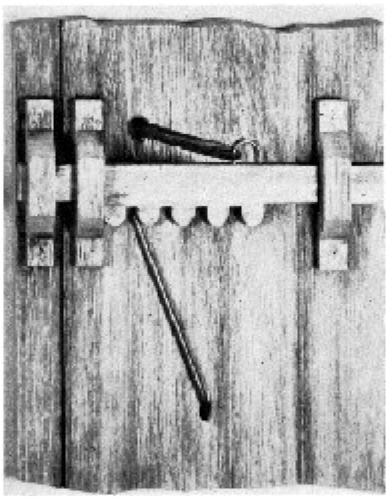


The reference in Bonomi's book described a lock as having secured the gate of an apartment in one of the palaces near Ninevah. He wrote that **"the gate was fastened by a large wooden lock, the wooden key with iron pegs at one end to lift the iron pins in the lock, being so much as a man can carry."** He described the length of the key as ranging from a foot to two feet. The reference clearly described the Egyptian pin tumbler lock.

There are a number of references to locks and keys in the Bible, leaving no doubt that the lock as we understand the concept today, has existed for at least forty centuries.

1_1.2 The First Fasteners and Locks: Greek and Egyptian

It is logical to believe that primitive man's treasures were initially buried or hidden in caves, hollow trunks of trees, or other physical locations that could be easily created or exploited. Once doors or other solid surfaces were employed to secure a perimeter, the next obvious step would have been the capability of locking the door in place. In the beginning, of course, there were no latches as we understand the term today. It appears that the Greeks, who developed crude wooden fastening devices on the inside face of the door, conceived the initial concept of using bars and boltwork. These bolts were lifted from the outside by a cord passing through a hole in the door; later a crude key was utilized.



Realizing that one of the drawbacks of the Egyptian lock was its vulnerability to attack, the Greeks placed their locks on the inside of the door but provided access to the mechanism from the outside through a keyhole. Although it is unknown whether the Greeks took these ideas from the Romans, they are credited with the concept of interior locking mechanisms, operable from either side of the door.

They utilized a massive bolt with a large sickle-shaped key. It had a semi-circular blade, measuring a foot or more in diameter, and a long handle that tapered to a blunt point. The Greek "keys" would often be inlaid with precious metals, for locks were utilized by the wealthy. The major problem with the Greek design was that there were very few different key patterns available. Thus, there was little security against bypass through the use of primitive "skeleton keys." The only possible variations (or differs) were those of curvature and length of the key.

1_1.3 The Greek Influence

The development of the Greek and Egyptian door locks appear to have occurred at about the same time. Interestingly, Greeks are credited with making simple bolt-locking mechanisms available to the middle class, while the Egyptian pin tumbler locks were affordable only by the wealthy. In the days of Homer, doors were tied shut with intricately knotted ropes. They were so cleverly laced that only the owner could find the correct method of unknotting them. Moreover, the superstitious beliefs of the times insured that no one would dare to tamper with the ropes, lest a curse fall upon them and their families. Ropes, of course, gave way to a number of different configurations involving the use of a beam of wood mounted to the door.

Some evidence suggests that the first mechanical barring of a door was by a cross-beam that was dropped into sockets or by sliding staples affixed to the door. It is theorized that a vertical pin was probably dropped into a slide to secure the beam. If the beam were to be placed on the outside of the door, then the locking pin would have to be hidden, yet retained and accessible through a hole in the beam or staple. In order to make the lock function from outside, the cross-beam was shortened into a long bolt which was made hollow to allow the pin to be reached. To move the bolt, a **key** was fashioned that had pegs matching the hidden pins within the bolt.

A variation of this early lock was a configuration wherein the pins were reached by holes in the staple, not through the bolt. This design was very popular and was utilized in different parts of the world, including Scandinavia, the Faro Islands, Africa, and the Balkan states. There was a principal difference between the Greek and Egyptian lock. In the Greek mechanism, the key moved pins into position to allow release of the bolt, which then was moved back by hand. In the Egyptian lock, the key actually was used to withdraw the bolt.

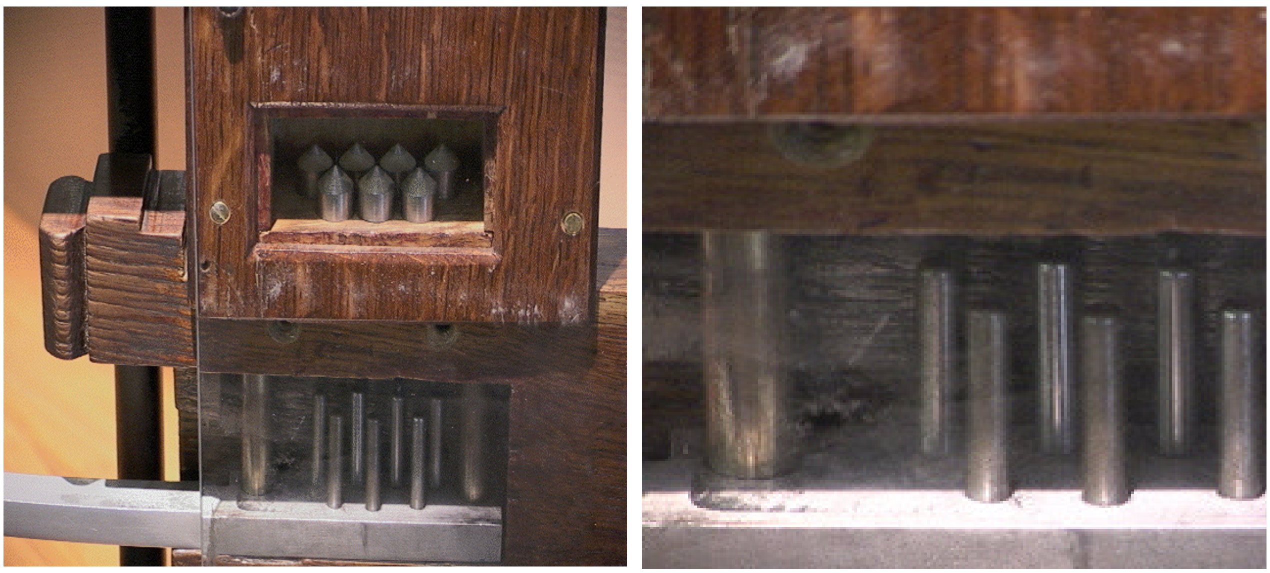
The next improvement was mounting the bolt on the inside surface of the door. Keys appear to have been sickle-shaped pieces of iron, apparently put through a hole in the door and used to push or pull a retaining pin.

The final "primitive" style lock also placed the bolt on the inside surface of the door, but with the addition of a **spring** that would spread against the sides of a staple. The key would compress the spring to open the lock; the bolt could then be

withdrawn.

The Greeks are credited with the concept of interior bolt mechanisms accessible through a keyhole. It is interesting and curious that they never applied their intellectual abilities to the design of locks, as did the Egyptians and Romans, in spite of the great academic, political, and scientific achievements of Athens.

1_1.4 The Original Egyptian Pin Tumbler Design



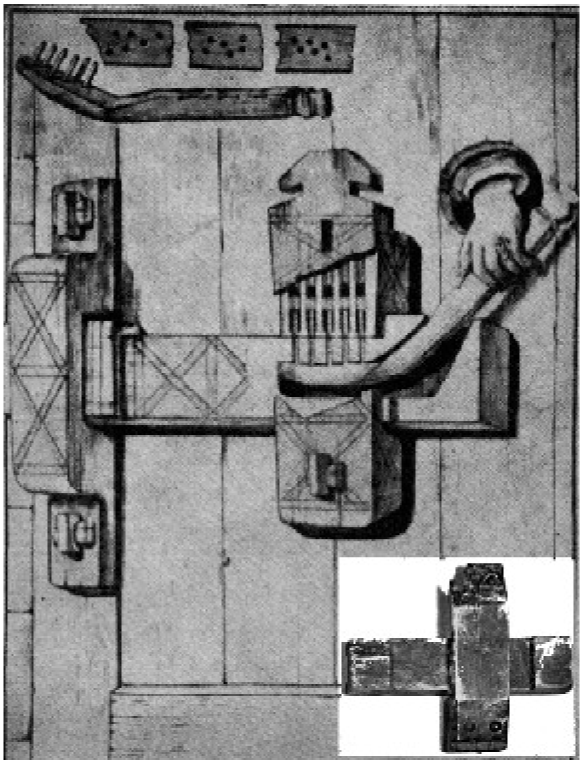


Figure LSS+101. A mock-up of the original Egyptian lock, produced by the British Museum, London. This replica shows the interaction of the protruding pegs with the internal pins.

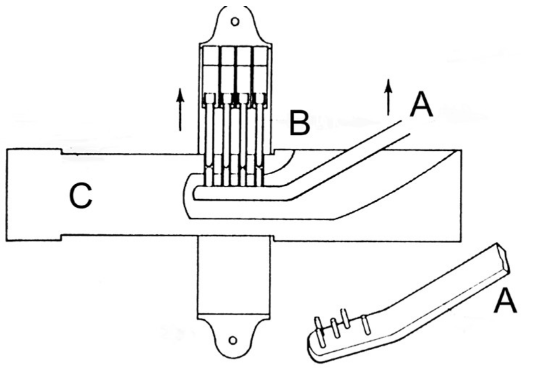
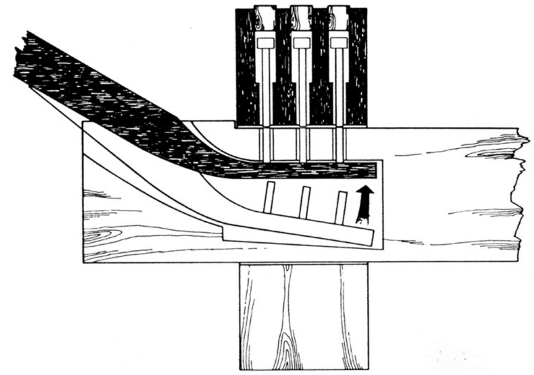
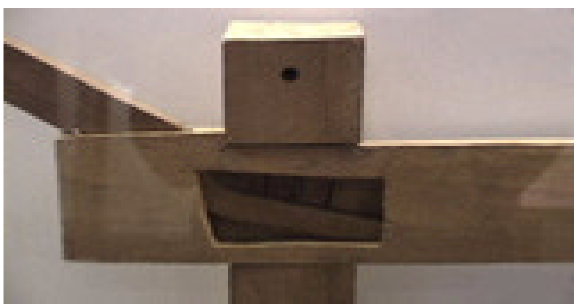
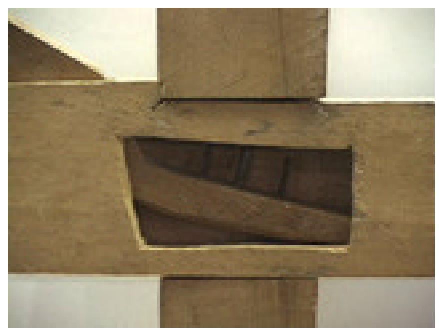


The Egyptian craftsmen are responsible for conceiving one of the principles upon which all modern lock designs are based; the pin tumbler. Their invention would ultimately lead Linus Yale to perfecting and patenting the modern version of that mechanism.



The real genius of the Egyptians was in conceiving **double-acting detainers** that had to be lifted to the correct level in order to create a **shear line** to allow the lock to operate. Their clever innovation set the stage for the development of every mechanical locking mechanism in existence today.





Yale would base his lock design upon this principle, with the further refinement that the detainers or pin tumblers could not be lifted too high or too low: they would have to be raised precisely to the correct height.

The Egyptian lock was attached to the outside surface of the door. First made of wood, later models were constructed of brass and iron and ornamented with inlaid pearls, gold, and silver. The locks measured two to three feet in length. The mechanism was housed in a rectangular container into which the bolt would slide. Inside this hollow container was placed several irregularly shaped wooden pegs or pins, usually numbering from three to seven. They were arranged in random patterns and were set to move up and down. When in the locked position, the pins rested half in the bolt and half within the main lock housing.

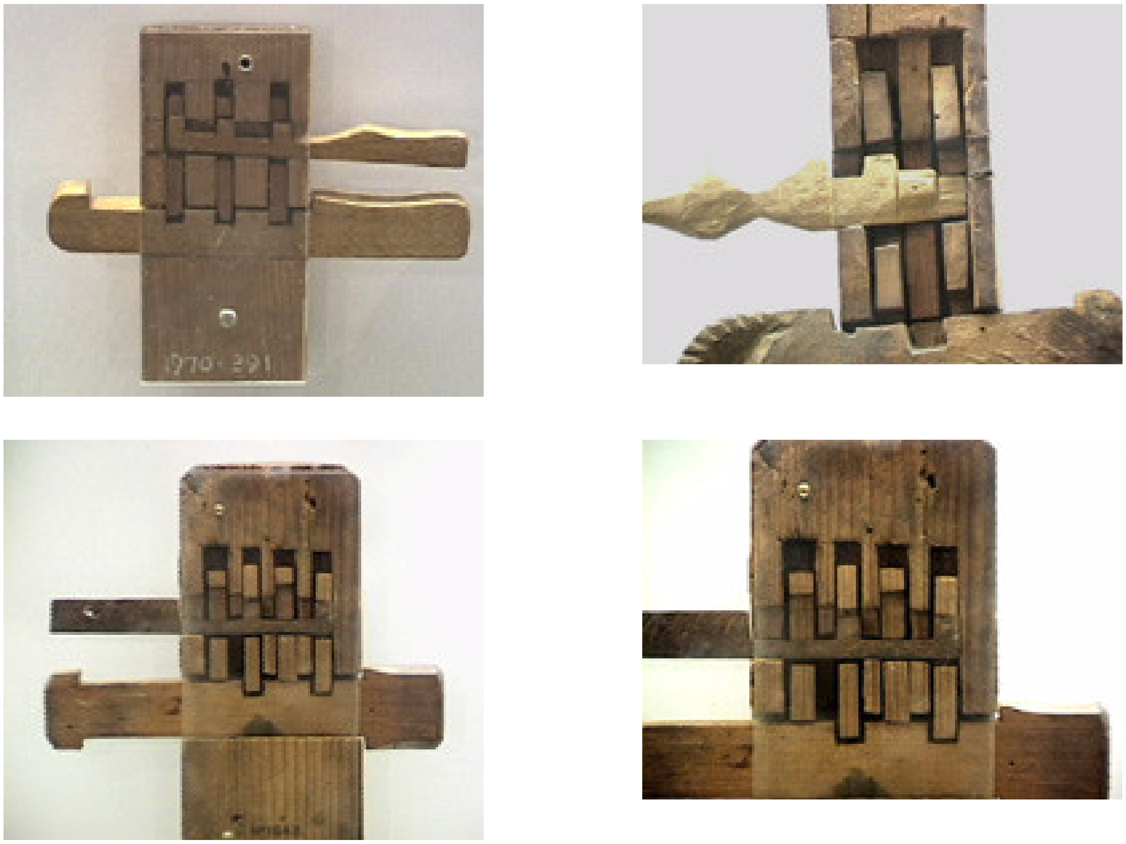
INV.1868-18

INV.1868-18



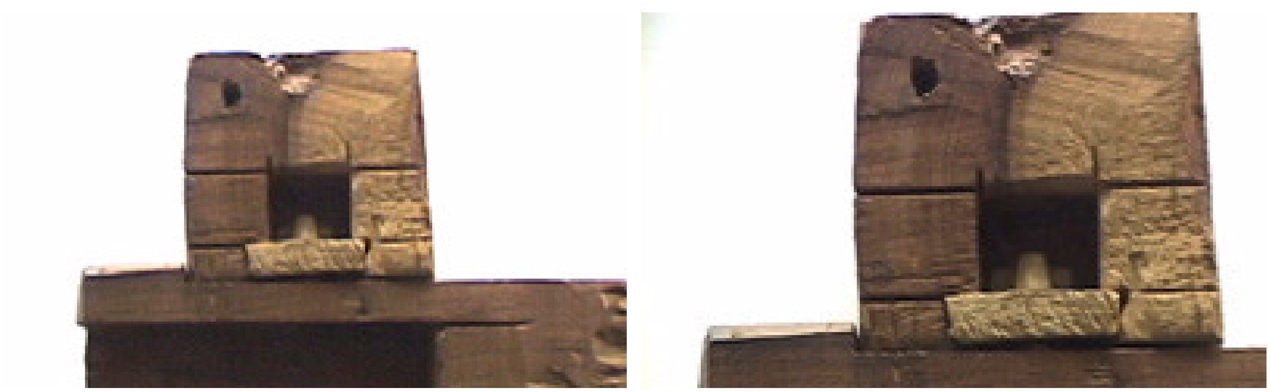


Figure LSS+102. Examples of different approaches to the original Egyptian pin tumbler design. These locks have been gathered from different countries, and demonstrate that the idea of using pins or pegs to secure a moving bolt or locking piece was not unique to any one society, although the Egyptians are credited with the initial concept. These exhibits are on display at the Science Museum in London.

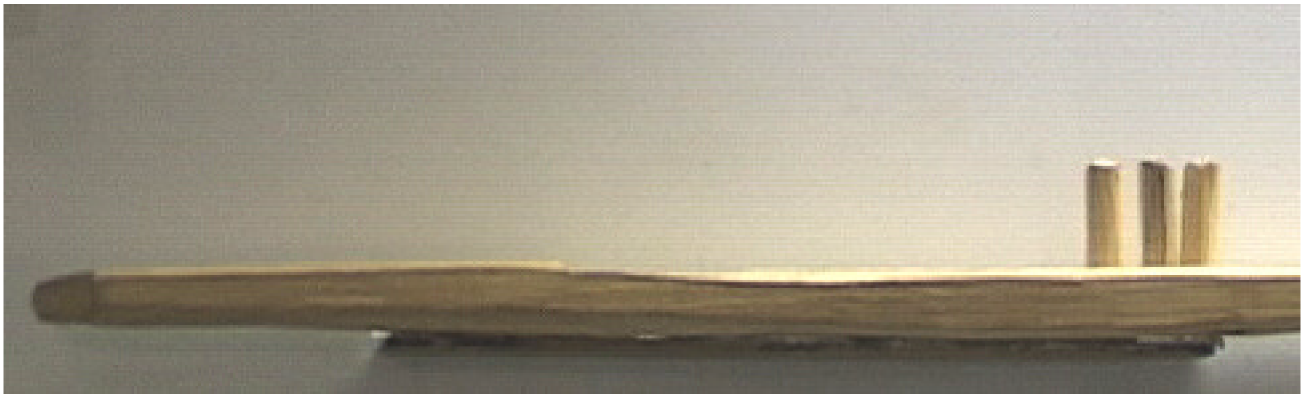

Figure LSS+103. An example of a pin tumbler lock found in North Africa during the last century.

The key for the Egyptian lock was also two to three feet in length and had wooden pegs inset in a vertical position at one end. These pegs were placed on the key to match the pin positions inside the lock. The function of the internal pins was to hold the bolt solid in the lock housing. Keys came to represent a sign of spiritual and temporal power. They symbolized man's ability to gain access to those things he considered to be of greatest significance.

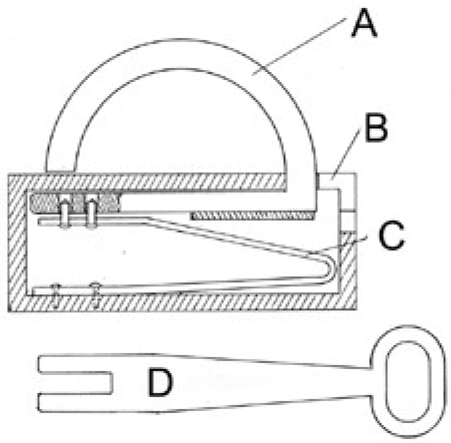
The pin tumbler concept was widely imitated, and even to this day similar locks are occasionally dug up in places as remote from each other as ancient Assyria, Scotland, Japan, and America. Apparently the skill and techniques of the ancient lock makers, as well as the fundamental soundness in design, survived the fall of great empires and even time itself.

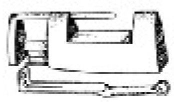
1_1.5   Early Roman Locks

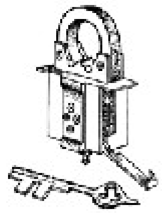
The craftsmen of the ancient Roman Empire are credited with a number of major advancements in the development of the lock. Recognizing basic defects in earlier devices, they took the best of the Greek and Egyptian designs to produce sophisticated locks, as well as the revolutionary **warded** design. They also popularized padlocks, originally developed by the Chinese. The Roman artisans were familiar with working in metals; thus they dispensed with large bolts and keys. They recognized that smaller keyholes made locks more difficult to pick. Their keyholes were mounted on the interior surface of the door and were operated with a key from the outside. Although keys for the Greek and Egyptian locks were

quite cumbersome, the Roman counterpart was small, ornate, and intricate.

Evidence of the sophistication of Roman lock design can be found in the ruins of the ancient city of Pompeii which was engulfed by the volcano Vesuvius in 64 A.D. One of the significant finds in the lava of Pompeii was the discovery that keys were required to rotate within locks **less than 360º** to actuate the bolt. Thus, it appears that the Romans were the first to introduce a **spring-loaded bolt** into their locking mechanism, thereby eliminating the problems encountered in gravity-locking devices.







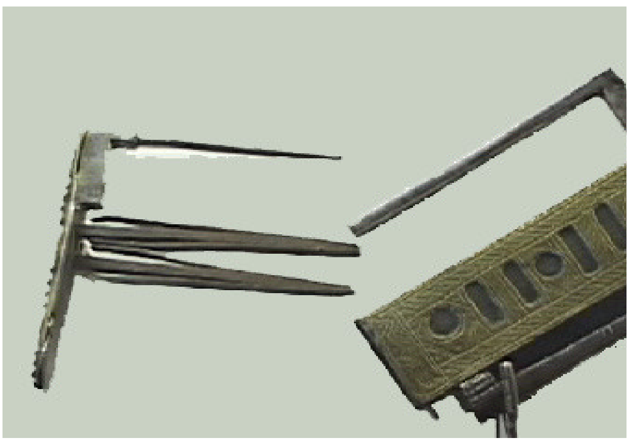


Figure LSS+104. An example of a seventeenth century Persian padlock.

1_1.5.1 Roman Padlocks

Padlocks are the logical extension of fixed mechanisms and provide a connecting link between primitive devices and the beginnings of the development of the modern lock.

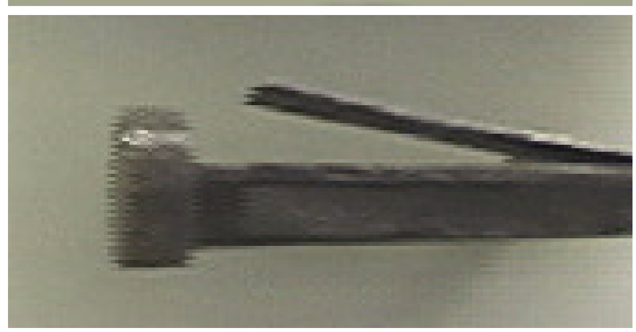

Figure LSS+105. Examples of early Roman and African padlocks.

Figure LSS+106. An example of an early European padlock.

Although the Chinese and Near East peoples developed the padlock, the Romans are credited with having popularized it. They made it a practical device, even going so far as to produce the key as a part of a finger ring for convenience in carrying by the owner. The fact that the Romans had no pockets in their togas may have inspired their locksmiths to devise keys that were small and inconspicuous.

1_1.5.2 Warded Locks

Figure LSS+107. An early warded lock, showing the obstructions to rotation of the key.

Figure LSS+108. This mock-up of a warded lock demonstrates its principle of operation. The key is allowed to rotate the bolt only when the obstructions are cleared. This and the following illustration were produced by the Science Museum, London.

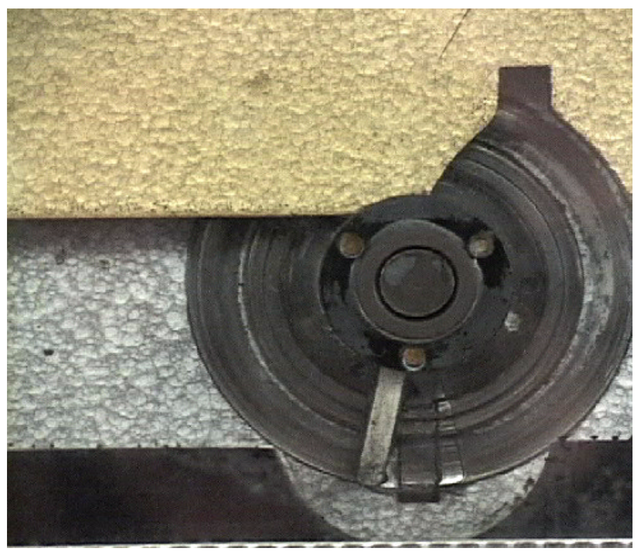

Figure LSS+108 This working model of a warded lock shows the circular wards and how they interact with a key.

While Roman artisans knew that their locks provided greater security, they continued to seek refinements in the mechanisms to frustrate the conventional forms of bypass. The answer came in

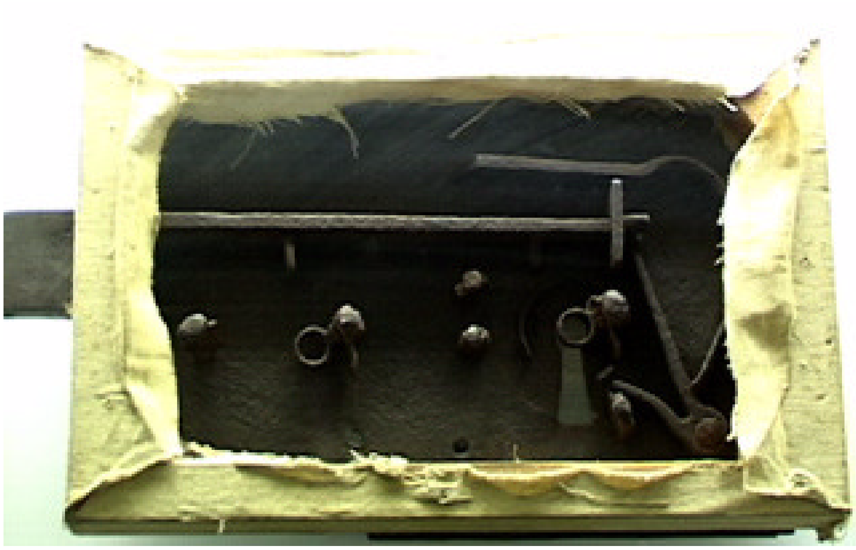
the form of **wards** that were incorporated within the lock design. The origin of the warded lock is obscure. It is likely to have been invented by the Etruscans in northern Italy, although recent evidence indicates that the Greeks also knew of the concept. Regardless of its origin, the warded mechanism was perfected by Roman artisans and was to remain the most popular design until the middle of the nineteenth century. It is still found in wide use today.

Wards were a logical extension of the primitive alteration of the shape of a key to frustrate entry into a lock. Some ingenious lock maker discovered that he could place a series of obstructions in the path of a turning key and thus make the lock secure. Only the correct key with the same spaces on its body could pass the obstructions. Thus, the essential principle of the warded lock was to provide one or more internal obstructions to block entrance and rotation of all but the correct key. The incorporation of wards added a completely new dimension to security against picking and led the way for the production of many different shapes and sizes of locks.

Craftsmen continued to improve upon the mechanism, making the keyway and ward pattern more intricate. Then, when this was not enough, they began to use multiple locks for greater security. As an example, it was reported that in 1415, Queen Isabelle of Bavaria called her locksmith to secure the apartment where the ladies-in-waiting were quartered. The doors were fitted with locks that required five different keys to gain access.

1_1.6 Lock Design during the Middle Ages and Renaissance

The Middle Ages followed the fall of the Roman Empire. While scientific achievements were few, locksmithing flourished during this period in history. Warded locks were now not only complex mechanisms but became works of art. Prestige and respect was accorded those with the most intricate locks.



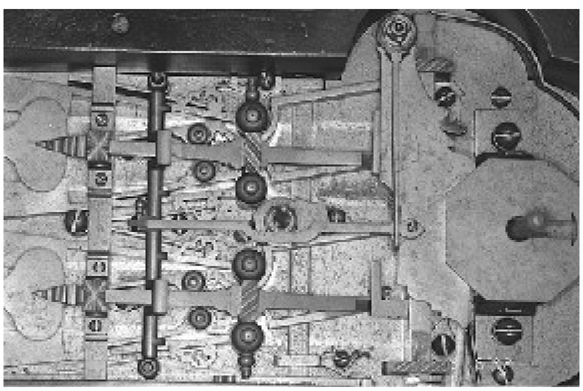


Figure LSS+109. This is a warded lock that was produced between the fifteenth and eighteenth century. Note that multiple keys were required.

These were the days of castles and knights, of robber barons, and of monasteries containing books and manuscripts of great learning from ancient days. Security took on new and more urgent dimensions.

The warded lock had been designed to perfection, and yet it was not secure enough. The demand for more security increased to match the accumulation of wealth. The late eighteenth century produced the next significant refinement of locking mechanisms: the **lever** concept.

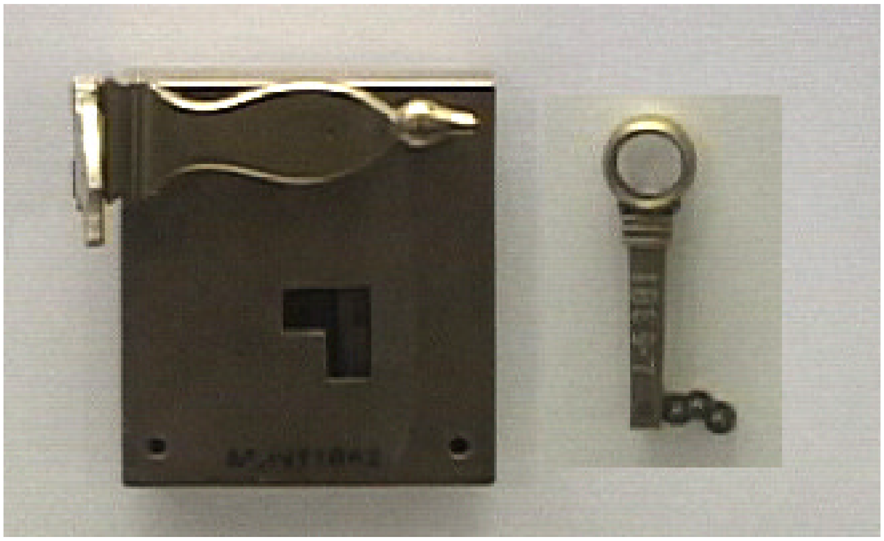

Figure LSS+110. This replica is made from a lock preserved in Pompeii after the eruption of Mt. Vesuvius in in A.D. 79. It closes with a hasp.

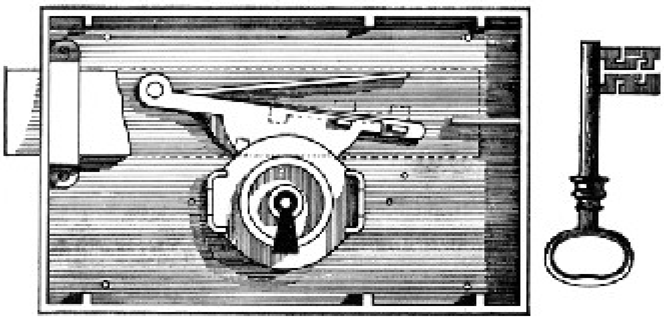
Figure LSS+111. Early warded door lock.

1_2.0 Origins of Modern Locking Concepts



Most of the significant achievements in modern lock designs find their basis in developments of the past two hundred years. From the time of the Romans until the end of the eighteenth century, security was based upon fixed obstructions and elaborate keyholes, fine slits, perforations, and intricate keys. Falling pins, invented by the Egyptians, were forgotten. No other methods had been invented to put more security into the locks.

Towards the end of the seventeenth century, traditional sliding and pushing of keys gave way to the concept of **turning**. Keys would rotate around a pin or slide through a keyway. As developments progressed, many different key designs emerged, incorporating both art and utility.

In 1778, **Robert Barron** developed a new and radically different locking mechanism. Over the next two hundred years, many modifications to the Barron lock would be introduced, as well as completely new and fundamentally unique designs. Because of the many different advances since 1778, a chronological summary of important inventions, beginning with Robert Barron, is presented in the remaining portion of this chapter. A detailed treatment, examining the significance of each of these major developments, will be found at the beginning of the chapter relating to the corresponding basic locking mechanism. This format will allow the reader to logically trace and understand the changes made to each type of lock and how various designs evolved.

1_2.1 Barron Lock: 1778

With the exception of the Egyptian pin tumbler design, most locks had relied upon wards prior to the lever principle. The Barron lock, first introduced in England, was based on a completely new locking theory: the **double-acting lever tumbler**. It was probably the most significant development since that of the ancient Egyptians. Through many refinements and modifications, the lever lock would become one of the most popular mechanisms in the world to this day.

Originally, the lever was a form of catch. Until raised by a key, it would normally hold the bolt in a fixed, immovable position. In the first lever locks, the key merely had to **lift** a single spring from a notch in the bolt and then force the bolt forward. The height of the lift was not important, provided that the notch was cleared. The **Banbury** wooden locks employ this principle.

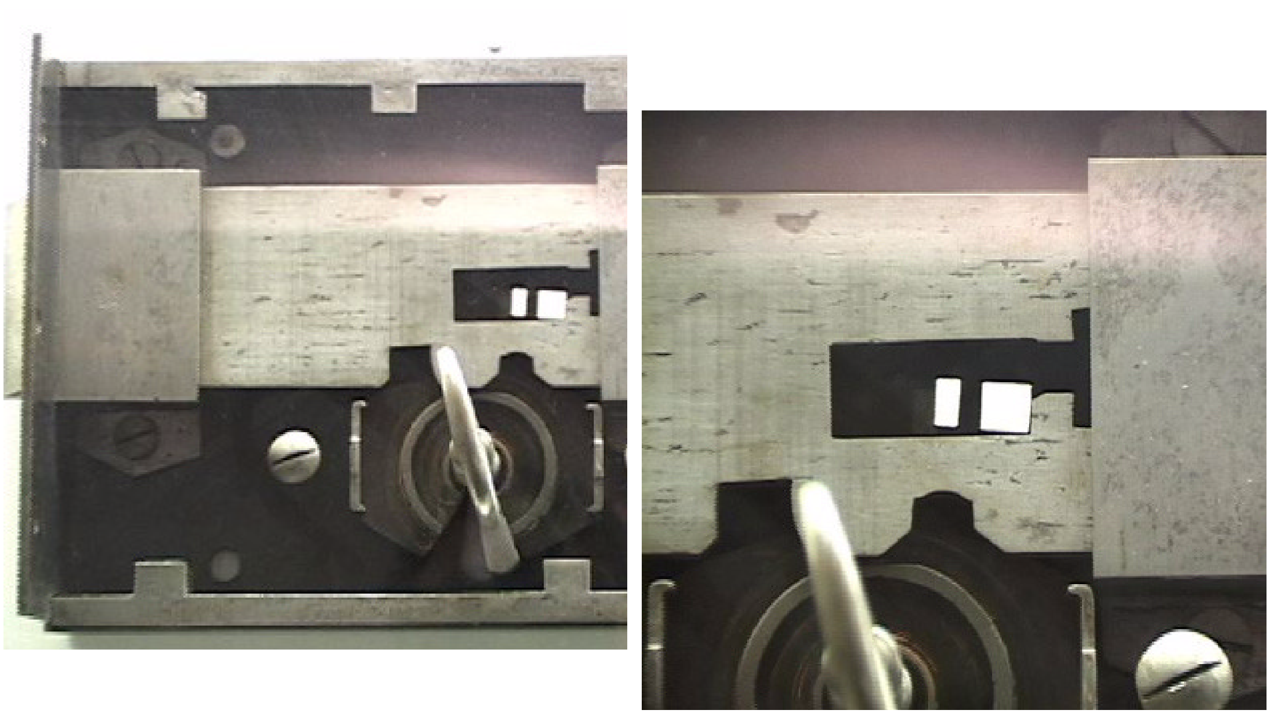


Figure LSS+112. A replica of the original Barron lock, showing the action of the key and levers.

The bolt of the Barron lock had a square-cut notch, called a **gate.** Stumps, formed as part of the levers, would project into

the gate, thereby preventing them from moving. The key would lift all the levers until the stumps cleared the gates, allowing the bolt to slide into a locked or unlocked position. If any of the stumps were raised too high or not high enough, the bolt could not move. The lever principle was a great improvement over wards, because it was believed that wax could not be used to determine precise details of the mechanism. This was true, at least for a few years.

Levers offered the first real security against picking because the lever not only was used to hold the bolt but to block its movement until the correct key was used. Several levers were employed, thus eliminating the use of skeleton keys that had defeated all security in the earlier warded lock.

Essentially, all lever locks for the next two hundred years would adopt a design based upon the original Barron concept. Each were based upon the idea that a moveable, pivoting lever should have a square gate cut into its end opposite the pivot point. When lifted to precisely the correct height, it would allow a stump to enter the gate, and thus permit the bolt to laterally move. Today, locks of seven or move levers can provide extremely high-security against picking and other forms of bypass.

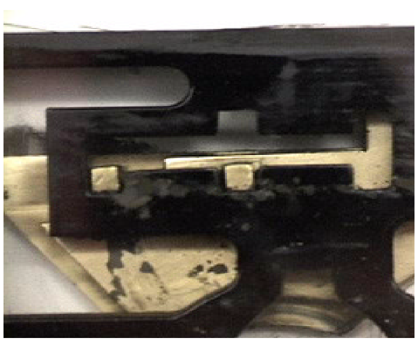

Figure LSS+113. The three photographs depict the movement of the bolt in the Barron lock, as

In this photograph, the levers have been raised to clear the gate, and the bolt has been

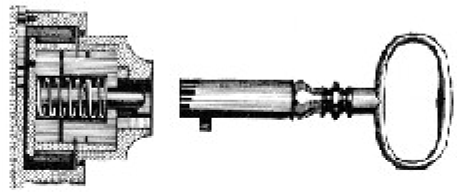
partially moved. Note the stump is floating between the gates.



rest.

1_2.2 Bramah Lock: 1784

Figure LSS+114. The Queen of England recognized Bramah for its excellence in the manufacture of locks.

In 1784, **Joseph Bramah** was the first to receive a patent for a lock in which the key did not actually reach or make direct contact with the bolt. Rather, it acted through an intermediate and intricate slider mechanism. This design allowed the lock to be physically small, yet secure.

The Bramah key was a tube with narrow longitudinal slots cut in the end. Depressing the key into the lock would cause a number of sliders to align at a shear line. The Bramah design resembles, in some respects, the modern axial pin tumbler of Chicago Lock Company and others. Interestingly, Bramah's invention initially found no commercial acceptance. For many years, the pickproof lock, on display in the window of the Bramah Lock Company at 124 Piccadilly, in London, remained unopened; the reward for picking this lock uncollected. Seventy-five years later, a subsequent version of this lock was to become the focus of a contest at London's **Great Exhibition** of 1851 and a catalyst for competition in the development of pickproof locks.

1_2.3   The House of Chubb: English Lock Makers

For almost two hundred years, the name **Chubb** has been associated with quality lock manufacturing, design innovation, and many revolutionary patents, including the Detector lock. Chubb was the name of a famous inventor who originally founded the company in 1818, after the immediate commercial success of his **Detector Lever Lock.** Charles Chubb and his younger brother, Jeremiah were born in England in 1779 and 1793 respectively. The Chubb's originally worked as iron mongers in Portsea, England, building ships. In 1818 Jeremiah patented the Detector lock, which was an immediate success. The brothers then opened a lock factory in Wolverhampton the same year to produce and market the product. Since that time, the company has grown to be one of the most highly respected lock and safe makers in the world.

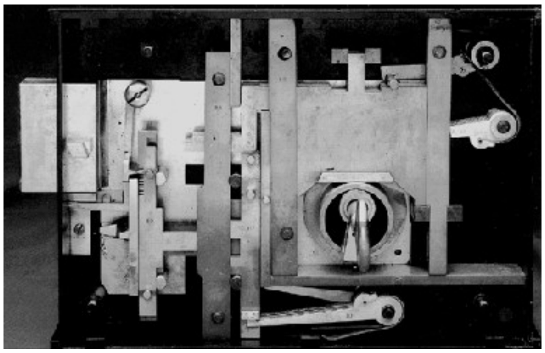


Figure LSS+117 Map of England

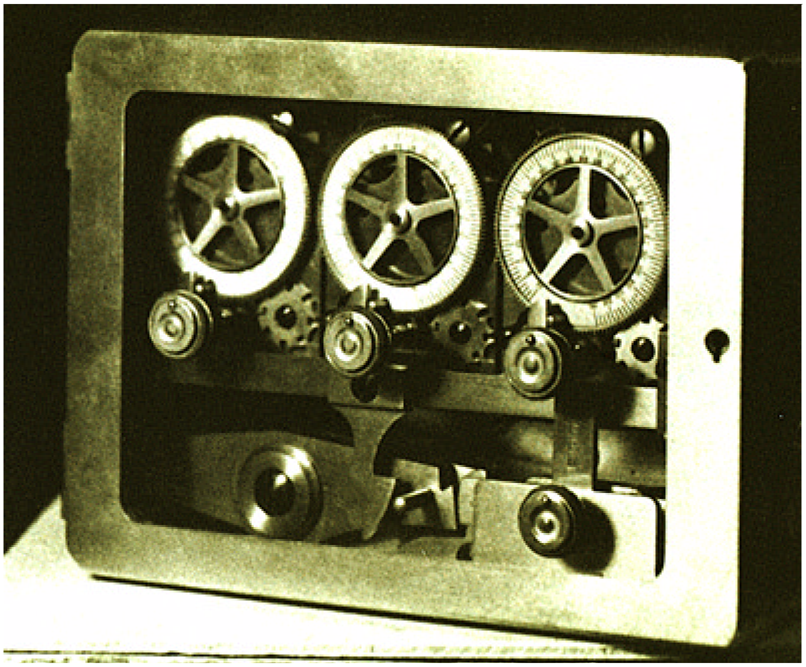
At the end of the nineteenth century, their products were so respected that in the Chinese colonies the natives would refer to "Chubby pot of jam" or "Chubby pair of trousers," meaning that they were of the highest quality. The Chubb Safe Company, still headquartered in **Wolverhampton(50)**, today has offices throughout the world. The firm manufactures a broad range of security products, including safes, lever locks, and electronic alarm systems. They have received numerous awards for design and production excellence, including recognition by the Queen of England for their contributions. Innovation, based upon research and development, has been the hallmark of the company. Chubb, for example, recently was the first to receive a patent for an all-plastic fire and burglary-resistant safe, called the "Planet." The reader is directed to **Chapter 33**, for detailed information on unique Chubb products.

1_2.3.1 Chubb Detector Lever Lock: 1818

The Detector introduced a totally new concept to lever lock design. Its commercial success provided the foundation for the future growth of the Chubb Safe Company. The Detector was a

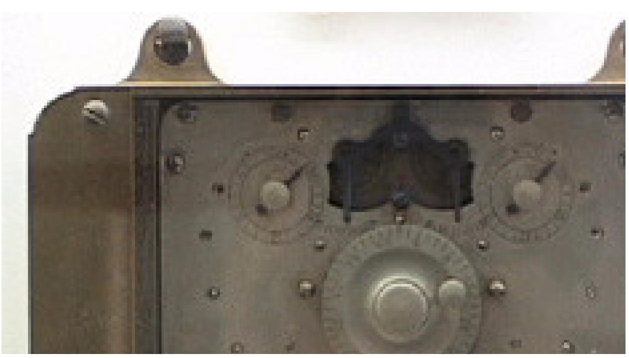
mechanism with a slightly different lever design than found in the earlier Barron lock. Chubb conceived of a different configuration, wherein the ***gates*** formed part of each lever, in contrast with the Barron lock, where the gate was actually part of the bolt. This significant enhancement remains in use to this day.

The essential element of the Detector lock was its ability to show if any attempt had been made to pick open the mechanism. This feature, coupled with the capability of completely disabling the operation of the levers once an unauthorized attempt to pick or use an improper key was made, provided a high level of security and confidence to the owner. Chubb made many improvements in the design of the lever lock, including the introduction of a curtain that surrounded the keyhole internally. This enhancement would revolve with the key, making picking impossible.



1_2.4 Time Lock: 1831

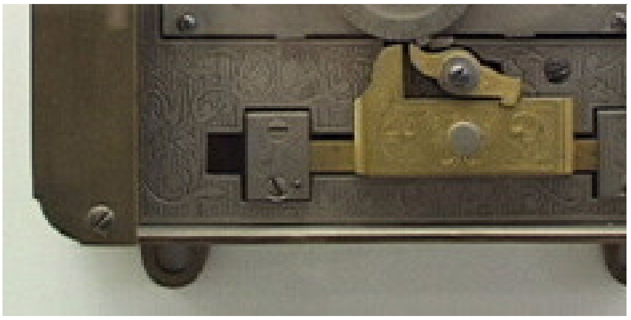
While refinements in the lever lock were being made, there were also efforts to increase the security of the combination lock (sometimes called letter, number, or permutation locks). These made their appearance during various stages of the world's history, dating back thousands of years to early China. Their application was usually confined to padlock designs and offered very little security against opening by "feel" or manipulation. They were never popularly accepted as secure locking devices until modern machine methods achieved high tolerances. In fact, until the middle of the nineteenth century, they were mainly looked upon as locks of convenience only. Although combination locks were used on safes and vaults prior to the introduction of the time lock mechanism, they did not provide security against robbery. Criminals, especially in America, determined that the simplest way to obtain the contents from the bank vault was to



kidnap the cashier or bank manager and force him to open the safe.

A Scottish inventor, William Rutherford, developed a combination lock utilizing a disc with a notch cut in the side, to be driven by a clock. Rutherford placed a circular stop-plate at the rear of the lock. This prevented the operation of the bolt until the plate had rotated to a certain position, which was controlled by the timing mechanism. The modern version is simply a variation of this design.

The introduction of the time lock revolutionized the security of safes and vaults. The original Rutherford invention did not receive much attention until an American, James Sargent, of Rochester, New York, improved upon the design in 1865. Sargent made the use of these locks practical. Because of the introduction of the Sargent design, combination locks gained wide acceptance in the United States during the second half of the nineteenth century.



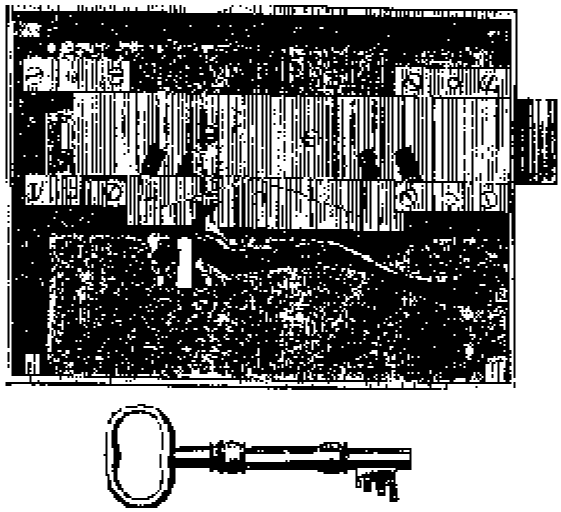


Figure LSS+115. An early example of another time lock developed by Pillard.

1_2.5 Parsons Balanced-Lever Lock: 1832

The **Parsons** balanced-lever lock was significant because of the change in design of the levers. These were set to **pivot in the middle**, rather than at one end. The lock was designed so that if any lever were raised too high, as with a false key, it would hook into the bolt, thereby becoming immobilized. This lock was produced with seven levers and provided an innovative design.

1_2.6 Newell Parautoptic Lock: 1841

The Newell Parautoptic lock was shown at the Great Exhibition in 1851. It was invented by Robert S. Newell of New York and manufactured by the Day and Newell Company. The word **parautoptic**, taken from the Greek, means **concealed from view.** The lock was designed so that it was almost impossible to reach the working parts from the keyhole. By utilizing a double set of lever tumblers, one acting in sequence upon the other, and a rotating plate that would block the tumblers from inspection, the lock was virtually impossible to pick.

In a further innovation, the combination of the lock could be changed at will by altering the relative positions of the parts of the key bit. The key is comprised of fifteen separate segments that are interchangeable and which controlled the derivation of the combination. This design provided the idea for instant rekeying systems, which would become popular a century

later.

1_2.7 Hobbs Protector Lock: 1851

The Hobbs **"Protector"** was introduced the same year as the Crystal Palace Great Exhibition. This was a simple four-lever lock, following the original Chubb design, with some modification. Alfred Charles Hobbs, an American locksmith, is also credited with being the first to pick the world-famous Bramah lock. His achievement attracted so much publicity that he remained in England to found a lock manufacturing company called **Hobbs & Company**, later to become **Hobbs, Hart & Company.** Chubb would later acquire Hobbs & Hart.

Figure LSS+116 The lever lock developed by Hobbs and Hart.

1_2.8 Tucker and Reeves Safe-Guard Lock: 1853

A variation of the Chubb lock was introduced in 1853 which featured four levers formed in the shape of a wheel, mounted on a central pin and enclosed in a moveable barrel. The barrel formed the true keyhole that was offset from the key. The design made it impossible to insert a picking tool to reach the levers. To increase its pick resistance, the inventors also required that the key turn the moveable barrel before the stump on the bolt could enter the gate.

1_3.0 The Race for Security: The Great Exhibition of 1851

Until the eighteenth century, lock designers appeared to be more concerned with creating works of art than of security. Eventually, true craftsmen and scientists applied their talents

to raising the security of locking devices rather than appearance. Chubb, Bramah, Newell, Parsons, and many others improved upon designs and received patents for concepts that can be found in use today. A public rivalry developed between inventors, in a constant quest for greater security against picking. Public contests were held as new inventions were introduced. The masters pitted their lock-picking skills against one another in an attempt to defeat each new innovation. This intense competition was responsible for many of the significant improvements in certain lock designs which previously had not changed in three thousand years. The most famous of these contests was held at the London Exhibition in 1851.

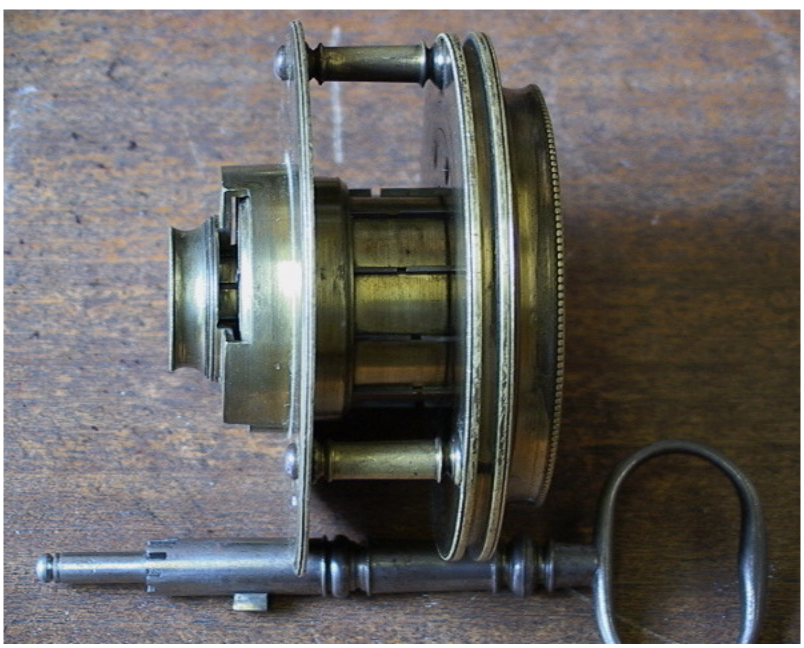

Figure LSS+118 The Bramah lock that was successfully opened by Alfred Hobbs.

The London Exhibition occurred at the peak of British industrial power. Because Britain was noted as the "workshop of the world," the English decided that they needed a chance to show their products and technology. This was an effort to bolster trade and to demonstrate that their varied technology ranked favorably with their foreign competitors. The exhibition was an epic event. Its catalog, running hundreds of pages, described commodities and technologies, with diversity that included steel furnaces, pottery, firearms, and locks. Locomotives, steam hammers, sewing machines, musical instruments, photographic equipment, and every other significant product and process available was on display. In the context of locks and keys, the exhibition was a great

success. Public confidence in the locks of the day was high, especially as each new improvement was introduced, and the difficulties of defeating these inventions was demonstrated to the public. The exhibition gave lock makers a chance to offer rewards to anyone who could pick their wares, and thus, they were able to show the security of their devices.

Alfred Hobbs was able to bypass the Bramah lock. Courtesy of Hans Mejlshede.

The high point of the exhibition was the offer of two hundred pounds by the Bramah Company to the person who could successfully open their pickproof lock. It will be remembered that this lock, originally developed some fifty years before, had remained one of the most secure in the world; nobody had succeeded in manipulating it open. Then Alfred Charles Hobbs arrived from America. Hobbs announced that he could easily pick the most difficult of lever locks, the one made by Bramah. Of course, he was scoffed. But he persisted. The Bramah Company finally set up an impartial panel of judges, gave him a sample of their lock, many blank keys, a place to work, and thirty days in which to crack the invincible device. While the two hundred pound reward was a great deal of money, the company believed that they had nothing to lose, since no one had been able to break the lock.

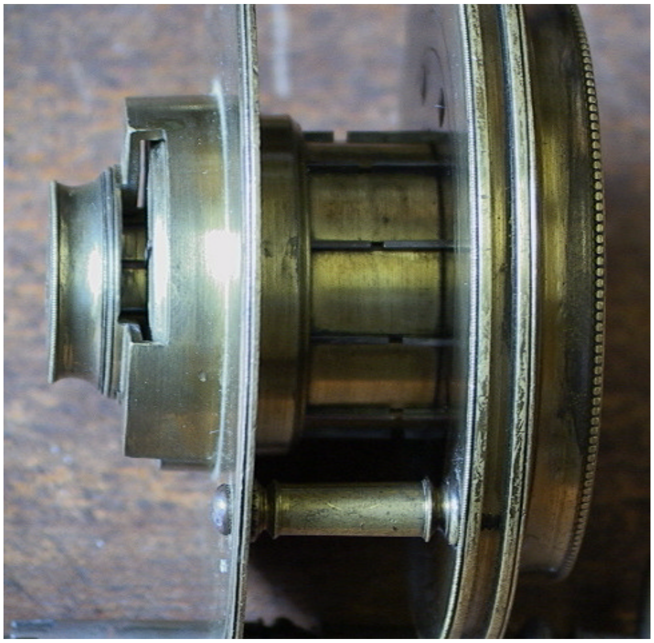

Figure LSS+119 The Bramah lock utilized a series of sliders that were depressed and aligned with two fixed curved "fences." The sliders that are shown were moved forward by the key so that all of their gates fell directly under the fixed fence, which resembled two arc rings that prevented the lock from rotating until the sliders were in the correct position. The "fence" had multiple slots corresponding with the position of each slider..

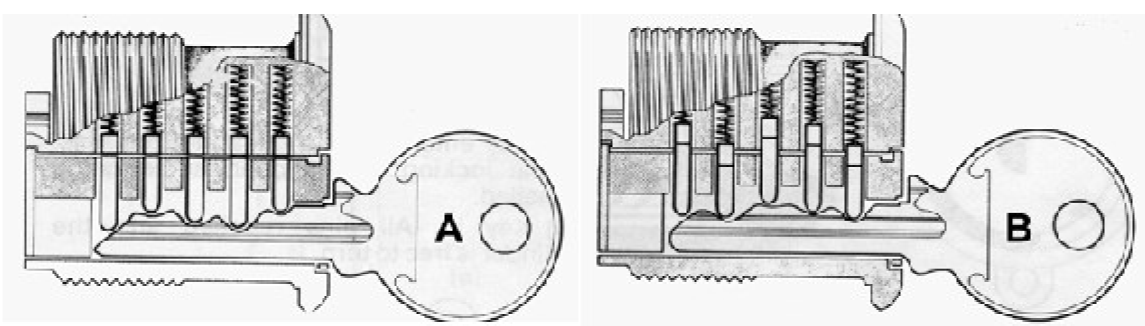
Hobbs diligently worked at his task. One day he would spend many hours at his workbench, another only minutes. At the end of twenty-four days, he summoned the judges. With his observers watching, Hobbs confidently took the key he had made, inserted it into the lock, and unlocked the mechanism. The judges were incredulous. The lock makers claimed that it was a trick or that it was just luck. So he relocked the lock, opened it, and again relocked it, all very easily. Nevertheless, said the manufacturer, the mechanism is surely damaged. Not so, Hobbs claimed. To the chagrin of Bramah, the most secure lock of the time had been defeated. The task was clear: a new, more secure device had to be developed. Both American and English locksmiths took up the challenge. In 1861, the answer came in the form of the Yale pin tumbler, which today is used throughout the world. Its development revolutionized the lock-making industry as the lever lock had done a hundred years before.

LSS101: Interview with Jeremy Bramah

It is interesting to note that Hobbs never disclosed to the Bramah Company precisely how he was able to open the lock. In an interview with the author, Jeremy Bramah, (a direct descendent of



Joseph Bramah and present owner of the company) indicated that Joseph Bramah had died several years before his lock was bypassed by Hobbs, and so was not available to analyze just how Hobbs performed his feat. The company felt that Hobbs had used some form of trick to open the lock, and that the competition was unfair.

After a careful examination of the original lock, it is the author's conclusion that Hobbs decoded the slider position in much the same fashion that John Falle constructed his pin and cam system to read minute tolerance variations. It would have been relatively easy for Hobbs to determine the play between the gate within each slider, and the barrier that formed a fence, and then to construct a key.

The Chicago Tubar lock and many other variations of the sidebar mechanism can be viewed as an offshoot of the original Bramah lock. In the case of the Tubar, the sliders were replaced with two rows of four pins with gates cut into the lateral area of the pin. In the Bramah lock, the "sidebar" is comprised of two fixed rings that block the movement of the sliders. In the Tubar, the sidebars are moveable; however, they perform the same function. See the accompanying video of the interview with Jeremy Bramah.

1_4.0 Yale Pin Tumbler Lock: 1861

Linus Yale, Sr., was born in Middletown, Connecticut, in 1797. He was an ingenious and successful inventor and manufacturer of bank locks. His son Linus Yale, Jr. was born in 1821; he began his career as an artist. First developed by Yale in 1844, the pin tumbler mechanism was refined and presented to the public by Yale, Jr., in 1861. Between 1860 and 1868, Yale, Jr., conceived and produced the now familiar cylinder and incorporated most of the refinements which exist today.

The lock worked on the same basic principle as its ancient

Egyptian predecessor, using several small pins to block the movement of the bolt. A small key provided greater security while at the same time offering many thousands of combinations. The major difference between this lock and that of the Egyptians was that the Yale device was smaller and was manufactured to close tolerances. In addition, the lock utilized a small, flat steel key, cut with several grooves. These grooves would line up with the internal pins. The Yale lock had a number of spring-biased pin tumblers, each in two parts or segments that were set in line with the key. Once inserted, its serrated upper edge would raise each pin to the correct height, so that the plug could be turned. Tolerances were such that a difference of .02" in pin length would be sufficient to prevent rotation.

Linus Yale, Jr., is credited with actually making the modern pin tumbler lock available to the public. Although he was never in partnership with his father, he followed in his father's tradition, designing and making locks in his own factory. He succeeded at improving his father's original design, ultimately allowing it to be mass produced. For the first time in history, Yale's lock made possible large-scale use of a secure locking device at a modest price. It was produced in many forms and allowed complex keying systems to be introduced. Today's locks are but a refinement of the original Yale pin tumbler design.

In 1868, Linus Yale, Sr., died. In the same year, his son took on as an associate, Henry Towne. As a young engineer, he had worked in Port Richmond Ironworks during the Civil War, then went to Paris to study at the Sorbonne. In 1883, the Yale Lock Manufacturing Company became the **Yale and Towne Manufacturing Company**. It is now known as Eaton, Yale, and Towne, Inc.

1_5.0 Disc Tumbler Lock: 1890

The modern disc or flat-tumbler lock was originally introduced in England in 1890 and was later refined in the United States. It has wide acceptance today in many low to medium security applications, ranging from vending machines, to desk locks, to key switch locks.

1_6.0 Knobset Locks: 1919

W.R. Schlage introduced the Knobset in England in 1919. It provided the basic design for the key-in-knob lock, found today in most homes and offices. Ultimately, Schlage would found one

of the largest manufacturing facilities in the world.

1_7.0 Sidebar Lock: 1935

Briggs and Stratton introduced the sidebar in 1935 for use in the automobile. The design of this lock was a radical departure in mechanisms employing wafer tumblers and remained impervious to bypass for almost fifty years. The sidebar design has been incorporated into pin tumbler and other types of locks, to provide a high level of security against picking.

1_8.0 Lock Developments of the Past Fifty Years

Improvements in designs, combinations of technologies, introduction of electronics, sophisticated metals and production techniques have occurred within the past fifty years. These improvements are surveyed in **Chapter 2**.

1_8.1 From Blacksmith to Locksmith: The Development of the Locksmithing Profession

Locksmithing is one of the oldest handicrafts known to civilized man. Long before the great Pyramids were built, blacksmiths plied their trade in Egypt, Babylon, Assyria and China. For four thousand years, their primary mission has been to design and construct locks that would make picking and bypass difficult.

1_8.1.1 Guilds in Europe

The traditions and customs of locksmithing, as it is known today, are derived from the great medieval **guilds** of locksmiths which had their formation during the Middle Ages. The guild was the all-powerful force. It regulated everything from the terms of apprenticeship, the rules and conduct for journeymen, and the techniques of the masters, to prices, and the number of rivets that could be placed in a lock. The guild was the supreme master over the craft; the penalty for defiance was expulsion and the loss of the right to earn a living as a locksmith.

Of course, in the earlier days, the strictness of the guild masters helped maintain the integrity of the locksmith's trade.

Like all autocratic and dictatorial organizations, however, guilds became overbearing, jealous of power, and unwilling to advance. The locksmith trade became a father-to-son enterprise and remained so until the end of the eighteenth century. This is one of the reasons that lock design did not progress much beyond the creation of intricate artistic patterns while the guild was so active. Lock making would have to wait until the Industrial Revolution before utility designs and mass production techniques were employed.

The Renaissance was a humanistic revival of learning that originated in Italy in the fourteenth century and marked the transition from medieval to modern times. While the rest of the world awakened to the wonders of science, art, and engineering during this period, locksmiths amused themselves and their customers with trick locks and fancy designs. For hundreds of years, the locksmith's stock in trade consisted of false keyholes, false wards and many "gingerbread" designs. Chests that cut off fingers, fired shots, ejected murderous knives, or other exotic devices were the order of the day.

As has been previously described, only one notable improvement was added to locks during the Renaissance: the lever tumbler was introduced. Amazingly, the lever principle was never fully appreciated by Renaissance locksmiths, who simply handed it down to their more skillful heirs of the nineteenth century.

1_8.1.2 American Locksmiths

In America, old-guild traditions and customs did not fetter locksmithing. Rather, they took full advantage of the advanced mechanical knowledge of the day and produced masterpieces of precision and security. As has been noted, the two primary contributors to nineteenth-century American lock technology were Yale and Sargent. As mass-production methods were introduced, the locksmithing craft broke into two distinct groups: lock makers and lock repairmen. The manufacturing end of the business became a highly technical and complex function, leading to the creation of multimillion dollar giant manufacturing organizations. The term "locksmith" now refers to the repairman rather than the manufacturer of locks.

Several inventions increased the scope and efficiency of locksmiths. The first of these, the **key duplicating machine**, was invented by Henry Gussman in 1909. his machine ended the drudgery of hand filing and made accurate reproduction of keys within a

matter of minutes a practical reality. The next significant advance was the development of the **code machine** in 1926 by the engineers of the Independent Lock Company. This device created new opportunities for locksmiths, because it enabled them to make keys according to the "serial number" of the lock.

Many inventions and devices designed to make locksmithing more lucrative and technically advanced have been introduced in recent years. The trade will be forever indebted to men like H. Hoffman and Jerry Hoffman, Ted Johnstone, Eli Epstein, Nick Gartner, Harry and Clayton Miller, S.A. McClean, the Chubb Group in England, and scores of others. Their tools, devices and methods have become standard in the locksmith industry. Locksmithing in America is a vital, growing field. The industry has formed significant international trade associations. These include the Associated Locksmiths of America **ALOA**, Safe and Vault Technicians Association **SAVTA**, and National Safemans Organization **NSO**. They all have raised the level of proficiency of the entire profession by offering educational and certification programs to insure the competence of the industry.

Specialized schools in the United States provide excellent technical manuals and on-site training for locksmiths of all skill levels. The **HPC Learning Center** in Chicago, as well as **MBA and Lockmasters**, both in Lexington, Kentucky, lead the industry in their educational programs for the professional lock and safe technician. With modern techniques, scientific tools, and continuing education, the locksmith profession has progressed from a small handcraft to a flourishing service industry.

Locksmith training in Denmark, in comparison to the United States. Courtesy of Hans Mejlshede.

CHAPTER TWO: RECENT DEVELOPMENTS

The Last Twenty-Five Years

2_1.0 Advances in Security

The first edition of ***Locks, Safes, and Security*** was written in 1970. At that time, there were really only two "new technology" high-security cylinders available in the U.S. market: the Keso dimple lock and the Medeco sidebar rotating tumbler lock. Twenty-five years ago, the market for locks in the United States

was primarily supplied and supported by American manufactured products. Simply stated, locks sold in America were made in America. Today, the market for locks is international, with U.S. companies manufacturing and selling their products throughout the world. More importantly, vendors from many countries produce or offer their wares to the U.S. consumer. Security requirements and standards are now formulated and adopted on an international basis.

When the first edition of this book was published, automatic teller machines were just beginning to appear. Magnetic stripes on credit cards had recently been developed, and the use of computerized access control systems and high-security locks were not yet popular. Neither Corporate America, nor the general public was as security conscious as today. But then, the problems of international terrorism, theft, sabotage, and issues relating to overall security were not as serious, either. There were no personal computers (PCs), nor hackers or high-tech thieves. Modems and fax machines were not prevalent, and cellular was still in the minds of Bell Laboratory engineers. Medeco had introduced the most sophisticated lock in the late 1960s, based upon a patent granted for the innovative rotating tumbler and sidebar. This lock set the standard for high-security mechanisms and retains its superiority to this day.

During the past quarter century, many developments have dramatically affected the lock and security industry. Optics, magnetics, RF and induced fields, electronics, tiny microprocessors, and sophisticated mechanical designs utilizing new alloys and materials have emerged to become standard implements in the arsenal of security hardware. These devices, including locks and safes, enable government, commercial, and the private consumer to reap the benefits of technology in their quest for security. The integrated circuit, surface mount technology, and many spin-offs from the space program offer manufacturers the option to design and produce any desired product.

Perhaps the greatest advance has been in the integration of computers with mechanical locking devices. The use of microprocessors has made possible an incredible array of security features that are now required in the modern work environment. Options such as multiple levels of access control based upon security clearance, location, time of day, and direction of entry or exit, can all be provided simply and economically. Detailed audit functions, supervisory control, and remote authentication

are standard items.

Security and sophistication of master key systems has been greatly enhanced. The use of computer-based control can allow an infinite number of key combinations, without cross-keying problems associated with earlier and less complex systems. It is not unusual for a large physical facility to have 100,000 or more master keyed cylinders with incredibly complex keying requirements, without any loss of security that was typical in older systems. In today's market, one may find low-priced to highly sophisticated and expensive locks, alarms, and enclosures. There is a product to meet virtually every need and budget. If a desired product cannot be found in America, then it surely can be obtained in Europe or the Orient. Security requirements are now universal, and manufacturers from every part of the globe are scrambling for the business.

The author has observed certain design trends since the original edition of this book was published, the most significant of which are outlined below. Harry Miller, the genius behind the Sargent & Greenleaf Company for over thirty years, recognized early in his career that very few entirely new inventions were conceived. Rather, **new combinations** of old ideas were what drove most industries, especially the security industry. Today, one may find ideas incorporated in products that were originally introduced many years ago. Their application in new devices attests to the soundness of the original concept and to the sophistication and diversity of the marketplace.

The sidebar lock is a prime example. Originally developed by Briggs and Stratton in 1935 for use in cars, it has not only remained the standard for the automotive industry, but several high-security cylinder manufacturers have adopted the basic idea. Thus, the original premise is now the basis of designs by General Motors and Ford, as well as by Medeco, Assa, Schlage, Ikon, and others. Sidebar locks provide extremely high-security, if designed correctly. Many variations of the original principle can be found that offer sophisticated keying and pick resistance. They have become popular in government and commercial installations, where key control, resistance to physical attack, and other criteria are important.

Other major innovations have occurred in both pin tumbler and wafer locks. Dimple locks, first introduced and patented by Keso in a high-security configuration, have become extremely popular and are presently manufactured by many vendors throughout the

world. Mul-T-Lock of Israel, Keso of Switzerland, DOM of Germany, and others have improved upon the original design introduced twenty-five years ago. Now, for example, telescoping tumblers are utilized for increased pick resistance. These locks, utilizing from four to twelve or more pins, can be very difficult to pick, although some may be impressioned.

Magnetic locks have become prevalent within the past twenty years as an adjunct or alternative to the pin tumbler principle. Although there are a number of different schemes employed, the basic theory is the same in all such devices: like poles repel and opposite poles attract. The magnetic locking principle has been applied in conventional as well as high-security cylinders. Probably the most clever and unique cylinder design was developed by Evva in Austria and produced under license by Ikon in Berlin, Germany. This lock utilizes two rows of four round, freely rotating disc magnets which control two sidebars. Corresponding embedded magnets within the proper key will cause individual rotation of the discs within the lock, so that they align properly to allow sidebars to engage.

The magnetic locking principle has also been applied to card locks both for access control and higher-security applications. A pioneer in the industry, Corkey of Hong Kong devised and patented a lock that utilized up to 42 magnetic pins. These had to be lifted by corresponding magnetized spots in a barium-ferrite vinyl card inserted into the lock. The security of this, and similar mechanisms, is based upon the location and polarity of each of the magnets. Card locks utilizing magnetic pins as in the Corkey and magnetic stripes such as found on credit cards have become popular, especially in the hotel industry. Hoteliers have recognized increased security needs, stemming from losses by their hotel guests that have translated into large money judgments against the hotel. The flood of litigation has forced the industry to install specialized locking systems, even in the smallest inn.

Hotels throughout the world now utilize a wide array of locking systems, all designed to provide access control, security, and ease of key change. As noted later in this text, many of these systems provide key control but not security. The hotel guest will find locks that utilize magnetic stripes on credit cards, cards with magnetic spots hidden throughout the card surface, and cards with holes punched in various locations. Door locks in these hotels will read cards utilizing infrared optics, magnetic readers, magnetic pins, or other technologies that did not even

exist twenty-five years ago.

Instant rekey locks, such as offered by Winfield, are also popular. Introduced in the late 1970s, they allow maintenance staff to instantly rekey a cylinder, either to a different guest key or to a different master key.

Electronic access control systems have become extremely popular. Keypads are utilized at entry points and allow secure control of mechanical locks and strikes. There are many systems to choose from, both domestically and in Europe.

Developments by Medeco, LaGard, Hirsch, Mas-Hamilton, Evva, Keso, DOM, Ikon, S&G, Ford, GM, and a host of other companies throughout the world have provided the industry with innovative approaches to access control utilizing microprocessors and transducers embedded in keys. These electronic systems offer excellent flexibility, allowing customers to define exactly who, when, where, and how an employee shall gain access.

Locks based upon RF induced fields have also become popular in access control and automotive applications. These devices sense proximity through the use of passive transponders that receive a coded signal, then rebroadcast that signal at a different frequency back to the initiating station. Transponders are now built into keys, credit cards, and other similar wafer-sized devices.

In the realm of safes and vaults, three dramatic advancements and innovations have occurred within the past ten years. In 1987, Chubb Research and Development, in Wolverhampton, England, developed and patented a process and materials that would allow the company to offer an all-plastic fire and burglary-resistant safe. The product, called the "Planet", will protect the contents for one hour, at 1800°F. In addition, the special plastic resin is extremely resistant to most forms of penetration. This is the only fire and burglary-resistant safe available in the world as of 1993. The materials utilized by Chubb may be poured into any configuration and are already being utilized in certain other specialized applications.

The electronic combination lock patented in 1991 by the Mas-Hamilton Group, in Lexington, Kentucky, is the second major development to occur involving safes. The X-07, in the view of the author, is perhaps the most innovative enhancement within the safe and vault industry since the time lock was introduced over

one hundred and fifty years ago. The product was originally conceived and developed by an award-winning team of designers, including Clayton Miller and Jerry Dawson, and has set the world standard for a computer-controlled lock. Clayton Miller, who ran Lockmasters school in Nicholasville, Kentucky, is an internationally recognized expert in the field of safes and vaults. His father, Harry Miller, is regarded as the dean of the combination lock industry in the last half century. No doubt, Harry Miller's influence contributed to the design of the X-07.

What Miller, Dawson, and others accomplished in their design would completely revolutionize mechanical-based three and four-wheel combination locks. The configuration relies upon an on-board computer, powered by three generators, driven by the dial as it is turned. Thus, no batteries are required. One million actual combinations are available without compromise of security. The lock allows for a number of audit and control functions and will surely set the standard in the industry for the next hundred years. To date, eleven United States government agencies have evaluated the lock and concluded that it cannot be manipulated or compromised. It is the only lock to receive DoD approval, to date, as a Group 1 rated device for top security enclosures.

The third major development in the safe and vault industry is a direct result of the introduction of the Mas-Hamilton X-07 lock. Computerized robot dialers and manipulation devices have become available within the past five years. These are typically comprised of a sophisticated computer-based portable servo stepper-motor that is attached to the dial. They will test every possible combination within preset parameters, in forty-five minutes to eighty hours, for a three-wheel lock. The electronic combination lock was developed as a response to these devices and cannot be manipulated or auto-dialed like conventional mechanical locks. Mas-Hamilton is developing its own manipulation robot, which may be capable of opening both Group 1 and Group 2 locks, utilizing advanced optical computer links to sense sound and dial rotation.

A number of very sophisticated picking, impressioning, and decoding tools have appeared within the past twenty years, introduced by HPC, MBA, John Falle, Lockmasters, Jeff Cookson, and other vendors. Although many companies offer such tools worldwide, the leaders in the industry are undoubtedly HPC for the commercial sector and John Falle for government applications. Jerry Hoffman, at HPC, is well known in the trade. He has

developed an extensive product line that is marketed throughout the world. His company, which was originally begun in the 1930s by his father, is recognized for their innovative approach to serve the locksmith industry.

Today, a rich diversity of complex tools is offered to the professional locksmith to decode, pick, and impression almost any lock. They are described in detail throughout this text. HPC, ILCO, and Silca of Italy have lead the industry in the development of sophisticated, computer-based key-cutting machines, since 1965. These companies produce machines to read and duplicate virtually any type of key, including the three-sided "laser" or "sidewinder" used on certain foreign automobiles. Silca has even developed an attachment to one of their machines to laser-read a key and reproduce it to original factory code standard. HPC, in conjunction with LaGard, has introduced a number of key cutters and decoders that have become invaluable aids to the industry and have allowed code cutting to become the preferred method of reproducing keys. The HPC 1200 and Codemax are perhaps the best-known code machines in the world and most accepted by the American locksmithing industry.

A number of tools, chemicals, and techniques have become available within the last twenty-five years for use in forced-entry applications involving safes, vaults, and buildings. Probably the best known of these is the thermic lance. Initially developed for underwater applications in shipbuilding and repair, a lance will generate up to 10,000°F, which can be delivered without danger to the operator. A thermic lance manufactured by Broco, in Rialto, California can be handheld and can precisely cut, pierce, or gouge to or through virtually any material. The lance will cut 2″ steel in a matter of a few seconds, effortlessly. They are equally effective at penetrating concrete and cinder block to gain access to buildings.

Advances in explosives have also been made since the first edition of this book. Many varieties of plastique and flexible placed charges are now available to cut precise holes in almost any material. Advances in microcircuits brought about by the requirements of NASA, has allowed alarm technology to take a quantum leap forward during the past two decades. Sophisticated motion detectors, utilizing microwave and infrared technology, have become common, as have a host of other alarm-sensing devices, based upon on-board microprocessors.

Since 1970, sophisticated new penetration techniques, based upon

the use of computers, robots, radioscopic imaging, fiber optics, ultrasonic, and highly sensitive sensing equipment, have been developed for looking into containers and locks and for compromising them.

Since the last printing of this book, the professional locksmith trade has become a craft of highly skilled technicians, requiring a diverse amount of knowledge to properly service and open the myriad of locks and containers in use today. Continuing education is a requirement in order to remain competent in this rapidly changing field. A skilled locksmith must now have an understanding of electronics, mechanics, and manipulation and bypass techniques for many types of locking mechanisms, if he is to perform properly in today's environment.

The professional locksmiths of the world are today required to be college graduates and businessmen. They must be specially schooled in the trade, educated regarding complicated products and capabilities, and able to evaluate, recommend, install, and service a great many different products and needs. Locksmiths are now security technicians. International locksmith organizations and schools have developed special programs over the past twenty-five years to meet the needs of the profession and insure that its technicians have available the latest information regarding new products and techniques. ALOA, HPC, MBA, and Lockmasters, as well as many manufacturers have been driving forces in providing such technical support.

Finally, international standards in security hardware are being proposed and adopted. Major organizations throughout the world are agreeing upon criteria for the testing of materials, security, bypass, manipulation, forced-entry, and other requirements for locks and enclosures. Underwriters Laboratories (UL), the British Standards Institute (BSI), the International Standards Organization (ISO), American National Standards Institute (ANSI), American Society for the Testing of Materials (ASTM), and many other organizations have all contributed to the development of accepted standards for manufacturers. This book will detail both the history and current state-of-the-art in locks, safes, and security.

CHAPTER THREE: TERMINOLOGY

Definition of Terms

Master Exhibit Summary

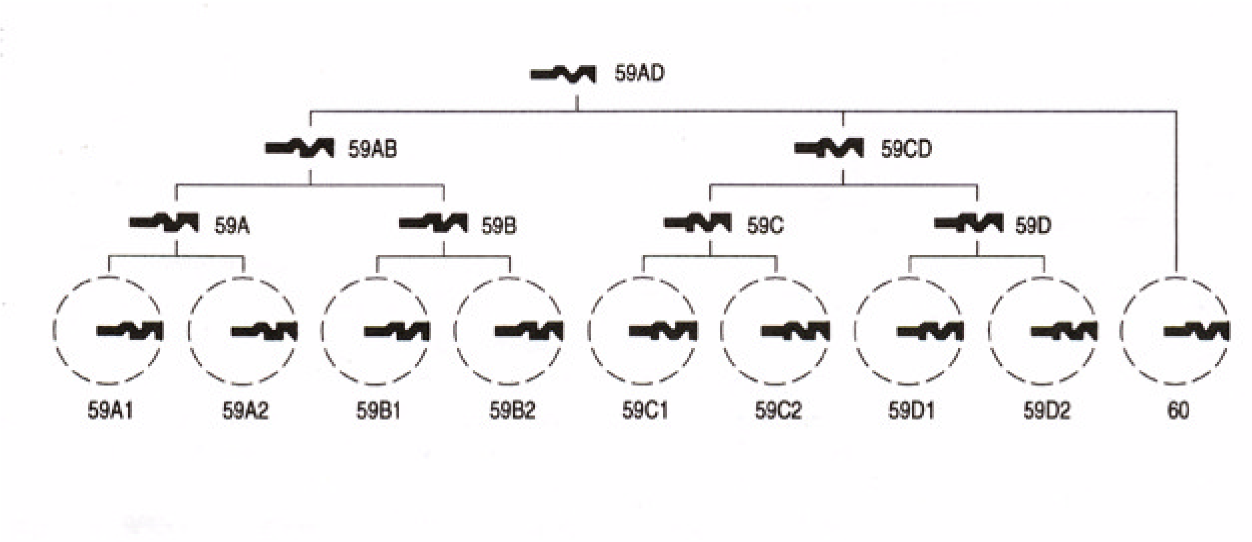
3_1.0 Definitions

The lock, safe, and security industry has developed jargon to describe and define its products and product-component parts. Although there is some difference in terminology throughout the world, there is general agreement regarding the major elements within most of the primary locking systems. In order to assist the reader in understanding the materials presented throughout this text, a basic definition of general terms is presented in this chapter. Specialized definitions applicable to materials within a specific chapter are presented within that chapter. A clearer understanding of detailed material can be achieved using this format. If you are searching for a definition or

identification of a component that is not explained in this chapter, check the Index and perform an advanced search query. The etymology of certain terms is presented within the definition where relevant.

Ace Lock: A term often used to describe an axial pin tumbler or tubular lock. Ace is a registered trademark of Chicago Lock Company, the first to introduce the mechanism.

LSS+301 An axial pin tumbler lock



Actuator: A device or extension that is usually connected to the movable component of a cylinder or lock that in turn causes a mechanical locking component to activate or deactivate. Such can be a tailpiece, cam, bolt or other linkage.

Adjustable Mortise Cylinder: Certain mortise cylinders can be physically adjusted to compensate and precisely fit doors of varying thickness. A **flexible head mortise cylinder** can be extended against spring pressure to make it slightly longer.

AFTE: Association of Firearms and Toolmark Examiners. This is the professional group of technicians, criminalists, and scientists that perform forensic examinations in crime laboratories.

AHC: Architectural Hardware Consultant, as certified by the Door and Hardware **Institute.**

All-Section Key Blank: That portion of the blank that enters all keyways within a multiplex key system. In the diagram, keyway 59AD will enter all subsections.

ALOA(51): Associated Locksmiths of America. This is the largest locksmith trade group in the United States.

Angularly-Bitted Key: A key in which one or more bitting angles are not cut in a parallel plane, but rather at different degrees of rotation from a perpendicular angle.

ANSI: American National Standards Institute

Arc Ring: A ring that is also called a circlip, with open ends that can be sprung into place to retain a plug within the shell of a lock.

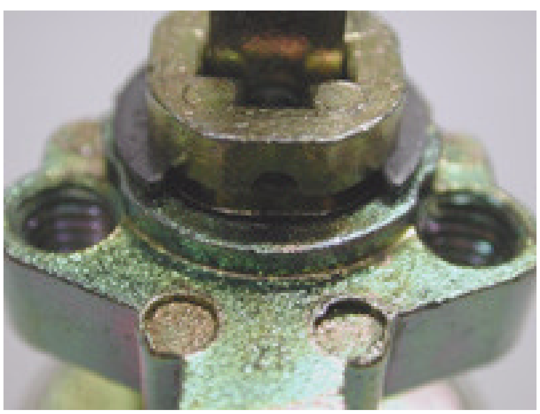


Figure LSS+302 An arc ring retains the core.

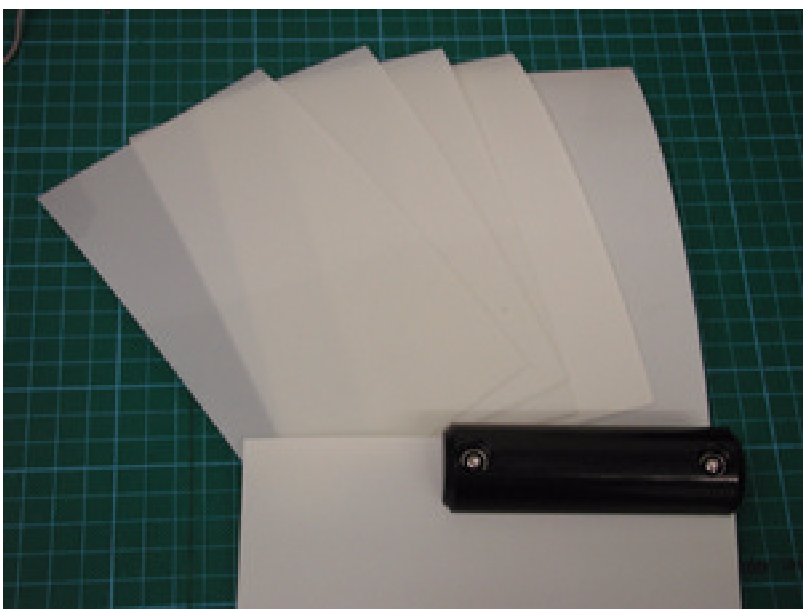
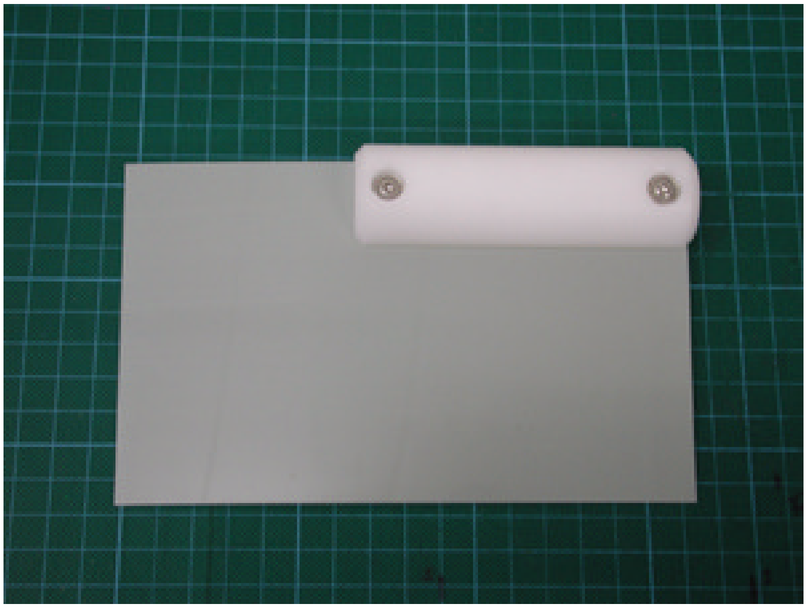
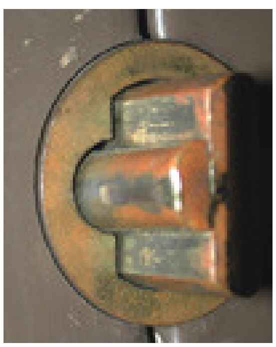


ASIS: American Society for Industrial Security. This is the largest professional security organization in the world.



ASTM: American Society for Testing and Materials.



Astragal: A molding that is used to cover the space between two doors that meet at a common closing point.

Auxiliary Deadlock Latch Bolt: An additional bolt is provided that is depressed by the strike when the door is closed to automatically deadlock the bolt against end pressure. The diagram shows the two states (left) fully extended in the unlocked position, and (right) secondary bolt depressed to block retraction of the primary bolt. A loid, such as produced by MSC and shown below, can be utilized to force the bolt to retract in the absence of a secondary bolt. A demonstration of the MSC loid is provided in LSS203.

LSS203: Demonstration of the use of a loid, by MSC

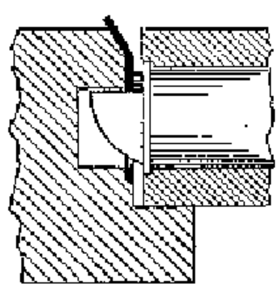


Figure LSS+303 An auxiliary deadlock latchbolt provides secondary protection against loiding. A plastic loid, produced by MSC (Germany) is shown above.

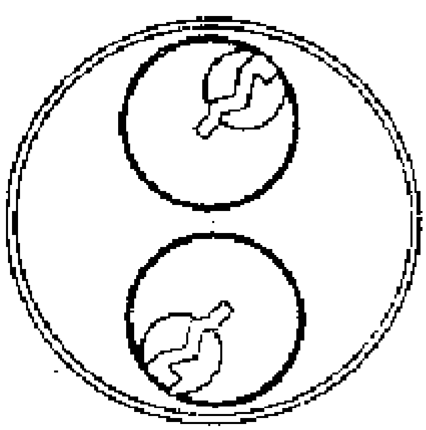
Backset: The lateral distance from the outside edge of the strike plate or face plate on the door, and the center of the keyway.

Ball Bearing: A metal ball that is placed in the pin stack in

some locks for specialized keying systems such as hotel or construction, or as a portion of the bottom pin stack in one or more chambers.

Balanced Driver: A top pin length that is varried for each chamber, and which is based upon the total length of the bottom pins. The function of the balanced driver, also referred to as **compensation driver** or **graduated driver**, is to make the overall pinstack length constant between chambers. Best locks, for example, require that the overall pinstack length for each chamber be 23 depths.



Barrel bolt: A locking bolt that is surface mounted on the door.

Bell-type Key: A key with longitudinal grooves that often run the entire length of the key. See also **Lasertrack** and **sidewinder** keys.

BHMA: Builders Hardware Manufacturers Association

Bible: That portion of the lock that contains the pin chambers.

Bicentric Cylinder: A cylinder containing two separate plugs, generally with two different keyways.

Bi-directional Cylinder: A cylinder that allows operation by rotating the plug in both directions.

Binary Cut Key: A key that allow for only two bitting depths for each position: cut or no-cut. The Winfield lock and the Schlage

wafer lock, described elsewhere in this text, are two examples. Such keys are used in **binary cylinders** or locks.

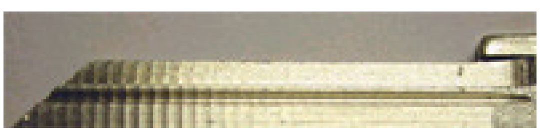
Bit or Bitting: That portion of the key that contains depth cuts corresponding to the tumblers in the lock. It can also be defined as the blade portion of the key, usually in a warded or lever lock.

Bitting: It is those portions of the key that contains depth and space information that corresponds to wards, wafers, levers, or pin tumblers. The bitting interacts with the internal locking components and is contained within the blade of the key. The term can also refer to the numbers that represent the physical dimensions of the actual cuts, or describe the combination of the key.

Bitting Depth: The depth of a cut made in the bitting, or blade of a key.

Bitting Position: The location of a key cut, with reference to the shoulder or tip of the key.

Blade of Key: That portion of the key that contains the bitting surface. The **bottom** of the blade is opposite to that surface which is cut, and the **top** of the blade is the surface upon which cuts are made. Almost any part of the blade can form a portion of the bitting area, although bitting is generally confined to the upper half of the blade, as shown in the exhibit below. Measurement of the depth of a cut is made from the root to the bottom of the blade, although in some instances a manufacturer may choose to compute from the root to a register groove.



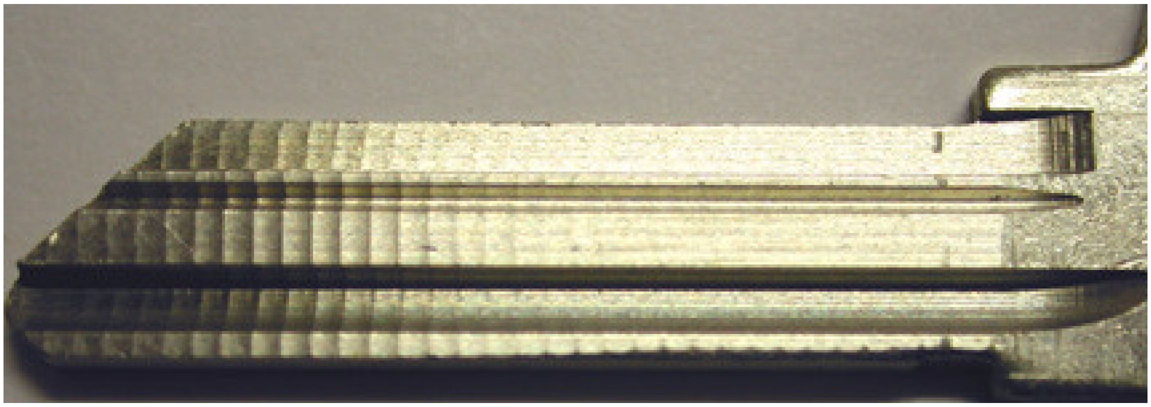


Figure LSS+304 The bitting surface of a blank key is known as the blade.

Blank or Blank Key: A key that has not been cut.

Figure LSS+305 A blank key. All of the material constitutes the blade.

Blind Code: See **indirect code.** This is a code that is unrelated to the direct code of the key.

Bolt: The active external locking component of a lock that secures the moving member to which it is affixed. A **flush mounted** bolt is one that is designed to be equal with the surface of the door and not protruding from it. A **mortised** bolt is one that is installed within the door.

Bogus Key Blank: A non-original knock-off, or bootleg key blank.

Bottom of Blade: In a single bitted key, it is the portion of the blade that is opposite to the cut edge.

Bottom Pin: Any form of tumbler that makes physical contact with the bitting. Its shape may be cylindrical, conical, ball or chisel-pointed at the contact end.

Bow and Bow Stop: The bow is the portion of the key that is held for control and serves as a handle. The bow stop is located near the bow to prevent further forward movement.

Broach: This is a hard steel die that is used to cut the keyway into a plug. The term can also be a verb, indicating the process of cutting, and is described more fully in later chapters.

Bypass Key: A key that operates a cylinder that overrides normal operation.

Cam: The tail-piece, thrower piece, or tongue that is attached to the end of the rotating plug, and is used as the actuator for the locking mechanism. A wafer lock is shown, with cam attached.

Figure LSS+306 The cam transmits rotational energy and forms the locking bolt.

Cam Lock: (shown above) A cam lock comprises the complete locking system, whereby the cam constitutes the locking bolt or mechanism.

Cap: This term has two definitions. It is that part which links and retains the plug to the shell and acts as an actuator. It can also be the spring cover for a single pin chamber.

Case Ward: Within a warded lock, the ward or obstruction that is formed as part of the case. Note the circular bands around the keyhole. Corresponding removal of material from the bitting surface of the key will allow rotation.

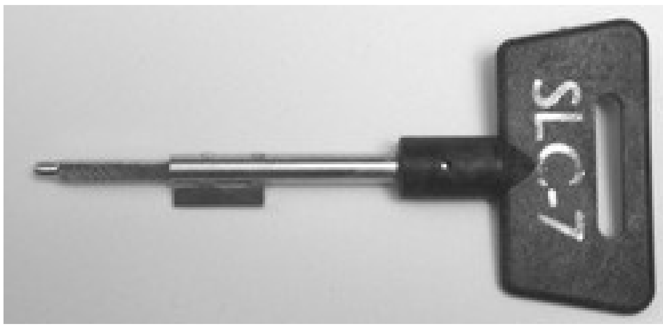

Figure LSS+307 A case ward is integral to the lock body.

Chamber: Any opening, hole, or cavity within the shell or plug of a lock that contains tumblers.

Change Key: The lowest individual level of keying. A lock may

have a change key and several levels of master keys. The term also refers to a special/ key used with combination locks to alter the relationship between the gates and drive pins in each disc within the wheel pack.

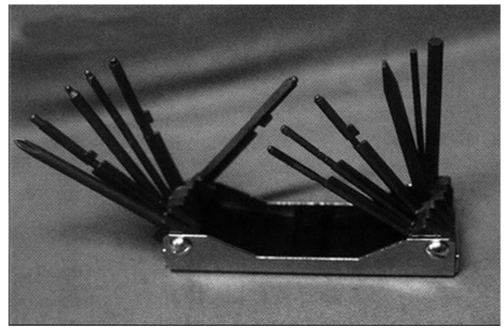

Figure LSS+308 A change key for a combination lock. Complete sets(52) are also available.

Changeable Bit Key: A key that allows for the interchange of the bitting surfaces in order to alter or rearrange its combination.

Chubb: The name of a famous English lock maker who founded a company in 1818 that still exists today. The name Chubb is identified with many revolutionary patents, including the Detector lock.

CK: Symbol for change key or control key.

Clevis: A metal link that is utilized to join a chain to a padlock.

CMK: Construction master key.

Code: A record of the bitting corresponding to a particular key. A "code cut key" is one made from such information, rather than from a physical copy.

Code Original Key: A code cut key that conforms to the lock manufacturer's specifications. Note that the factory direct reading code appears on the key head, and correlates to the depths of each cut, from front to shoulder.

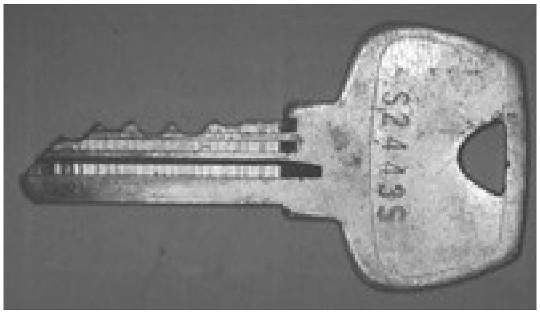

Figure LSS+309 A factory original with a direct reading code.

Combinate or Combination of Lock: The group of bitting which form the various tumbler positions within a lock. Combinating a lock means to set a specific combination. An uncombinated lock is one that is supplied without keys, tumblers, or springs.

Combination or Permutation Lock: The name for a keyless lock utilizing numbers, letters, or symbols. These will correlate to the internal location of gates, the precise alignment of which will allow the lock to open.

Combination Pins: The lower pins within a pin tumbler lock that are utilized to set the individual bitting pattern for a specific lock.

Combination Wafer: A binary disc tumbler that is used in certain key-in-knob wafer locks, such as Schlage.

Compensation Drivers: See also balanced drivers and graduated drivers.

Complementary Keyway: A keyway within a wafer lock that has been master keyed. The design will allow different key sections to make contacts with different areas of the disc.

Composite Keyway: An enlarged keyway that has been designed to accept more than one key section. The keyway may allow sections from several manufacturers to pass the wards.

Compound Bitted Key or Cut: A complex bitting that contains a cut within or overlaid upon another cut.

Concealed Shell Cylinder: Generally a mortise cylinder wherein only the plug face is visible or accesible when properly installed.

Connecting Bar: A bar, rod, or other linkage that transmits motion from the rear of the lock plug to the bolt, latch, or other opening mechanism.

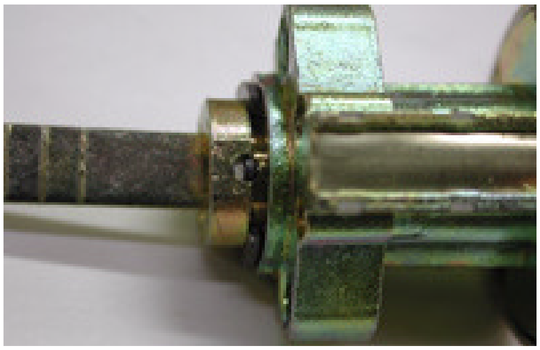

Figure LSS+310 A connecting bar transmits rotational energy to the bolt.

Construction Master Key CMK: A special key that is utilized during the time a building is under construction. Once a building has been completed, such keys will be rendered inoperative. A **construction core**, often keyed alike, may be utilized for this purpose, then removed after the project has been completed.

Control Key: A key that is used for the sole purpose of installation or removal of an interchangeable or removable core from the shell of a lock. The bitting of the key that releases the **control lug** (and the core) is referred to as the **control cut(s)**.

Core: See **Plug**. A core can also consist of all components in the lock (plug, shell, all pins, plug retainer and springs). The core in an interchangeable lock may take the form of a figure eight.

Corrugated Key: A key having longitudinal striations or corrugations corresponding to the locks keyway. These keys are used in warded padlocks.

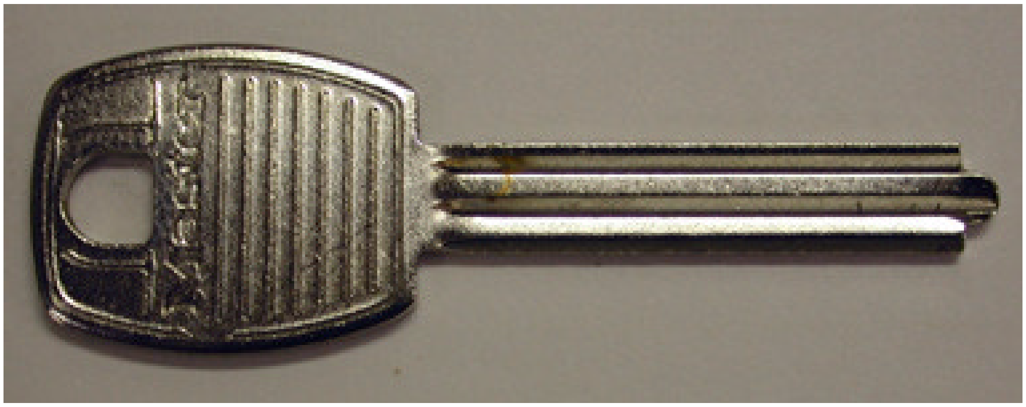

Figure LSS+311 A corrugated key is used primarily in warded padlocks.

CPL: Certified Professional Locksmith (by ALOA.

CPP: Certified Protection Professional (by ASIS.

Cross-Keying: Cross-keying can be described both as intentional (controlled or intended) or as a system keying error (uncontrolled cross-keying) that is caused or created by setting the combination of a master keyed cylinder so as to create one or more virtual shear lines to allow more than one key to operate the lock. Uncontrolled cross-keys may allow unintended or unauthorized keys to open one or more locks, and can also permit two or more different keys that are grouped under higher level keys to operate one cylinder. When a lock is master keyed, many virtual shear lines are created as the result of multiple pins being placed in each pin stack. Each added pin creates another shear line. In a six pin lock with a lower pin and master pin, there would be a total of 64 (2^6) combinations created.

Cruciform Key: A special key bitting design, or keyway that takes the form of a + or X.

CSI: Construction Specifiers Institute.

Cut: An indention, depression, or notch made in the bitting of a key.

Cut Angle: The measurement, expressed in degrees, of the combined angles created by making a cut in a key.

Cut Edge: That area of the key blade that contains the cuts.

Cut Key: A key that contains bittings.

Cut Root: The base or bottom of a key cut. The photograph shows an individual cut of a key for a pin tumbler lock. **"A"** represents the cut angle; **"B"** shows the root or base of the cut. The shape denotes a key that was cut by code.

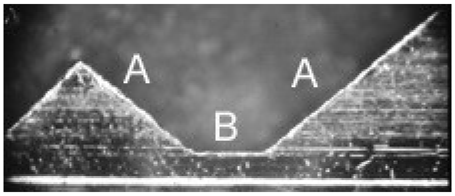

Figure LSS+312 The root of one cut from a pin tumbler key.

Cut Root Shape: The shape of the bottom of a key cut. In the case of a lever tumbler lock, the cut root shape will be flat, having 90° corners. In the **pin tumbler** lock, the shape will usually be curved or angled, as shown in the photograph above (cut root). The root has a specific dimension that may be flat, radiused, or be a perfect "v".

Cutter: The active portion of a key machine that creates bittings. This may also be described as a cutting wheel.

Cylinder: A self-contained lock assembly that consists of the plug, shell, tumblers, springs, plug retainer and tailpiece.

Cylinder Clip: Certain cylinders are secured in place by a spring steel mechanism.

Cylinder Collar: A protective ring, often hardened, that fits around the lock cylinder on the outside of the door on mortise and rim locks. Their function is to provide a mounting surface and protection for the cylinder.

Cylinder Guard: A protective device that forms part of the mounting hardware. It may also be referred to as the **security collar**.

Cylinder Key: A general term that denotes the key for pin and disc tumbler locks.

Cylinder setscrew: The retaining screw that is utilized on a mortise cylinder to secure it in place, and to prevent its rotation and removal.

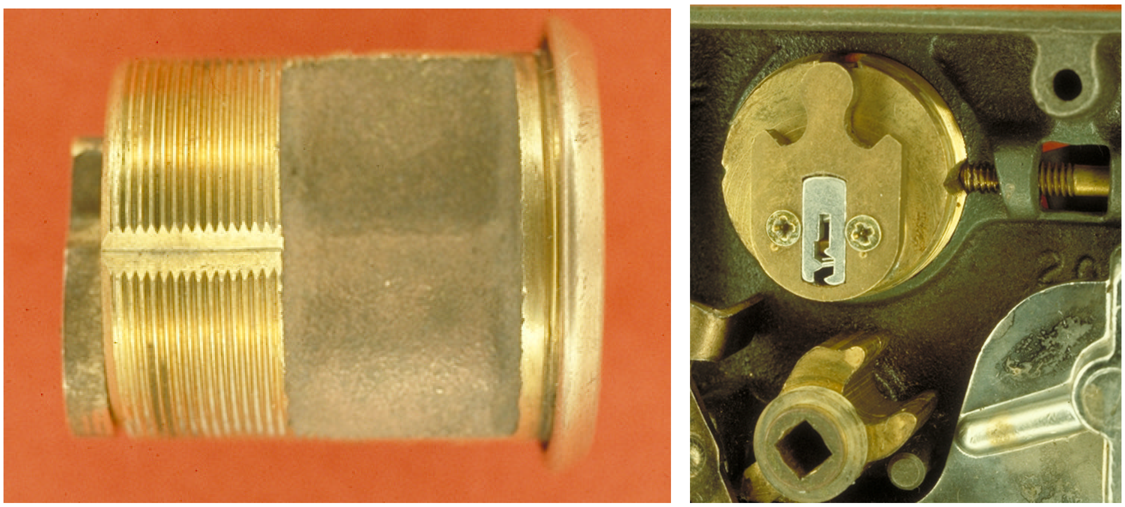

Figure LSS+328 (ISP 49-2963 left, and 50, right). A standard mortise cylinder showing its mounting and retention by setscrew.

Dead bolt: A square-shaped bolt that extends into the strike or recess of the door frame in such a way as to be locked into place, and incapable of retraction as the result of end pressure. In the photograph, a dead bolt that extends three inches is shown.

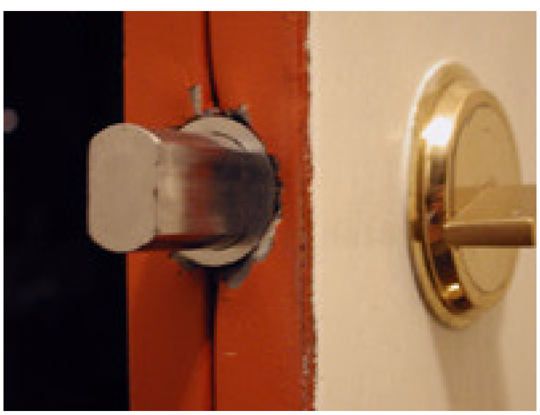

Figure LSS+313 A dead bolt can extend horizontally or vertically from the door.

Declining Step Key: A bitting pattern that contains cuts that progress from shallow to deep from bow to tip. A stair step pattern. It is also referred to as a shedding key.

Decode: To ascertain the bitting or combination of a key or keys that fit a lock by physical measurement, or extrapolation through the use of specialized tools or procedures.

Degree of Rotation: Certain high security locks such as Medeco provide for the rotation of cuts made into the key blade. The degree of rotation specifies the angle of the cut and is referenced from the perpendicular. Medeco defines three angles: right (R or 2), left (L or 1), and center (perpendicular or C).

Depth Key Set: A set of reference keys made for a specific lock that provide complete depth and spacing measurements. A key can be duplicated from such a reference. Each key within the set is cut so that all bitting positions are the same, with the proper spacing between positions. One key is cut for each depth.

Derived Series: A series of indirect or blind codes that represent bittings that are directly related to those contained in another bitting list.

DHI: Door and Hardware Institute.

Differs and Differing: The term "differing" originated in England and refers to the designated change key that fits a lock. It also describes the number of different possible combinations and numbers of change keys that can theoretically open the same lock. The number of wards, levers, pins, discs, design of the keyway, and tolerances determine "differs". Although the number is mathematically based, it is not absolute. Differing is also affected by the method of cutting a key. The number of combinations may be increased by complex lock design, utilizing for example, magnetic and mechanical locking action, or standard pin tumbler combined with a sidebar. The author prefers the term "differs" for use in this text to denote possible combinations, although other terms are accepted. The **theoretical number of key changes** or combinations may greatly exceed the actual number of useable differs.

Dimple Key: A key in which the cuts are produced by drilling holes and removing material from the bitting surface. In the photograph, a Sargent Keso key that is cut on three surfaces. The depressions are called "dimples."

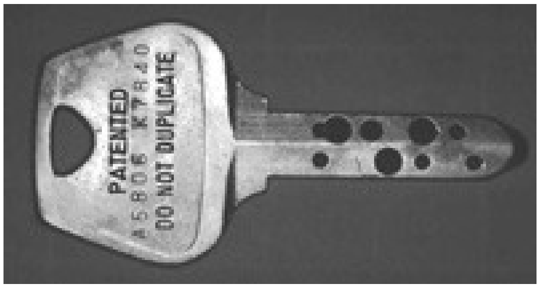

Figure LSS+314 A Sargent Keso dimple lock requires a key with three active surfaces.

Direct Code: See **code.** A direct code corresponds precisely to the bitting patern of the key. The code designates a bitting depth for each chamber that correlates directly with the measurement of each pin.

Disc Tumbler: A flat metal tumbler utilized in a variety of cam locks to retain the plug in a fixed position until the proper key is inserted. The term can also refer to a tumbler, usually flat and rectangular, that contains a gate that must be aligned to one or more sidebars by the proper key.

Double-Bitted Key: A key that is cut on two surfaces, usually opposite each other. These surfaces meet the internal mechanism of the lock.

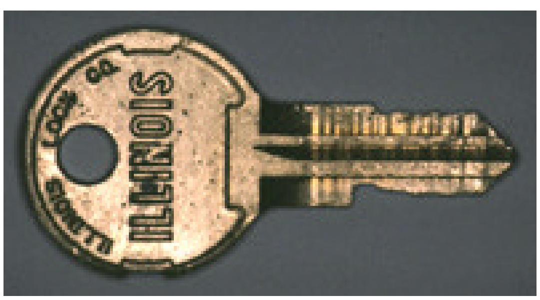

Figure LSS+315 A double-bitted key. Note bitting on both vertical surfaces.

Double Pin: When two or more master pins or wafers are placed within one chamber, the lock is said to be double-pinned.

Driver Pin: A driver pin provides the top portion of the pin stack and is biased directly by the spring (driver spring). In a chamber with only two pins, it provides for double detainer locking of the plug. The preferred nomenclature today is **top pin.**

Effective Plug Diameter: This term applies to pin tumbler locks and is the actual diameter of the plug. It is computed by adding the length of the bottom pin to the position in the root of the cut where the tumbler actually rests, thereby establishing a perfect shear line. The effective diameter may be slightly greater than the actual diameter of an empty plug.

Ejector Holes: Within certain interchangeable core locks, there is a hole at the bottom and under each chamber. It provides a path for the ejector pin, which uses a tool to drive all of the elements of a chamber out of the lock, to aid in rekeying.

Emergency Key: A key that can bypass a lock (often in a hotel) or privacy feature. It may also be referred to as an emergency key (abbreviated EMK), and is used to open every lock within a hotel.

Escutcheon Plate: A protective or ornamental plate that provides an outer protective cover for locks and related components when mounted on a door.

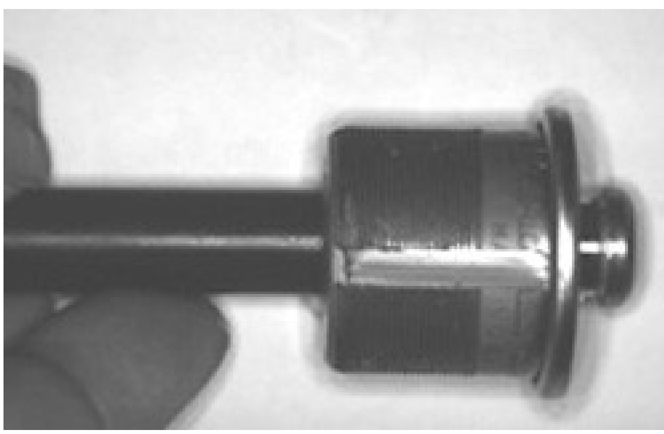
Extractor: A tool that is used to remove a broken key from a keyway. It is usually made of fine saw-teeth.

Factory Original Key: This is the key provided by the manufacturer for a specific lock. It is referred to in this text as the **Source Key**.

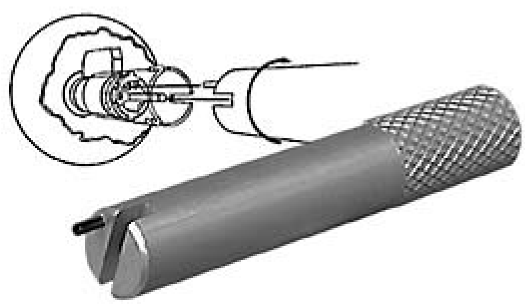
Feel Picking: This is a method of lock bypass requiring that each individual tumbler, wafer, or lever be manipulated or raised by a curved or similar pick tool. Feel picking is the traditional method of lock picking, and is contrasted with rake picking and other methods described throughout this text.

Fence: Generally in lever locks, but the term can be applicable to sidebar, combination and other locks. It denotes a projection on the bolt that is designed to prevent movement of the bolt unless proper alignment occurs between a corresponding gate.

Firemans Key: A key that is used to bypass or override normal operation of elevators in an emergency, usually fire.



First Generation Duplicate or Copy: A key that is reproduced directly from a factory original or code-cut key. This is contrasted with a "first key" that is generated other than by copying of a source key.



Flat Key: A key made from sheet metal, without grooves or keyway, used in warded or lever locks. Most safe-deposit locks utilize flat keys.

Figure LSS+316 A flat steel key, usually made of brass or steel. This key fits a safe-deposit lock.

Following Tool or Follower: A round tool utilized when disassembling a pin tumbler lock. A follower resembles a dowel or round metal tube and has the same diameter as the plug it replaces. In the photograph, a follower is partially replacing the plug, shown at the front of the lock. The tool will "follow" the plug through the shell, until the plug can be completely removed. The follower will replace the plug, maintaining the top pins and springs within the shell. A segmented follower is a special tool that is divided into sections and is utilized in profile cylinders.

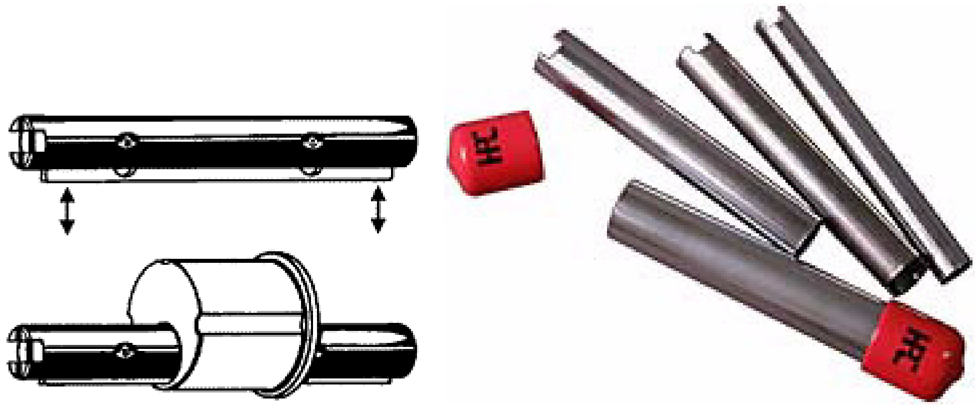


Figure LSS+317 A variety of following tools are available to fit virtually any plug diameter. Shown are a fixed diameter, and a spring-loaded tool produced by HPC to adjust to different plug sizes. Also shown is the HPC hollow follower set for several different plug diameters.

Gate: A notch or indent that is cut into the tumbler edge to correspond with and accept a fence or sidebar protrusion.

Graduated Driver: See balanced driver. These constitute top pins of different lengths that are used to compensate for the overall length of the pin stack, so as to make the total length of the pin stack constant.

Grand Master Key: A key that operates locks in several series, all of which have their own group master key.

Guard Key: A safe deposit box lock, generally of lever design, usually requires that two keys be used in concert to accomplish an opening. One key is utilized by the "guard" or bank; the other by the renter. A **prep key** is a form of guard key that is used in locks with only one keyway. It must be turned once and withdrawn before the renter's key can operate the lock.

Hand of Door: The orientation of the lock, determined from the hinge position on the door. Thus, "right hand" means that the hinges are on the right side of the door.

Hand of Lock: This term primarily applies to combination locks, and indicates the mounting orientation with respect to the bolt. Handing is specified as vertical up (VU), vertical down (VD), right hand (RH), or left hand (LH).

Hardware Schedule:(53) This is a specification that details the door hardware to be utilized on a job.

Hasp: A fastening arrangement comprised of a fixed staple and corresponding slotted hinged member (hasp).

Heel: This term refers to the moveable locking portion of a padlock shackle that is not removed from the body when unlocked.

High-Security Lock: A lock designed to offer a greater degree of resistance to surreptitious and forced-entry methods, including picking, impressioning, key duplication, drilling, and other forms of entry.

Hold-Open Cylinder: A locking mechanism that has a special cam that will retain the latch bolt in the open or retracted position when so set by the key.

Holding Fixture: An apparatus that is designed to hold or retain cylinders, plugs, and other lock parts to facilitate their installation and maintenance. A setup tray can also be considered as a holding fixture.

Hollow Driver: A top pin that is reamed or hollowed out to allow insertion of the spring into the body of the pin. This is especially useful where there is limited clearance within pin chambers.

Housing: The part of the lock that holds the plug. See **shell.**

Impression System: A technique to produce keys for certain types of locks without taking apart the mechanism. The process is used to determine the position and depth of cuts corresponding to the tumblers. Another form of impressioning involves the **copying of keys** through the use of wax, clay, or metal impressions. An "impression" refers to the mark left by the tumbler on the key.

Increment: The measured difference between depths of the bitting of a key. These differences are usually uniform (for example, .015") and will correspond to changes in the length of bottom pins (in a pin tumbler lock).

Indirect Code: A reference number that can be correlated to the actual bitting of a specific lock or key through an independent reference. This may also be called a **blind code.**

Interchangeable Core: A locking system that allows the rapid interchange of the entire locking assembly is referred to as an interchangeable core. All of the components (plug, shell, pins,

springs, retainer) are self-contained within the core, which can be easily removed through the use of a control key. The term "removable core" can also describe this mechanism.

Interlocking Pin Tumbler: A system wherein all pin segments within a chamber are interlinked when the plug is in the locked position. See **section 17_4.4.**

Jamb: The vertical portion of a door or window frame.

Jimmy-resistant Rim Lock: A type of rim lock that resists prying of the door from the jamb to bypass the bolt. A vertical movement prevents the bolt from being withdrawn.

Jumbo Cylinder: A large mortise cylinder that may measure 1 1/2" in diameter. See **section 23_2.4.**

K: The symbol for Key.

KA: The symbol for Key Alike.

KBA: The symbol for **key bitting array.** It is a graphic matrix of all of the possible bitting for change keys and subgroup master keys within a master key system.

KD: The symbol for Keyed Differently.

Key: There are many different kinds of keys. A key is a device that can be carried by its owner. It is inserted into a particular lock or group of locks to cause the internal mechanism to align, thereby allowing an opening. The modern spelling dates from 1632. Before that time, other spellings can be found. The reader may be interested to know how the word is spelled in different languages: clef (French), schlussel (German), llave (Spanish), chiave (Italian), sleuted (Dutch), lukke (Norwegian), nyckel (Swedish), clavis (Latin), and cleis, (Greek).

Key Alike: A system of keying where all locks are fit to the same key-bitting pattern or combination. Locks that are keyed alike may or may not be part of a keying system. Locks may also be **keyed different**, which would be the opposite of keyed alike.

Key bitting array: A matrix of useable depth codes that is used to define a master key system. The KBA shows all depths that form the basis of keying progressions for all master keying and change key levels. It is derived after the code for the top level master

key is specified. The KBA is more fully described in **chapter 11.**

Key Bitting Specifications: The mechanical information provided by each manufacturer so as to allow the bitting of key blanks for one or more locks, or groups of locks.

Key Blank: See **blank.**

Key Changeable: A lock or cylinder whose combination can be changed without disassembly through the use of a key is said to be "key changeable." In combination locks, described in later chapters, a special change key tool may be required to reset the wheel pack.

Key Control: Procedures established to limit or restrict the unauthorized possession, distribution, or duplication of keys. The term now encompasses access control issues, as well as the location, organization, and inventory of keys. **Visual key control** is the process that requires the stamping of standard keying symbols on all locks and keys.

Key Cuts: The portion of the bitting that remains after a key is created.

Key Cut Profile: The shape of the key bitting, which takes into account the root shape and cut angle.

Key Changes: See **Differs.** This refers to the number of different bitting combinations available within a given lock.

Key Gauge: A mechanical device that can measure the individual depths of a bitting pattern and provide precise information as to depth coding or length. A key micrometer, HPC HKD-75 or similar device is used for this function.

Key Head: The portion of the key that extends past the shoulder and provides a gripping surface for the user is referred to as a key head. Its design is unique to a specific manufacturer, and often carriers information that allows identification of the lock, keyway, and code. The photographs show a Sargent LE series blank, a Schlage generic head, and a Schlage 923E blank, with a factory original key code of 33699. This code is direct reading, allowing the key to be precisely reproduced from this number. The key fits a five tumbler lock.

Figure LSS+318 Key heads provide identification of the manufacturer and specific blank.

Key Picking: A lock may be jiggled open by moving a key back and forth across the tumblers, much like a rake pick. Maison-keyed locks are especially vulnerable to the practice of key picking because of the multiple virtual shear lines that must be created to allow access to all tenants.

Key Records: Records that are maintained by a facility to manage its locks. The information should include:

- **Key system schematic;**
- **Number of keys and cylinders that have been issued and comprise the system inventory;**
- **User list with keys issued to them for which locks or keying levels;**
- **Hardware and keying schedule;**
- **Bitting list**
- **KBA**

Key Retaining: This term often refers to a lock that is designed so that it must be in the locked position before the key can be withdraw, or reqiure the use of a second key or tool to allow the key to be removed.

Key Section: The precise configuration of a key blade as viewed from bow to tip and laterally.

Key Symbol: The designation utilized to identify any key within a standard key coding system. A full list of symbols is provided in chapter 11.

Keyed: How a lock is combinated.

Keyed Random: One or more cylinders that are chosen from a group of cylinders that may or may not have any relationship to each other in terms of combinations. As a result, there may be duplicate bittings in one or more locks.

Keying: How a cylinder is combinated.

Keying Conference: This is a meeting between the locksmith or system vendor and the end user to define keying levels, system requirements, future needs, and security. A **keying schedule** is provided, detailing the specifications of the system. This will identify how all locks are to be combinated, quantities, markings, and delivery instructions of cylinders and keys.

Keying Levels: A master key system is divided into **levels or hierarchies of access(54)**, with standard definitions for each level as provided by the Standard Key Coding System (SKCS).

Keyhole: The opening in a lock that allows the entry of a key. The term can also mean a keyway, but is more generic to a warded lock.

Key Interchange: Usually occurring within master key systems, whereby a key that is designed to open one specific lock will also open one or more unintended locks. This is more fully explained in **chapter 11**, regarding cross-keying.

Key Manipulation: A key designed to open one lock may be manipulated or jiggled to open another. This can occur due to wear of the lock components or key, or result from the use of too thin master pins.

Key Milling: The grooves, wards, or bullets along the side of the key are referred to as milling. The term can also denote the alteration or modification of a key blank to enter a restricted or different keyway than intended by the blank manufacturer.

Key Override: In many electronic, combination, push button, or specialized locking systems that do not ordinarily rely upon the use of a key to open, an override system is provided in case of malfunction. This function, however, can significantly reduce the security of the locking system, especially where master keys are utilized. See chapter 31 for a discussion of a method to compromise conventional master key systems through a process of decoding and extrapolation using the change key. In such instances, the key override function can completely neutralize the associated access control system.

Key Profile: The shape and appearance of a key after being cut, taking into account cut angles and root shape. The term can also refer to the specific keyway.

Key-Pull Position: The vertical or horizontal position where the key can be physically withdrawn from the plug. This may be in one or more orientations, depending upon design of the lock.

Keying Levels: The divisions of a master key system into access hierarchies, beginning with the individual change key. The standard keying levels are:

Individual key
Keyed alike
Keyed different
Master key

Keyway: The opening in a (lock) plug into which the key is inserted. A keyway provides a certain measure of security within most modern locks, based upon the placement of wards to block entrance of all but the correct key. “Keyway” appears to be a relatively modern term; the earlier references appeared to use the word “keyhole.”

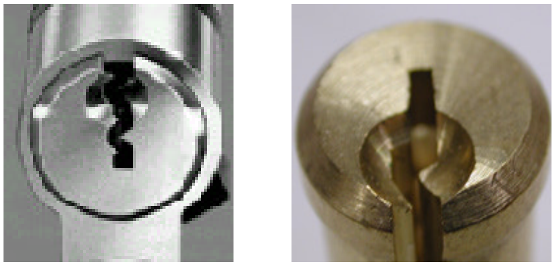

Figure LSS+319 A keyway provides security and indexes the key to the active locking components.

KWY: The symbol for Keyway.

Laminated Padlocks: Padlocks that are constructed with layers of metal plates. The Master Padlock is typical of this method of construction.

Lasertrack Key: See also **sidewinder key** or **bell-type key**.

Latch: A component that secures a moving and non-moving device, but has no locking function.

Layout Tray: A container with compartments to house cylinder parts. It is used for keying and service. It may be similar to a setup tray to hold pins, springs, and plug.

Lazy Cam or Tailpiece: A lock may be designed so that the cam is somewhat free-floating in certain positions, so that it remains in one position while the plug is partially turned.

Levels of Keying. See Keying Levels.

Lever Tumbler Lock: A lock mechanism operating with flat metal tumblers with a gate. The levers are actuated by the bitting of the key, and are aligned to a certain height to allow the bolt to be actuated.

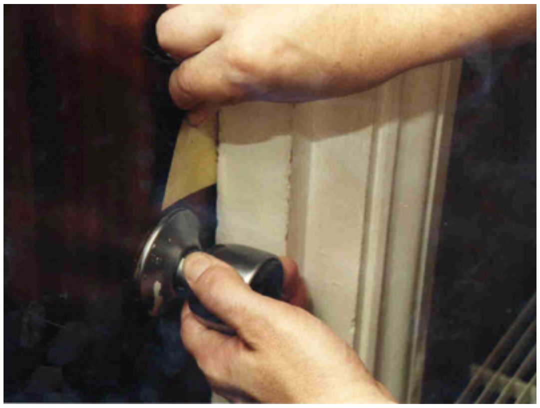
Loading tool: A device that is used to facilitate the installation of components into the shell of the lock.

Lock: In its simplest form, a lock consists of a case containing a bolt that is fastened to, and employed to retain a moveable object such as a door. The bolt is normally actuated with a key. The term lock, as currently spelled, appeared between 1300 and 1400 A.D. Prior to that time, the English spelling of the word

took the form of **loke** or **locke**, until the seventeenth or eighteenth century. The word "lock" seems to have many derivations. Thus, it appears as **serrure** (French), **schloss** (German), **cerradura**, (Spanish), **serratura** (Italian), **slot** (Dutch), **las** (Norwegian and Swedish), **sera** (Latin), and **kleihron** (Greek).

Lockout: A condition wherein the normal functioning of a lock is not possible.

Lockout Key: A system whereby a key is formed in two separate parts to block access to a lock. One portion of the key is inserted into the keyway to prevent any other key from entry. A second mating piece (removal key) is used to withdraw the portion residing within the keyway. This technique has been utilized in construction keying systems, and may also be referred to as a **construction breakout key**.



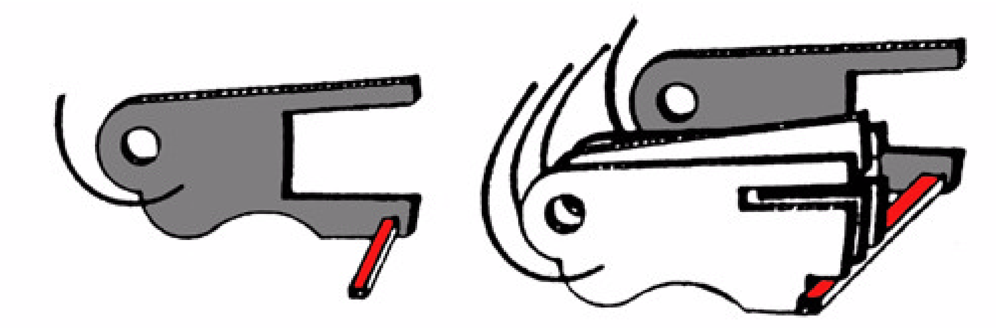
LOCKMASTERS: A company in Nicholasville, Kentucky, that is known throughout the world for training of locksmiths and government agents regarding locks and safes.

Locksmith: A locksmith is one who is skilled in the art of working with locks and keys. Originally, locksmiths were blacksmiths, until they formed a separate guild and became specialists in their trade. The earliest use of the term may be found as **locksmythe** in 1440. After 1627, the term may be found as two words, **lock smith**, or hyphenated. Sometime after 1841, the term, as we know it today, came into use.

Loiding: A technique to bypass a bolt by inserting a shim or thin flexible material between the moveable locking component and strike or frame.

Loiding a lock, by Harry Sher

LSS203: Demonstration of the use of a loid, by MSC



MACS: Maximum adjacent cut specification. This is the maximum allowable depth of cuts in single and double-bitted and dimple locks that can be made without interference to each other. MACS is an integral factor that must be taken into account in a master key system. The MACS specification is defined by each manufacturer and will physically prevent a key from being properly cut.

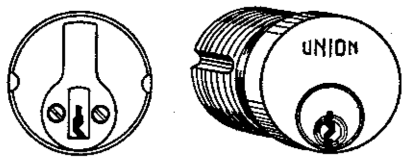
Manipulation Key: Any key that is designed to be moved within a lock for which it is not intended, and which can effect an opening through vertical and lateral movement of the active locking components. Rocker keys, tryout keys, jiggle keys, variable keys (John Falle system), and computer-generated picks described elsewhere in this text would all be considered as manipulation keys.

Master Key: A key designed to operate two or more locks having different change keys. Simple to complicated **master key systems** can be designed so that one or more master keys can operate one or many groups of cylinders. A system is said to be **"master keyed"** when a group of locks can be operated by individual change keys and one common key. Locks that are **only** combinated to a master key are said to be **master keyed only**.

Master Lever: A master keying scheme for lever locks wherein one lever tumbler is designed to to align some or all of the other gates of the levers within the lock to the fence. This technique is most common in locker locks, and is more fully explained in chapter 11.

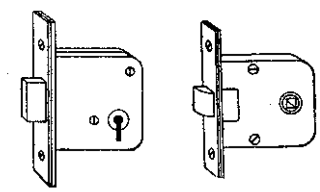
Master Pin: Originally, this was referred to as a master pin. It is the build-up pin that is used to create a different virtual shear line within a master key system, and is fully discussed in **chapter 11.**

Master Ring: In certain locks, a sleeve or tube is placed over the plug to form a second physical shear line. All master pins are aligned to this higher shear line to prevent unintended cross-keys from opening the lock.



Master Pin: See **master pin.**

Maximum Opposing Cut Specification (MOCS): This specification can be likened to MACS , but is relevant in dimple pin tumbler locks. It defines the maximum allowable depth for any dimple to prevent penetration of the key blade to the other side, thereby interfering with opposing cuts.



Milling of Key Blank: The longitudinal grooves machined into the key that makes up the keyway.

Mogul Cylinder: A large size pin tumbler lock that is primarily used in prisons. All components are increased in scale from a standard mortise cylinder.

Mortised Cylinder: A cylinder that is affixed to a locking assembly which has been inset into a door. The cylinder is generally screwed into the assembly, and held in position by a setscrew.

Mortised Lockset: A mortised lockset is inset into the door. In the accompanying diagrams, a dead bolt (left) and spring latch (right) is shown.

Multi-section Blank: A key blank that is milled to allow entry into more than one keyways within a **multiplex** keying system. This blank will not enter all keyways, however. A **multiplex keying system** is one that integrates a series of different key sections to allow for expansion of the master key system. Bittings can be repeated with locks having different keyway sections without compromise in security. However, the negative ramifications of the use of such systems is that if a locksmith or key duplicating vendor utilizes the wrong keying level blank, then the system can be compromised by allowing a key designed to fit one lock from opening another.

Mushroom Tumbler: A security driver pin or top pin that is designed to resist picking attempts. A **spool pin** is a form of mushroom tumbler. The **step pin** takes the form of a spool or mushroom tumbler, but has a portion of its end milled to a lesser diameter than the opposing end.

Negative Locking: See also **"Positive Locking"** below. Negative locking relies upon springs, gravity, magnetism, or force other than the key directly moving a detainer to block rotation of the plug. It is an indirect method of locking. An example would be a key with a cut that is too deep and which does not allow the plug to turn because the pin has not been raised to shear line. Positive and negative locking theory are employed in master key systems to deter the use of keys between systems.

Non-Key Retaining: A lock that does not prevent removal of the

key in either the locked or unlocked position. This is the opposite condition to **key retaining**.

Non-Original Key: Any key blank that is not factory original or provided by an OEM.

One-Bitted: A cylinder which has its bitting referenced to the number one bitting of the manufacturer. In contrast, a **zero-bitted** cylinder is one that is combinated to a manufacturers reference of zero bitting.

Operating Key: Any key that will operate a lock, and which is not a control or reset key. An operating key may be a change key or master key.

Operating Shear Line: The physical shear line within a standard plug to which all tumblers must be aligned to permit rotation.

Padlock: A portable lock used to fasten two objects together. The padlock has existed for thousands of years, with the original meaning of the term uncertain. **Pad** meant rubber in the seventeenth century. Prior to that time, pad and lock were hyphenated or appeared as two words, becoming one in 1663.

Paracentric Keyway: This term is used generally to describe the keyway within a pin tumbler lock. It refers to wards on either side of a keyway that protrude past the centerline of the plug. The key must be so milled to allow passage of the wards.

Figure LSS+320 An Ikon paracentric keyway.

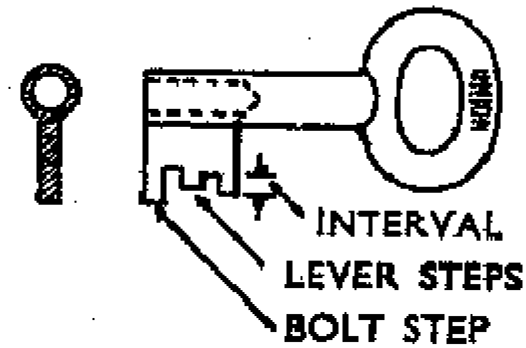
Pattern Key: Any original key that is utilized as a reference in making duplicates of that key.

Peanut Cylinder: A mortise cylinder that measures 3/4" in diameter.

Picking: The process of opening a lock through manipulation of the internal components, simulating the use of the correct key. A **pick** is the implement utilized to manipulate active locking components.

Pick Key: A key that has been modified to allow manipulation of locking components and operation of the lock.

Pin: (verb) To pin or repin a lock means to install active locking components (pins, springs) in order to set the combination. The noun refers to a pin tumbler.



Pinning Chart: A diagram detailing and graphically showing how each lock within a system is combinated.

Pinning Block: An apparatus to facilitate the loading of tumblers into a cylinder.

Pin-Stack: All of the tumblers within one chamber. The pin stack height is the total length of all pins within one chamber, expressed as depth increments or an actual measurement in inches or milimeters.

Pin Tumbler Lock: A lock, originally invented by the Egyptians, that utilizes moving pins to prevent the rotation of a round plug by all but the correct key.

Pipe Key: Keys for warded and lever locks may be configured with pipes or posts, depending upon the design of the mechanism and how the key is anchored. The pipe is hollow, as shown in the diagram.

Plug: The round, central part of a lock that contains the keyway and is rotated to operate the mechanism. It is sometimes called a core. The preferred term is **plug**, which will be used throughout this book.

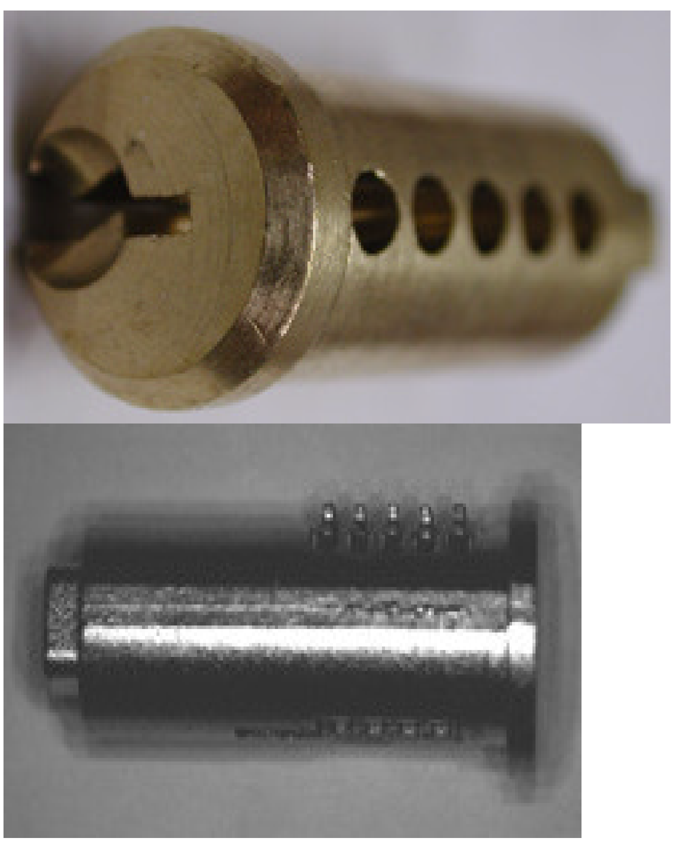


Figure LSS+321 A pin tumbler lock plug (left) and wafer plug (right).

Plug Follower: See **Follower**.

Plug Retainer: The mechanical component that secures the plug to the shell and prevents its release when the correct key is inserted.

Positive Locking: Within a double-detainer locking mechanism, the action of lifting a tumbler, wafer, or other form of detainer from the plug into the shell is called positive locking. A direct obstruction to the movement of the plug is created through the action of metal against metal. Thus, an incorrect depth on the bitting surface of a pin tumbler key will cause a pin to extend above shear line. It is the reverse of **"negative locking"** defined above. A cut on a key that raises its corresponding pin tumbler above shear line would positively lock the plug.

Practical Key Changes: The useable number of differs or combinations for a specified cylinder and manufacturer. This number will be different than theoretical differs which do not take into account tolerance issues, key design, depth and spacing, and MACS.

Privacy Key: A special key that operates a cylinder that is not on the master key system. It is an override key.

Profile Cylinder: A form of mortise cylinder that is not prevalent in the United States, but is mounted in similar fashion. The shape of a profile cylinder is quite different than the traditional mortised cylinder found in the U.S.

Proprietary Keyway: A keyway that is designated by the manufacturer for one customer, locksmith, or region.

Radiused Blade Bottom: The bottom portion of the key blade that is rounded to precisely conform with the base curvature of the plug in order to provide for a more uniform plug diameter and roundness.

Rap or Rapping of a Lock: A process to cause a lock to be opened by applying directed energy to a key or lock. This may occur by applying tension and shock to a specially prepared key (999 key) or to the lock body or shackle release mechanism of a padlock.

Recombinate: To change the combination of a lock or key. This may also be referred to as **rekeying**.

Recore: To change the combination of a lock by exchanging the core.

Register Groove: A reference point established at a certain position on the blade from which a manufacturer can define bitting depths.

Removable Core Cylinder: A complete locking assembly that is designed to be removed and replaced with the use of a control key. See **interchangeable core.**

Renter's Key: A key that must be used in conjunction with a guard key or prep key (or electronic release) to unlock a safe deposit box.

Reset Key: Some cylinders can be recombinated through the use of a special key. In certain cases, special tools and the new key are also required. See the discussion of **Winfield** locks for an example.

Restricted Keyway: A special profile that has been designed for limited use by one or more customers.

Reversible Key: A symmetrical key that can be inserted into the keyway in either vertical orientation to operate the lock.

Rim Cylinder: A cylinder that is utilized with a surface mounted rim lock.

RL: Registered Locksmith ALOA.

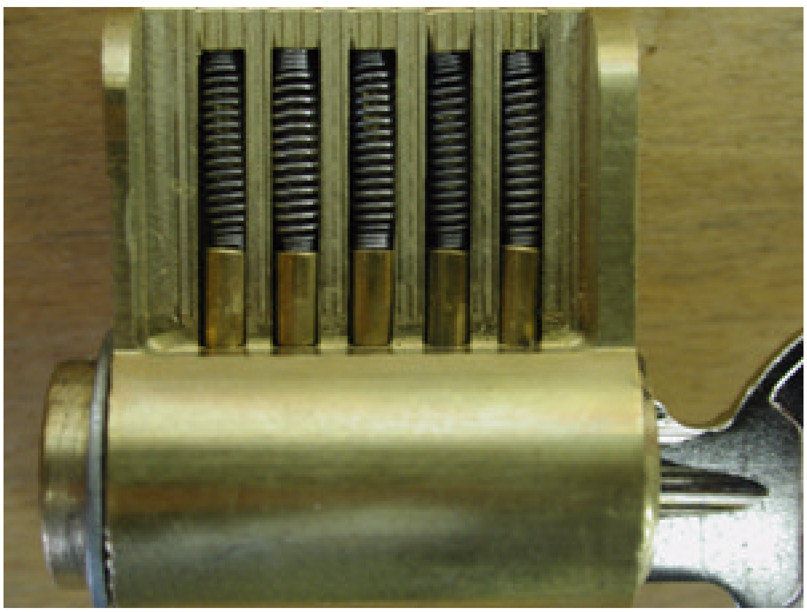
Root Depth: The dimension from the bottom of a key cut to the bottom of the blade.

Rose: An escutcheon that is usually circular in shape.

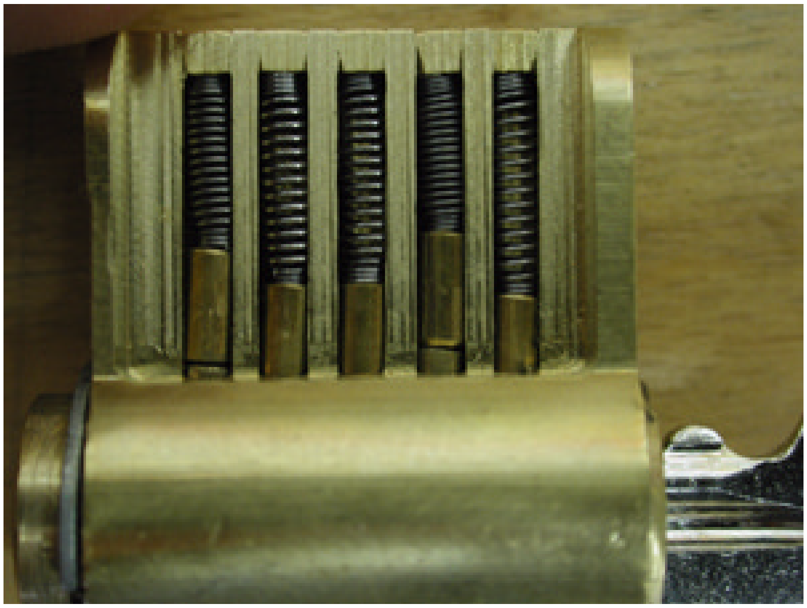
Rotary Tumbler: A pin tumbler with one or more vertical grooves or gates milled into its side. The key bitting angle causes the pin to rotate to the correct position to align with a sidebar or fence. Medeco received the original patent for this technology.

SAVTA: Safe and Vault Technicians Association.

Scalp: The thin outer skin of the front of the cylinder. It is usually crimped or spun, and may also serve to retain the plug.



Second Generation Duplicate: An original copy from the first



generation duplicate.

Set-up Plug: A type of follower that contains individual chambers to correspond with those in a lock. These chambers are loaded with springs and top pins, which are then forced into the shall of the lock.

Set-up Tray: A fixture that is used to hold pins and springs and plug during lock disassembly or pinning.

Shear Line: The space between the plug and shell of a lock that creates the ability for active locking components to secure or release rotation or movement of the plug. The photograph shows all pin tumblers at shear line (left), thereby allowing the plug to rotate freely. The plug cannot turn (right) because it is blocked by pins above and below shear line.

Shedding Key: See **declining step key.**

Shell: The non-moving part of a cylinder lock containing all the internal moving parts. It is also referred to as the cylinder. In the left photograph, a cylinder is shown without the spring retaining strip. The springs, drivers, and lower tumblers have been removed. In the right photograph, a profile shell contains springs and drivers. The portion of the lock that holds the plug or core may also be referred to as the **housing.**

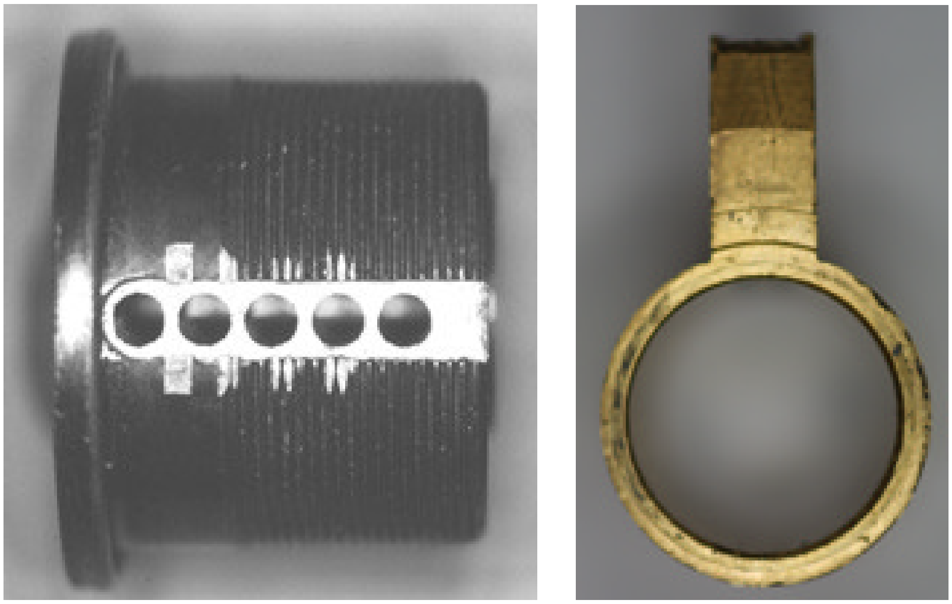


Figure LSS+322 The shell contains driver pins and springs.

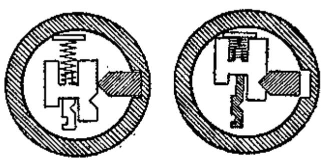
Shim: A very thin, flat piece of metal, generally .002" to .005" in thickness.

Shoulder of key or **Stop of Key:** The shoulder prevents the key from entering the keyway past a certain point, and provides a method of registration for the bitting to correspond with the precise position of the tumblers. Some keys do not have shoulders. In such cases, a small **tip stop** is provided. Best Lock Company keys do not have shoulders.

Figure LSS+323 The shoulder of a key provides a stop and indexes the blade to the chambers.



Shouldered Pin: A bottom pin that has a larger diameter on its top or flat side. This will limit penetration into a

counter-bored cylinder.

Shove Knife: A tool that is employed in conjunction with a setup plug to load pins and springs into the shell of the lock.

Shutout Key: A special key that is used to block access to a specific lock by all but an emergency key. This is generally found in hotel locks. In such status, the lock is said to be in shutout mode.

Sidebar Lock: A lock incorporating a secondary locking mechanism that appears in both disc and pin tumbler locks. A separate spring-biased projection will block rotation of the plug until all tumblers are properly aligned. The sidebar was originally developed by Briggs and Stratton for automobiles, and was introduced in 1935. The diagram below shows the original sidebar wafer design. The left illustration shows the sidebar extended; in the right drawing, it is retracted, allowing the plug to rotate.

In the left photograph below, the plug from a **Medeco** sidebar cam lock is shown. Note the protrusion on the bottom of the plug. This is the sidebar, in the normally locked position. In order for the plug to rotate, the tumblers must be properly aligned, in order to allow the sidebar to retract. This is a four tumbler lock; each tumbler is rotated by the key to the correct position. Note the three drill-resistant pins near the front of the plug.

In the middle photograph, an EVVA 3KS modular sidebar profile cylinder is shown. Note the sidebar is retracted into the plug, allowing rotation. In the right photograph, the sidebar is extended, blocking plug movement.

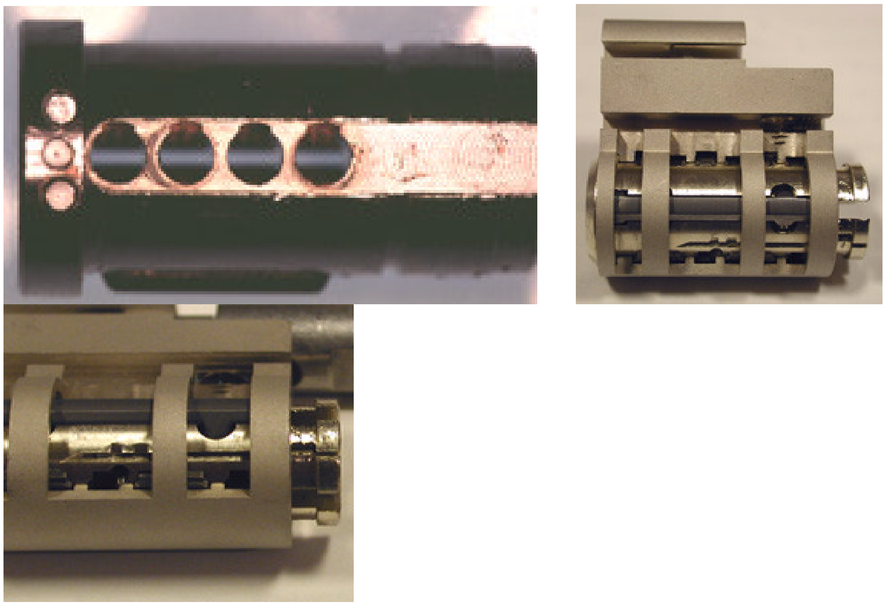


Figure LSS+324 Medeco and Evva sidebar lock designs.

Sidewinder Lock: See also **Lasertrack** lock or key, or **bell-type** key.

SKD: Single Keyed. The symbol indicates a non-master keyed lock. Certain rules apply to single keyed locks:

- **Single keyed combinations are never intended to be used as master keys;**
- **Combinations should never be selected at random, or the result may allow the opening of a master keyed lock;**
- **There can never be key interchange between an SKD and other cylinders in the system that are master keyed or have change keys;**
- **An SKD lock cannot be integrated into the master key system at a later date;**
- **The SKD should be selected from the bitting list and should not be used for any other cylinder in the system;**
- **Within a 1x progression, remove the combination from the system after use. Within a two-step system, the parity may be changed to allow reuse of the combination, althougnb not recommended. • In a rotating constant system, use constants that are not compatible with other system keys. This will assure that there is no interchange;**
- **A forbidden page master may be used as an SKD;**

• A SKD lock is one that has a single combination. In contrast, a NMK (not master keyed) lock is not keyed to any master level but is in the progression for a master key system.

Simplex Key Section: A single key section that is not part of a multiplex key system. This is different than a single key section that **can** be used in a multiplex key system.

Single-acting Lever Tumbler: A lever tumbler with limited or physically restricted vertical travel to allow movement of a bolt, but which cannot be configured to prevent travel of the bolt.

Source Key: See **Factory Original Key.**

Spacing: The distance from the key stop to the center of the first cut, or the dimension between cuts, center-to-center.

Spring retaining strip or Cover: Springs are often retained within a pin tumbler cylinder by means of a brass strip, crimped within a guide slot at the top of the shell. To remove, the strip is slid to the rear of the shell, or peeled back, thereby providing access to the springs, drivers, and lower pins.

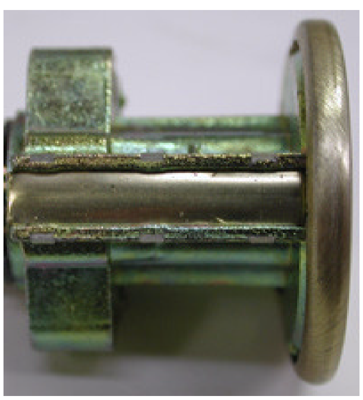

Figure LSS+325 Spring retaining strip.

Standard Key Coding System (SKCS): An industry-standard systemt for defining cylinders, keys, and their function and keying level within a master key system.

Standards: Standards are promulgated by both government and private agencies in almost every industrialized country. For a complete listing, see **security.org**, or National Resources for

Global Standards.

Stepped Tumbler: A wafer tumbler that is utilized in master keying systems must utilize two contact surfaces so that keys with different blade orientation can be utilized.

Strike: The metal plate that are installed as part of the doorjamb to allow receipt of the bolt. A **strike box** can be utilized as an enclosure formed by the strike to surround and protect the bolt.

Tail Piece or Connecting Bar: See **Connecting Bar.** It is a component of the rim lock or key-in-knob lock that is utilized to transmit rotational motion to the bolt.

Talon: The gap in the bolt of a lock, curved to the radius of a key, which has some resemblance in shape to the talon or claw of a bird of prey. A fly talon allows a small key to give a long throw to the bolt.

Theoretical Key Change: The total possible number of individual key combinations for a particular lock.

Throw of Bolt: The lateral distance that a bolt projects from the edge of the door or moving component.

Tip: That portion of the key that enters the keyway first.

Tolerance: The deviation or variance from an actual dimension or standard. In the context of lock manufacturing, it specifies the difference between a theoretical specification and the actual measurement. Chamber bores, for example, are theoretically all drilled in a straight line. In reality, there is a slight variance in each of their position, due to drill fatigue, movement, and wear. In this text, the term "high tolerance" refers to an extremely small deviation between theoretical and actual measurement. Tolerance error contribute to the ability to pick a lock. See the discussion in **chapter 11** and **chapter 29.**

Top Pin: Also known as the driver pin. This is the pin that is directly biased by the spring and which abuts against master pins or lower pins to form the pin stack.

Triple-Bit Key: A conventional key that is cut on three sides or surfaces. It appears that the original patent for a triple bitted

lock was granted to George Full in 1936 (**2030837(55)**).

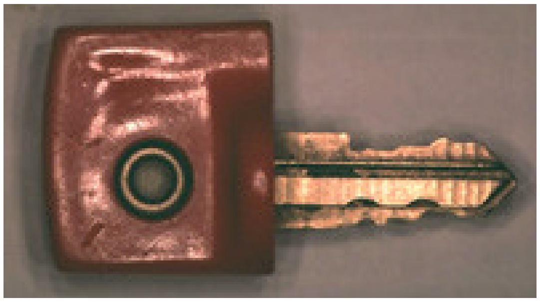

Figure LSS+326 A Dudley triple bitted key. Note the bitting on three surfaces.

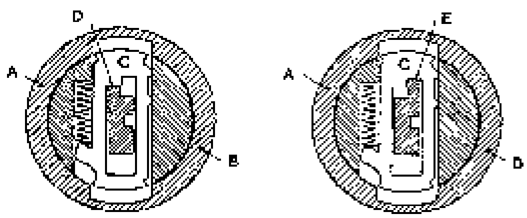
Tryout Key: One or more keys that is designed to manipulate the tumblers, wafers, discs or levers in order to open the lock. Tryout keys generally depend upon tolerance errors, and are often cut between normal depth codes.

Tubular Key: See axial key. A key in which the bitting is cut into the end of the bitting surface around its circumference, rather than laterally across the blade.

Tumbler: See also pin tumbler. An active locking component that can also be described as a disc, wafer, or lever. It is used to block rotation of a plug or movement of a bolt, and is the mechanical portion of the lock that comes into contact with the key.

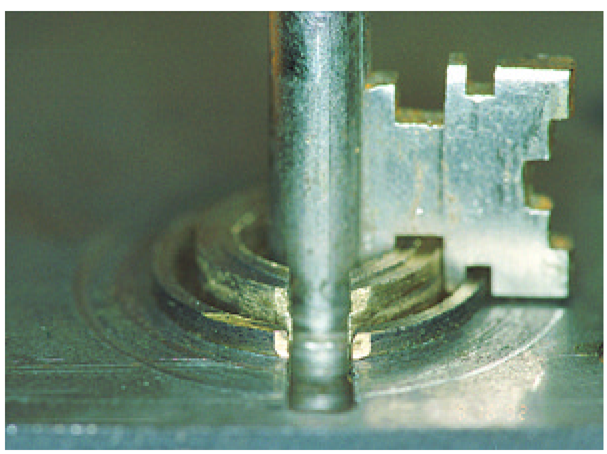
UL: Underwriters Laboratory.



Unidirectional Cylinder: A cylinder that can only be activated in one directon. Complete rotation of the plug may be blocked.

Virtual Shear Line: A shear line that is created by the insertion within a chamber of more than one bottom pin. When the pin stack is raised by the bitting, the pins "break" at more than one position with respect to the physical shear line. In contrast, interchangeable core and master ring locks contain two physical shear lines.

Wafer Lock: A locking mechanism that employs flat metal wafer tumblers. The linked **diagrams** show the positions of the tumblers in locked (**C**) and unlocked position (**A**). (**B**) shows the wafer properly raised to shear line, allowing rotation within the shell. As can be seen, the wafers are forced above and below



shear line, thereby blocking movement of the plug.

Wafer Lock Master Keying: Wafer locks can be master keyed by utilizing different bitting positions on the key and within the wafer. In the diagram, "A" and "B" represent the shell, "C" shows the wafer, "D" and "E" show the change and master key bitting levels. The keyway for this lock is designed so that the bitting contacts either "D" or "E."

Warded Lock: A minimum security device containing internal obstacles or wards, intended to block the entrance or rotation of all but the correct key. Shown is a simple warded key. Cut bitting is designed to bypass the individual wards within the lock. The photograph shows the circular wards and how they are bypassed by the corresponding cuts i the key. Bitting on the key is referred to as a "ward cut."

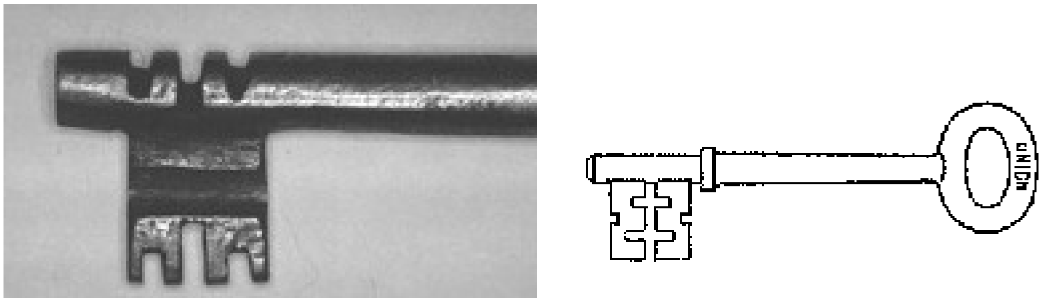


Figure LSS+327 Key for warded lock (left) and bridge ward (right).

LSS204: Brian Chan on lubrication of locks

4_1.0 Introduction

Techniques of disassembly, keying, rekeying, picking, impressioning, decoding, master keying, and forensic analyses of locks are detailed throughout this book. Certain tools and supplies are needed to properly perform those functions and operations. In this chapter, a catalog of primary tools has been compiled. This listing details what the author suggests to be the minimum requirements for both crime laboratory technicians and locksmiths. There are many specialized tools omitted from this chapter; they are covered elsewhere.

Unique tools that are used in the forced-entry of locks are described in **Chapter 32**; tools for the **penetration of safes** in Chapters 34-35; and instruments for non-destructive entry of combination locks and safes are described in **Chapter 36**. Information pertaining to the use of certain of these tools is also presented where appropriate. **Picking**, **impressioning**, and **forced-entry** tools required for such procedures are not listed here but rather discussed in those specific chapters (29-31). All tools and supplies related to work on safes are likewise listed in the pertinent chapters dealing with safes and vaults.

The author, for the past 25 years, has primarily utilized tools produced by **HPC** of Chicago. Although there are a number of other vendors in the United States and Europe who produce comparable items, **HPC** has the most extensive product line specifically geared for the locksmith profession. As noted elsewhere in this text, **John Falle** offers the most sophisticated **lock**-picking, impressioning, and decoding tools specifically and primarily designed for government agencies.

MBA and **Lockmasters**, both in Kentucky, have the most comprehensive collection of tools for the professional **safe** technician. Throughout this book, reference will be made to tools and supplies available through these companies, often with part numbers. Both **HPC** and **Lockmasters** can provide the reader with a convenient, central source for all needed supplies. Contact information, as well as a complete listing of tool vendors can be found at **Security.Org**.

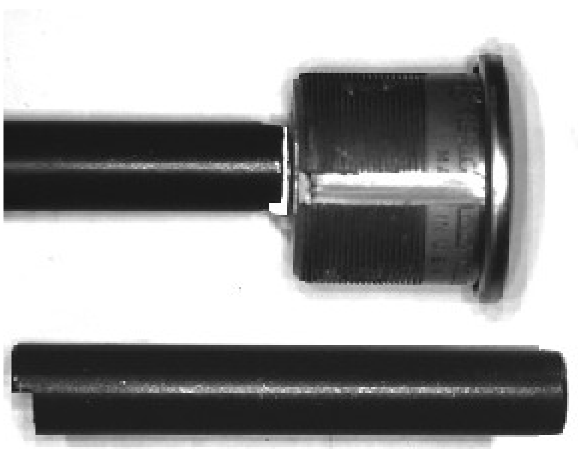
4_2.0 General Tools

A number of small tools and components are required in order to perform routine maintenance and keying operations. These are further classified as small hand tools, specialty tools, and files.

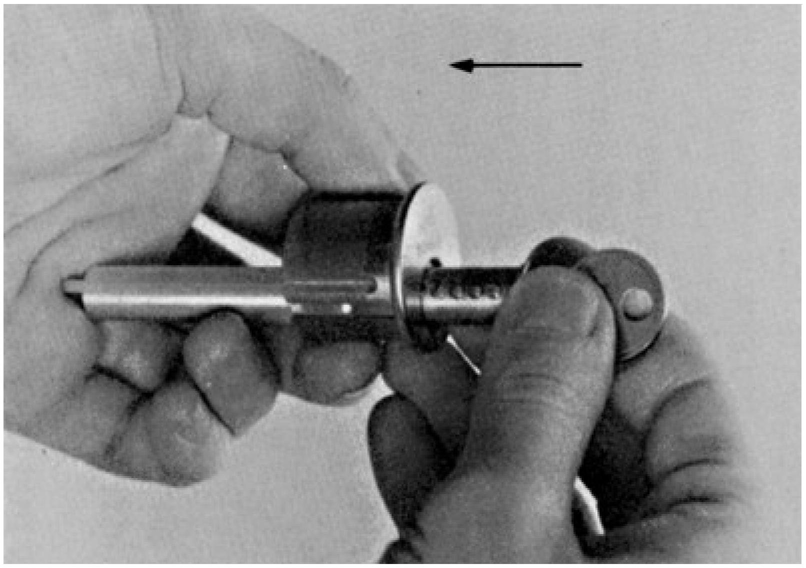
4_2.1 Hand Tools

The following hand tools should be available prior to beginning any work involving disassembly or rekeying.

- **Alligator forceps ;**
- **Allen wrenches;**
- **Bench grinder;**
- **Center punch;**
- **Clip removal tool ;**
- **Dremel tool, battery operated;**
- **Drills;**
- **Follower tool set ;**
- **Hacksaws;**
- **Hook tool;**
- **Ice pick;**
- **Impressioning files: see discussion below;**
- **Magnetic pickup tool;**
- **Mallet: either wooden or rubber, eight ounce is sufficient;**
- **Music wire;**
- **Needle nose pliers;**
- **Pen flashlight;**
- **Retaining-ring pliers (arc ring);**
- **Spanner wrench;**
- **Screwdrivers ;**
- **Small hammer;**
- **Steel wool;**
- **Swiss file set;**
- **Tension wrench assortment;**
- **Tubular hole saw;**
- **Vice: either bench or tabletop. The suction type models are very suitable. A Panavise is also recommended. This special rotating vice allows small parts to be held at any horizontal and vertical position;**
- **Vice grips;**
- **Warding file for safe-deposit keys.**



4_2.2 Special Lock Working Tools

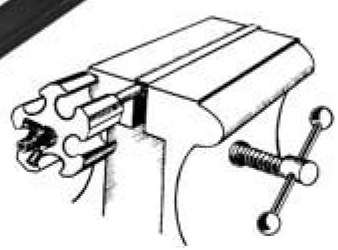


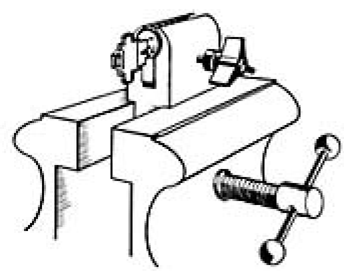
- **Blank keys: as required;**
- **Borescope: various lengths and fields of view;**
- **Broken key extractor: either commercially available, or use a fine-tooth hacksaw blade no more than 1/8″ wide. An extractor has many purposes, including use for removing broken pick ends, broken keys, Kwikset lock release, file cabinet lock bypass, and doorknob release;**

- **Code books: HPC, Silca, Reed;**
- **Dental picks (for broken keys);**
- **Dial calipers: .001″ gradation;**
- **Direct reading micrometer: HPC SKM-20. This device will allow depth and spacing measurements to be made to .001";**
- **Dust cover tool: holds gate open on automobile locks;**
- **Following tools: either made of metal and available from HPC, or wooden dowels may be used. A follower with a diameter of ½″ will replace most standard pin tumbler plugs. Other sizes may be obtained as**

needed;

- **Forceps, alligator;**
- **Impressioning pliers: HPC KIP-1. This is a special set of vice-grips with parallel jaws, having no grooves. The design allows excellent holding strength;**
- **Key decoders: Different HPC models allow the determination of factory depths for most keys, and contain depth and spacing information;**
- **Key gauges: standard and tubular;**
- **Key machine(56): A key machine can be extremely helpful for use in basic lock work;**
- **Lights, flexible;**
- **Mainspring wire: 1/8-1/16" wide, spring steel wire used in watch and clock mainsprings;**
- **Nose puller and door puller kits;**
- **Optivisor: Lockmasters or equivalent product to magnify objects in the work area. A Magni-Focuser, produced by Endroy Products, allows for working at different distances from 4"-20", with diopter adjustment from +2 to -10D. These devices are offered with magnifying powers from 1.5-3.5X;**
- **Ophthalmoscope: A more useful tool than the Otoscope or Optivisor is the ophthalmoscope. This device offers a variable focus from less than one inch, to two feet. It is used by ophthalmologists to look into the eye and is extremely effective for peering into locks and safes;**





Generally, the ophthalmoscope has a self-contained high-intensity light source. These instruments are produced by Welch Allyn and other companies. They sell for about $300.

- **Otoscope: Useful for visually decoding wafer locks. The device allows magnification of surface areas;**
- **Pick gun (snap type);**
- **Picks: They can be purchased, or made from .032" spring steel stock. A basic set of picks should be available whenever locks are disassembled or rekeyed;**
- **Pick set for lever locks;**
- **Pick set for warded padlocks;**
- **Pin and spring set: HPC Offers a complete assortment of bottom and top color-coded pins and springs;**
- **Plug holder;(57)**
- **Plug spinner: For use when the lock is picked backwards and the plug must be rotated without the necessity of repicking;**
- **Punch: Various lengths;**
- **Safe opening tools: See Chapter 35;**
- **Screwdrivers: flat, Philips, and mini, and holding tool;**
- **Setup(58) (pin) tray: These trays are available from many vendors, including HPC, and can greatly facilitate keying and rekeying of pin tumbler locks;**

- **Shims: various sizes, thickness, and diameter;**
- **Truarc removal tool;**
- **Tweezers(59): Utilize top pin loading type for placing drivers in cylinder, available from HPC. They should be at least 3" in length with non-pointed ends;**
- **Tension wrenches: An assortment is required for any lock work. See Chapter 29;**
- **Ultraviolet light source: Available from Lockmasters for use in impressioning;**
- **Vibrating pick tool;**
- **Weiser shim tool;**

A special key holder and gauge was invented in 1919 by Segal for precisely filing pin tumblers. See (**1307379(60)**). Likewise, a number of plug holders are available from HPC and other vendors.

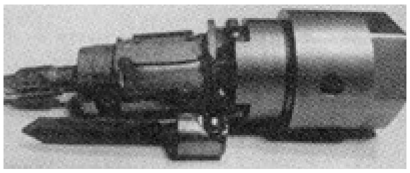
4_2.3 Cleaning Agents and Lubricants

LSS204: Brian Chan on lubrication of locks

Proper lubrication of internal lock parts is important. There are a number of acceptable wet and dry lubricants that will insure trouble-free performance. Iron and steel parts must be lubricated regularly, especially in damp or moist climates.

Although grease is often applied at the time of manufacture, it may disappear or become inefficient through use of the lock.

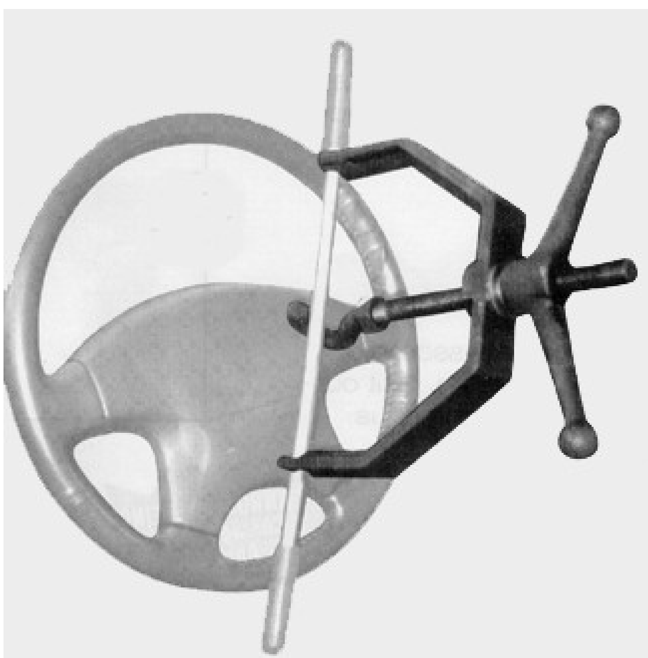
Light oil is acceptable for all but pin tumbler locks. Lubricants that thicken or mix with other materials and which tend to clog the parts should never be used. Employ either liquid or powdered graphite to lubricate pin tumbler locks. It should be squirted into the lock or rubbed on the plug, although the old way was to run a lead pencil over the key. Excessive graphite should be avoided, especially in locks such as Medeco.



Lubricants should not be used if a lock is to be impressioned; smooth operation of the lock is not desirable and residue can be left on bitting surfaces. If the lock is to be picked, lubricants or cleaners may be of assistance because dirt, grit, or grime makes picking difficult. A non-lubricating spray cleaner may be used to wash keyways and pins. Solvents, carbon tetrachloride, white gasoline, LPS, aerosol cleaners, spray oil, ether, electronic contact cleaner, silicon spray, or automotive cleaners such as GUNK (carburetor cleaner) are all acceptable. Although WD-40 is often used to clean and lubricate a lock, it is not recommended. It has too high a water content, and when mixed with graphite can cause gumming.

4_2.4 Automotive Entry Tools

There are a number of companies that manufacture specialized tools for automobile entry. These are designed to remove ignition locks, door panels, actuate door latching mechanisms, and decode and duplicate vehicle anti-theft key systems. Although not all-inclusive, the following listing of tools is representative of those available to the trade. Many patents have also been issued for such tools, the more significant of which include (**6044672(61)**) Steering wheel lock removing method; (**5701773(62)**) Dual function apparatus for opening and removing automotive sidebar ignition locks; (**4682398(63)**) methods for removing ignition pin type cylinders; (**4638567(64)**) Key decoding device for automobiles; (**4586233(65)**) Method of disabling various types of lock cylinders in General Motors motor vehicles; (**5402661(66)**) Tool and method for turning on Ford sidebar type ignition lock cylinders; (**5454245(67)**) Apparatus and method for removing sidebar automotive ignition locks without damage; (**4868409(68)**) Vehicular anti-theft system; (**4655102**) Locksmith tool for unlocking motorcycling doors; (**4683783**) Car door opening tool and method; (**4608886**) Keyless door unlocking apparatus for



automobiles.

AABLE Locksmiths Quick-On: This is a device for removal of ignition locks.

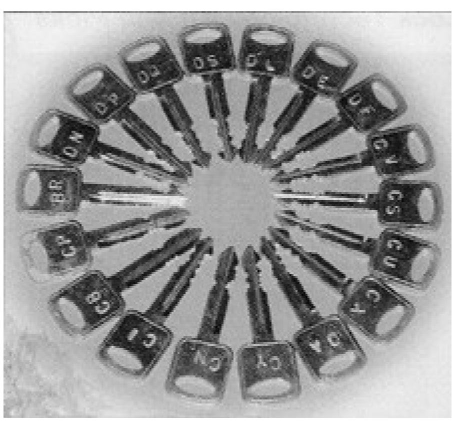
A-1 Service Kit: This is a picking and decoding system for the new GM-10 cut dash ignitions. The locks can be picked in minutes with this tool.

The Buster: This is an automotive steering wheel lock buster. The tool permits the removal of "the Club" style locks almost instantly. The author has also received a patent (**5277042**) for the modification of the Club in order to make it secure against shims to defeat the ratchet lock.

Determinator Tool System: A key can be generated in under fifteen minutes with this system.

High-Tech Tool System: High Tech Tools Car Opening System will unlock almost every vehicle from 1979-2000. The set includes

forty tools for opening virtually every car.



Lockmasters Mercedes Tool: This system is utilized to bypass the ignition bezel, thus gaining access to remove the ignition cylinder.

John Falle Vehicle Decoder Systems: John Falle produces several different sophisticated vehicle decoder systems for Ford Tibbe, Mercedes, Volvo, BMW, Honda, and other high-security locks. See **www.security.org** for a full listing of bypass tools.

PRO-LOCK Window Wiper: This simple tool is designed to clean the bottom portion of the window glass, both inside and outside of the door panel stripping.

Tech-Train Jiffy Jak Vehicle Entry System: This system allows most vehicles to be unlocked quickly and without damage. The tool is made from extremely strong plastic that allows more than eighty percent of all cars and trucks to be opened.

National Locksmith Ford 8-Cut Decoder: This system of 143 tryout keys allows bypass of the Ford 8-cut system.

Strattec DART: DART, or Diagnostic and Reprogramming Tool allows the interrogation of transponder-based security systems and the reprogramming of Daimler-Chrysler vehicles.

Gator MultiFace Cap Tool: Gator Tools Company produces a custom set of pliers that will remove lock caps.

Lock-Our Kits: Lock Technology, HPC, Steck, Z-Tool and other companies produce complete kits for vehicle lock-outs. They contain pick sets and opening tools, as well as comprehensive

instructions on most vehicles.

Slide-Lock Training: The Slide Lock Company provides seminars on the Internet, at **z-tool.com**.

4_2.5 Bypass Tools

As noted elsewhere in this Infobase, there are a number of companies that make a myriad of bypass tools for virtually every generic type of lock. Some of the predominant suppliers are HPC, John Falle, MBA, Lockmasters, PRO-LOCK, Lock Defeat Technology, and Rytan. These companies produce picks, decoders, and impressioning instruments for bypassing, decoding, and producing keys for most locks.

4_2.6 Bypass Tools for Safes and Vaults

There are several companies that manufacture tools specifically for the safe and vault technician. These are thoroughly discussed in **Chapter 35**. They include **MBA**, **Lockmasters**, **HPC**, **Mas-Hamilton**, MDS, Olympus, and Strong-Arm. Tools that are required by the professional safe technician are varied and many. They include drills, drill motors, fixed drill rigs, optical viewing devices, manipulation aids, robot dialers, software-based manipulation systems, and emergency opening tools and components.

4_2.7   Forensic Investigative Tool Set

The forensic investigator or investigative locksmith requires a number of specialized tools, instruments and implements in order to properly evaluate a crime scene, and to gather evidence that is legally admissable. The following items are recommended for field analysis.

HAND TOOLS

- **Hand microscope with lighting, minimum 30X (Lockmasters or similar)**
- **Tweezers: straight, right angle, fine point, broad point**
- **Small aperture Mag flashlight**
- **LED flashlight, high intensity, in white, blue, green**
- **Multibit screwdriver, with insert blades in Philips, flat-head, torx, hex**

- Magnetic pickup tool
- Multi tool, such as Swiss Army knife or Leatherman
- Side cutters
- Vice grips, small, medium, large

4_3.0 Files

4_3.1 Introduction

See **Chapter 30** for a detailed discussion regarding the proper use of files for impressioning. The standardization of Swiss file shapes and cuts began in 1812 when F.L. Grobet went into the file manufacturing business in Switzerland. Today, Grobet files are unsurpassed for their quality, precision, and hardness. Grobet and other fine files are usually made of chrome alloy steel. **Gesswein** is one of the largest producers of high quality files.

Many different kinds of files should be in the technician's inventory. The selection of the proper file is critical to successful key cutting and impressioning. Preliminary criteria are based upon the **shape** and **cut** to be produced. These issues in turn depend upon the type and form of material to be worked, the amount of material to be removed, and the desired finish. Files should not have handles but rather protective covers such as electrical tape, so that an excessive amount of pressure is not applied during use.

4_3.2 Nomenclature

Files are defined by their **shape**, **length**, **tang**, **cut**, and **coarseness**.

4_3.2.1 Shape

Files come in many shapes, including round, half-round, Pippin, flat, square, three-square, and warding.

4_3.2.2 Length

The length of a file will generally vary from 4″-8″. Sometimes, a file that is 8″ in length actually measures 6″, because it has a tang extending the added length. Files may also be tapered, so that their diameter changes over the entire body. Length of the file is measured from where the teeth begin near the tang, to the tip.

4_3.2.3 Tang

The tang is the uncut portion of the file. It enhances control or it is used to attach a handle.

4_3.2.4 File Cuts and Coarseness

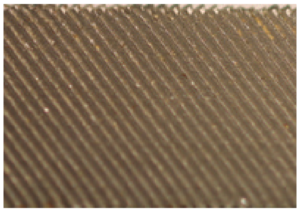
There are two worldwide rating systems for file cuts and measurement of coarseness: **Swiss** and **American**. The number of teeth per inch, identified by each system, determines the ability of a file to remove metal. The number will vary, based upon the length of the file and coarseness, and can run from 30 to 295. The Swiss utilize a numbered system, #00 to #6 (00,0,1,2,3,4,5,6) denoting the number of teeth per inch in relative terms. In the Swiss nomenclature, a 00 cut is the coarsest file; the #6 is a fine cutting file.

The American system utilizes the following primary cuts to define how much metal will be removed:

- **Coarse (for fast stock removal)**
- **Bastard (equivalent to Swiss 00, used for shaping and dressing steels and castings)**
- **Second cut (Swiss 0 for hard metals)**
- **Smooth (Swiss #2, for hard metals and as a finishing file).**

Files can have more than one set of cuts, meaning that there are two or more separate sets and angles on the surface. A **single cut** is one series of parallel teeth running diagonally across the

width of the file. This tooth design is used for sharpening tools and saws and for finishing-operations in machine shops.



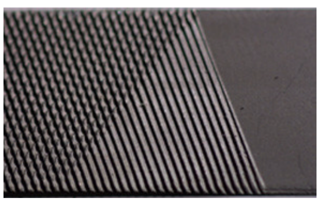


Figure LSS+401 Single and double cut files.

Double cut is two series of parallel teeth running diagonally across the width of the file surface, one series crossing the other. The tooth structure is fast cutting, and well-suited for rapid removal of material.

4_3.3 File Types that are based upon Shape

Standard files for working with keys include Pippin, round, rat-tail, triangle, and warding.

4_3.3.1 Pippin

The Pippin file resembles a teardrop cross section, rounded on one side, with two flat surfaces meeting at a knife-edge on the opposite face. A Pippin allows for the proper contouring of cuts so that a key will not catch on tumblers. Both curved and flat cuts can be easily made with the Pippin shaped file. The sharp side is used to mark tumbler points and spacing, and to make a straight-sided V cut in the bitting of a key. The rounded side is used to cut standard round tumbler cuts, and to open the sides of a key cut or to make the ramps wider. The flat surfaces are used like the flat file to shape the sides of the cuts.

Only a Pippin file should be used with brass, and files should not be used for filing lead keys. Cuts should be made straight down upon the key and not at an angle.

The **Pippin** teardrop shaped #4 Swiss pattern fine slim taper

Nicholson 40524 8" 2-XF) and round file are probably the most popular for use during impressioning. These files taper down to a smaller cross-sectional size towards the tip. It creates a very fine dull finish, and slightly ridged surface on the blade, thereby allowing observation of marks made by the pins. Proper filing continually renews the reflective finish. During impressioning or key duplication, the round file must generally be used in conjunction with a small flat or triangular file for shaping the ramps of the cuts.

4_3.3.2 Rat-tail

A rat-tail file is a long, tapered, round file. The diameter of the file will be greatest toward the middle and will taper toward the ends. Various grades of coarseness should be utilized, depending upon the material to be cut.

4_3.3.3 Warding

A warding file is rectangular, with all edges faced at 90°. It is used for making square cuts in keys, particularly for warded and lever locks.

4_3.4 Recommended File Set

The following files should be included within any maintenance kit for work on locks and keys:

- **Pippin, teardrop shaped, Swiss pattern Nicholson 40524 8" 2-XF), fine slim taper**
- **4" warding files (.045″-.05″ thick)**
- **6" warding file**
- **6" coarse rat-tail file**
- **6" #2 American Swiss rat-tail file**
- **6" #4 American Swiss rat-tail file**
- **Set of jeweler's files**
- **Swiss file set, available from HPC and Lockmasters**
- **4" triangle file**
- **6" triangle file**

CHAPTER FIVE: METALLURGY and CHEMISTRY

Materials and Processes

Master Exhibit Summary

Figure 5-11 Drill nomenclature for twist drill

Figure LSS+501, Periodic table.

5_1.0 Introduction

Except for the early Egyptian and Greek locks, metal can be found in virtually every key, lock, safe and vault which has been crafted or manufactured during the past four thousand years. Although Chubb utilizes certain high-technology polymers in their all-plastic Planet safe, metals will continue to be the favored material.

Metallurgy is the science of metals. Based upon both physics and chemistry, it deals with the methods of extracting and refining metal from ores and the manipulation of it into products. Through metallurgy, the behavior, internal structure, and properties of metals are studied, controlled, and manipulated. Metallurgists seek to learn why metals behave the way they do, and alter that behavior to suit particular needs.

The Romans are credited with producing the first metal locks made of iron. From that time until the Industrial Revolution, there were few metals and processes available for use. They mainly consisted of hot-rolled iron or steel sheets, bars, and forgings. Sand casting in brass and iron was considered as sophisticated. So primitive was the early technology that metals (except gold and silver) could only be produced with rough black surfaces until the end of the nineteenth century.

Now, there are many materials available to the lock maker which can be provided in virtually any finish, size, form, and grade. Metals can be extruded, rolled, drawn, hot-pressed, and stamped to close tolerances. Today, using high-quality steel dies, die-casting in zinc and other alloys is commonplace for many lock components.

Any detailed study of keys, locks, and safes must begin with an examination of the materials and processes employed in their production. Every aspect of the design, manufacture, use, and bypass of locking devices is based upon some form of metallurgy. The fundamental security of any lock or container is premised upon the molecular structure of the metals from which they are produced.

The reader may wonder why a chapter on metallurgy is included

here. When considering metals and the principles of metallurgy, many basic questions come to mind that bear a relationship to locks, keys, safes, and their penetration.

For example, three interrelated and very important fundamental questions must be answered: **Why are metals hard or soft? Which ones are which?** and **How do we gauge their hardness and test for it?** Depending upon the chosen material, the answers will directly affect the security of the lock or safe.

Further questions about hardness: **What is the molecular structure that determines whether a metal is hard or soft? Which alloys are hard?**

Other questions which are pertinent: **What basic changes have occurred during the past two hundred years in metallurgy? What makes a metal ductile or brittle? How do we protect against the effects of heat and cold, relating to fracture and bending? What are the characteristics of the metals used in locks, such as brass, aluminum, steel, zamak, aloxite, and stainless steel?**

Additional questions are raised: **What is and what affects tensile strength, shear resistance, and cutting of metal? Why does carbon make iron into steel? What is hardening and tempering, and what are the negative characteristics of these processes? Why and how does a drill, torch, or thermic lance work?**

Although this chapter is not a detailed treatise or explanation of the complex principles and theories underlying the science of metallurgy, it is intended to answer fundamental questions about metals as they pertain to locks and safes. How metals are formed, altered, produced, shaped, and cut are explored. The production, composition, and penetration of alloy hard plate, so important in the protection of safes and vaults, is detailed. The effects of heating and cooling are explained. The classification of metals by alloy content and the testing of materials for hardness is defined.

Finally, the complexities of drilling hard metals are examined from the perspective of the interaction of physics and chemistry, and the physical properties involved in metal cutting. Special emphasis has been placed on these principles and techniques because of its importance in safe penetration, and the analysis of such techniques in burglary investigations. Covered elsewhere in this book are the practical aspects of drilling and other

forms of penetration of metals. The reader may also wish to review the materials in **Chapter 11** of Alfred Hobbs classic work, regarding the use and working of metals in Wolverhampton and Willenhall, England during the Industrial Revolution.

5_2.0 Production and Use of Iron: A History

Iron, for more than five thousand years, was used for making tools and weapons. Ancient warriors had learned to heat the tips of their iron spears to harden them. This was probably the first **heat treatment** of metals. Iron was the principal metal for making keys, locks, and safes, well into the nineteenth century. Then, processes for the manufacture of steel became economical on a large-scale basis. Our discussion will thus concentrate on the production of iron and steel. For an excellent history of keys, locks, and the use of iron, the reader is directed to **Chapter 20** of the Price text, within this Infobase.

Originally, iron ore was heated with charcoal until it became a sponge-like material; it was then hammered into the desired shape. Very early, the Chinese had developed forms of furnaces, and in the fifteenth century, a technique originally developed by the Egyptians for working in bronze and brass was adopted to the production of iron. During the eighteenth century, this technology was greatly refined. A form of blast furnace was developed that used bellows to blow air across the iron, turning it into a molten state. This allowed it to be poured as a liquid. There was, however, a problem in shaping the hot metal: the liquid iron could not be formed using a hammer, for it would shatter.

The availability of charcoal was also a limiting factor in the early production of iron, and later steel because a great amount was initially utilized in the process. In the early eighteenth century, Abraham Darby was able to smelt iron with coke, making the mass production of steel a reality, at a reduced price. Advances in making cast iron led to the production of wrought iron. This used a more sophisticated procedure, higher temperatures, and required the addition of other materials. The process was called puddling. Wrought iron, a tougher material, would withstand greater stresses. It could be forged or hot rolled into plates and strips and was utilized by safe makers until the middle of the nineteenth century.

Until 1856, steel (a mixture of iron and carbon) was classified as an exotic metal. Then, Henry Bessemer developed a technique that allowed steel to be produced for a fraction of the then current price. The process relied upon blowing air through molten pig iron. It made possible the Industrial Revolution, and mass production of steel at affordable prices.

5_2.1 Iron + Carbon = Steel

There are many interrelated and complex factors occurring during the processes of production, which affect steel as a finished material. These include temperature, carbon and other alloy content, and heat-treating. Steel results from the mixture of carbon with iron. Carbon is the key element that gives steel its strength, up to three times that of iron. The more carbon, the stronger is the steel, until the content exceeds about two percent. With the addition of carbon, however, comes brittleness, coupled with the ability to finely hone the metal. The percentage of carbon, together with other alloys, will determine and control the type, grade, and structural qualities of the steel, as well as its strength and ductility.

Steel can be endowed with many special properties, some of which are produced through the addition of other metallic elements that are called alloy steels. These additions may improve hardness, strength, springiness, resistance to wear, and corrosion. Most well known of the alloys is stainless steel, to which nickel and chromium has been added. The metallurgist is concerned with creating many different grades and alloys of steel, to accomplish different purposes. Every metal can be described by its chemical, electrical, mechanical, and thermal makeup. Cost and weight are also factors to be considered. All of these characteristics contribute to the metals "properties". **Hardness**, **brittleness**, and **strength** are three key properties of metals. They are critical in the design of security devices, and they are of course interrelated.

It is a constant balancing act for the metallurgist to account for the many factors and processes to produce steel having the precise characteristics that are desired without compromising other properties of the metal. For example, one difficulty is how to increase hardness and strength without proportionally increasing the brittleness of the material. The solution to this particular problem is often the addition of alloys that add strength without a like increase in brittleness.

In the world of locks and safes, an example illustrates the difficulties faced by the metallurgist in optimizing strength and hardness without brittleness and fracture. One well-known technique for causing metal failure involves the saturation of critical components with Freon. For example, the application of Freon to a padlock shackle, or certain armor platting on safes, followed by mechanical shock will cause fracture. The metallurgist will alloy the metals to prevent this from occurring.

5_2.2 Classification of the Basic Types of Iron and Steel

Steel is a generic term that describes many variations of the metal. These definitions include low, medium, and high carbon steel, tool steel, and spring steel. Composed of mostly iron, steel is classified based upon its carbon and other alloy content, although it will always contain some carbon. The percentage will determine strength, brittleness, and the basic type of the steel. Carbon content will generally be between .15 and 2 percent.

Steels with low-carbon content (.05%-.35%) are used in bridges, buildings, tanks, and auto bodies. Medium-carbon steel (.35%-.50%) are found in wheels, crankshafts, gears, axles, and other heat-treated applications. High carbon steel (over .50%) is both hard and strong and is used in making tools, dies, knives, and railroad wheels.

5_2.2.1 Cast Iron

Iron with a carbon content between 2 and 4 percent is called cast iron or gray iron. If the carbon content is between 4 and 6 percent, then wrought iron is created (but no longer produced). Iron with over 6 percent carbon is so brittle that it is useless.

Cast iron is steel in which some carbon forms in little flakes or spears. Producing cast iron requires that the ore is first refined. Then, after further treatment in a smaller furnace, the iron may be poured into a sand mold for forming.

Cast iron is an extremely economical and convenient metal. It is used in engine blocks, brake drums, and other applications where high- compression strength is required. It is easily cast and machined and thus is popular for the production of millions of

different lock parts, often having unusual shapes.

5_2.2.2 Wrought Iron

Wrought iron is almost pure iron. It has low strength and hardness, is very ductile, and is corrosion-resistant. Prior to 1860, wrought iron and iron castings were the only ferrous materials available for lock making; thus, wrought iron was the most important structural metal available. It was used in wastewater pipes, sheeting on ships, and gratings.

5_2.2.3 Alloys

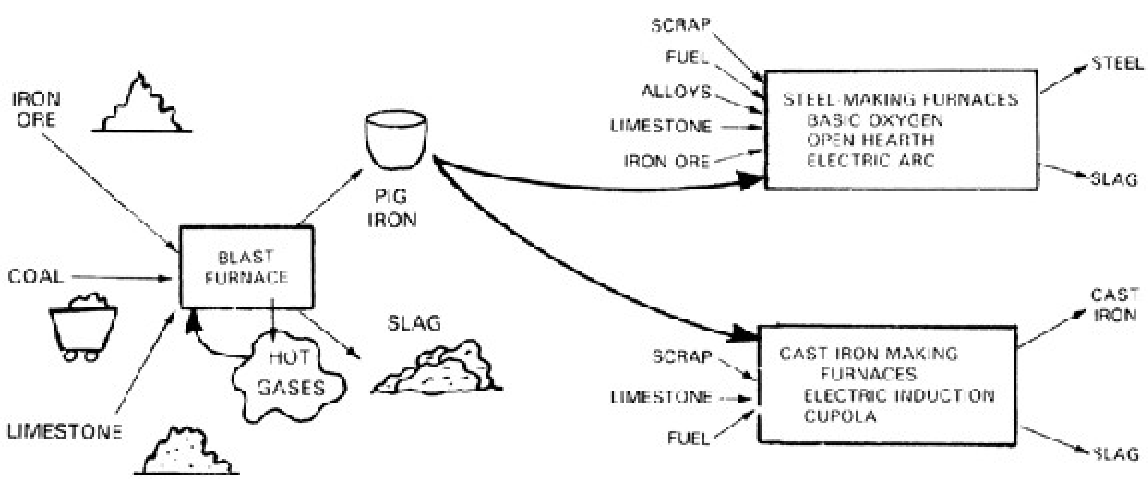
Generally, alloy steel has properties that cannot be achieved in carbon steel. Alloys, up to a maximum of 2%, are added to steel for many different and important reasons. Alloying elements most used in alloy steel production are aluminum, chromium, cobalt, columbium, copper (over .6%), manganese (over 1.6%), molybdenum, nickel, silicon (over .6%), titanium, tungsten, vanadium, and zirconium. Alloy content is directly related to the cost of the steel. Alloying metals are added to steel for many reasons. These metals include:

- **Carbon, manganese, and nickel: increase strength in the material;**
- **Chromium and copper: provide corrosion resistance;**
- **Lead or sulfur: added machinability;**
- **Tungsten and molybdenum: steel used at high temperatures;**
- **Cobalt and boron: hardness;**
- **Vanadium: toughness;**
- **Columbium and titanium: elimination of carbide precipitation.**

5_2.2.3.1 Different Alloys

Tool steels have high strength, wear resistance, and dimensional stability. There are eleven categories of tool steel, defined by shock resistance, hardening techniques, high speed, hot working, mold making, and special purpose.

Stainless steel is best known for its corrosion resistance. It contains high quantities of chromium and nickel.



Spring and **special steels** are created for hardness and strength. Their carbon content is between .35-1.4 percent, and will often contain up to .8% manganese, together with chromium, silicon, vanadium, and molybdenum.

5_2.2.3.2 SAE Numbering System

The Society of Automotive Engineers (SAE) has developed a four or five-digit numbering system to designate grades and quality of steel. This system will identify steel by alloy and carbon content. The first two digits of the identifier will indicate the type of steel, the last two give the approximate carbon content in hundredths of a percent (.01%). Thus, for example, an SAE 1030 rating would indicate a plain carbon steel (10) containing up to .3% carbon. Essentially, the higher the number, the harder the metal.

5_2.3 Techniques of Steel Production

Initially, the process of making steel involved the hammering of heated wrought iron. Then, in 1740, a melting process was developed to produce steel more efficiently. Low-carbon mild steel however, was not economically available until the latter half of the nineteenth century when Bessemer and Siemens perfected their process.

Steel is produced in two steps. First the iron ore enters a blast furnace and is mixed with coke, limestone, and hot gasses. This produces pig iron, which is utilized in making cast iron and steel. Once created, it is then transferred to a steel-making furnace in a molten state to make the actual steel.

Carbon is added to iron in amounts from .2-1.5%, depending upon the grade of steel required. The higher the carbon content, the finer is the steel.

5_2.3.1 Types of Furnaces

There are four types of steel-making furnaces: **oxygen**, **open hearth**, **electric arc**, and **Bessemer converter** (no longer used). The pig iron is fed into one of these, together with fuel, alloys, scrap steel, limestone, and small amounts of iron ore, at a temperature of about 3000°F. The molten metal is then brought to a carbon boil in the furnace. Actually, oxygen is combined with the pig iron to form carbon monoxide that bubbles off, then alloys are added.

A **basic oxygen furnace** (**BOF**)(69) utilizes an oxygen lance, which directs the flow of gas at high speed to create an intensely hot reaction for about twenty minutes. The BOF is used for the production of large amounts of steel. An **electric arc furnace(70)** uses electricity, rather than fuel, to create heat. This allows better quality control and is used for the production of special steel, such as stainless, tool, and high alloy. These furnaces process smaller quantities of metal per hour. Once out of the furnace, the molten steel product is first poured into ingots or molds and allowed to solidify. Later, it is uniformly heated and run through a rolling mill to be flattened to a desired thickness.

5_3.0 Basic Principles of Metallurgy

5_3.1 Introduction

Metals have a number of special attributes that are utilized, altered, and always considered in the design, production, analysis, and bypass of locks and safes. Our discussion of metallurgy will become particularly relevant in subsequent chapters relating to forced-entry techniques. In such cases, the unique properties of metals are defeated or exploited using special tools and processes.

5_3.2 From Atoms to Alloys

The earth is made up of over one hundred different individual

basic materials, called **elements.** If the earth were broken down into its most basic parts, it would be comprised of these elements.

5_3.2.1 Elements

An **element(71)** consists of only one material. Regardless of what is done to that substance, whether it is heating, cooling, compression, breaking, or any other process, it will remain the same. Some elements are metals. A metal has several special properties, including the ability to conduct electricity and heat, hardness, heaviness, and opacity. An **atom(72),** which means "cannot be cut", is the smallest particle of these chemical elements that can exist alone or in combination with other elements.

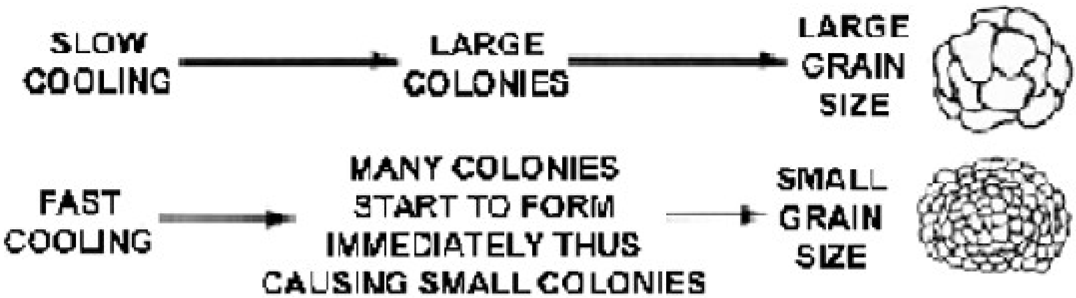
5_3.2.2 Compounds and Mixtures

Compounds and mixtures(73) are comprised of two or more elements but are quite different. The elements within a **compound** are chemically joined and often difficult to separate. A compound may take on entirely different characteristics than those of its individual elements. When elements are chemically joined, their atoms combine to form **molecules(74).** For example, common salt is a mixture of the toxic gas chlorine and a light metal, sodium. In contrast, the elements within a **mixture(75)** can usually be separated through simple processes, such as filtering, and do not completely lose their individual identities. An example is sand in water.

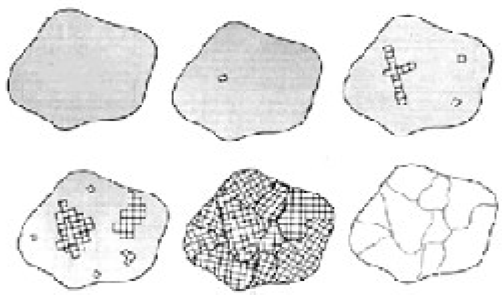
5_3.2.3 Solutions

A mixture in which one substance, the **solute(76),** is completely dissolved within the other, the **solvent(77),** is called a **solution(78).** Usually, a great deal more solvent is required than the solute in order that the dissolving action may occur. A solid solution occurs when both the solvent and solute are solid materials. Although common experience tells us that solids cannot be dissolved within one another, this process will occur at higher temperatures when both materials change to a liquid state at or near their melting points. Iron will dissolve many other elements, and particularly carbon and copper, as well as small amounts of zinc, tin, or nickel. Steel is approximately 99 percent iron, with only about one percent dissolved carbon. This is typical of solid solutions.

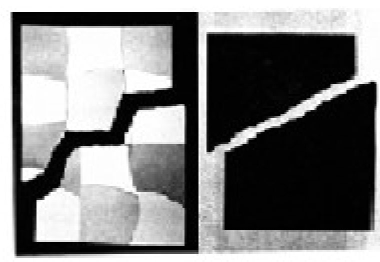
5_3.2.4 Alloys



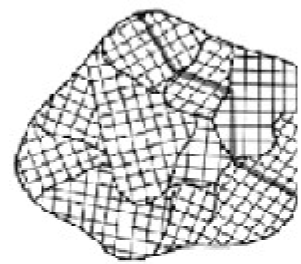
A new material called an **alloy(79)** is created when two or more metals are dissolved together in a solid solution. Thus, steel is an alloy of iron and carbon; bronze is comprised of copper and tin; and brass is made of copper and zinc. The solutes or metals that are dissolved are also called alloys. Thus, alloy actually has two meanings: the dissolved metal material, and the solid solution that is the combination of alloys and solvent.



5_3.3 Atoms and Molecules



The **atom** is the smallest part of an element, and the molecule is the smallest part of a compound. Just as it requires two or more elements to make a compound, it takes two or more atoms to make a molecule. Molecules are only formed within compounds, not in mixtures or solutions. Within such molecules, atoms are joined chemically through the sharing of electrons from each other. Molecules are not created in alloys or solid solutions. Finally, when a large group of atoms or molecules combine, they form a family, often visible by the naked eye. These families are called **grains** or **crystals(80)**. Within such formations, all of the atoms tend to orient themselves in neat and orderly structures, or **lattice** configurations.



5_3.3.1 Crystals and Molecular Structures of Metals

Metals are actually made of molecules, formed in several different crystal lattice configurations that establish characteristics such as brittleness, hardness, and strength. When, for example, molten metal rapidly cools and changes to a solid state, many small clusters or colonies of crystals form within the material. The size of these crystals and colonies directly affects the properties of strength, brittleness, hardness, and ductility. If there are many very small colonies of crystals, they will be more difficult to fracture and will be less brittle. In contrast, slow cooling allows larger crystal colonies to form.

Crystal structures will also vary, depending upon the metal and its treatment. The rise or fall in temperature and the rate of such change may affect each. The basic types of structures are described as **ferrite**, **pearlite**, **cementite**, and **martensite**. If, for example, steel is quenched or rapidly cooled, it may take on a different molecular structure than if the metal is slowly cooled. In the case of rapid cooling, it is said to go to a **martensite** form. Martensitic iron has a different geometric crystal pattern than other types of structures and is the hardest, strongest, and most brittle of crystal formations.

What does all of this mean? Simply, metals with large colony sizes are easier to tear, break or fracture. A small grain size has a greater resistance to fracture. Thus, the metallurgist goes to great efforts to keep the grain size small, if strength is important. It follows that **barrier material** has a very tight crystal lattice configuration.

5_3.3.2 Hardening of Metals

Hardness of martensite actually results from a restructuring of atoms. This structure appears as needle-like, termed **acicular(81)**. The material is hard because layers of iron atoms are inhibited from slipping over one another by the dispersion among them of smaller carbon atoms. This formation will force the iron atoms out of their traditional cubic structure, locking them into a highly rigid unstable structure. Carbon tool steel

is hardened by heating it to a temperature between 750°C-835°C (cherry-red heat), followed by rapid cooling. An increase in temperature above this range will cause no increase in hardness, but there will be greater brittleness as the crystals grow larger.

5_3.3.2.1 Alloying(82) with W(83), Mo(84), Co(85), C(86), Cr(87), and V(88)

Metal hardness, wear resistance, and other attributes depend not only on the martensite but also upon the size, composition, and distribution of the compounds, especially the carbides. The stability of the matrix at high temperatures is also related to these compounds. Alloying agents are used to produce special and enhanced properties. See the **Periodic table**. Many different elements are utilized for the production of locks and safes, and to **alter the characteristics(89)** of metals, depending upon the required application.

Carbon is required to facilitate bonding of the carbide-forming elements (W, V, Mo) and for martensite hardening. Between 4 and 5% chromium is used to insure the ability to harden, i.e., that the center cools slower than the outside and a consistent martensite structure occurs. Tungsten (W) and molybdenum (Mo) were used for the first high- speed steels. Today, Mo is probably the most popular alloying agent. Vanadium, up to 1%, may also control grain growth. Higher percentages, up to 5%, will produce many hard microscopic particles that will resist wear when cutting abrasive materials. Cobalt, between 5 and 12%, will raise the temperature at which hardness begins to fall.

5_3.4 Specific Attributes of Metals

Metals have certain attributes such as hardness, ductility, strength, and brittleness. In the following discussion, each of these is described.

5_3.4.1 Hardness and Hardness Ratings

Hardness measures a metals resistance to deformation and penetration and results from two factors: the speed of quenching or cooling and the percentage of carbon content. A higher speed of cooling, coupled with more carbon, will provide harder steel.

The best known of the hardened materials is tool steel, which is

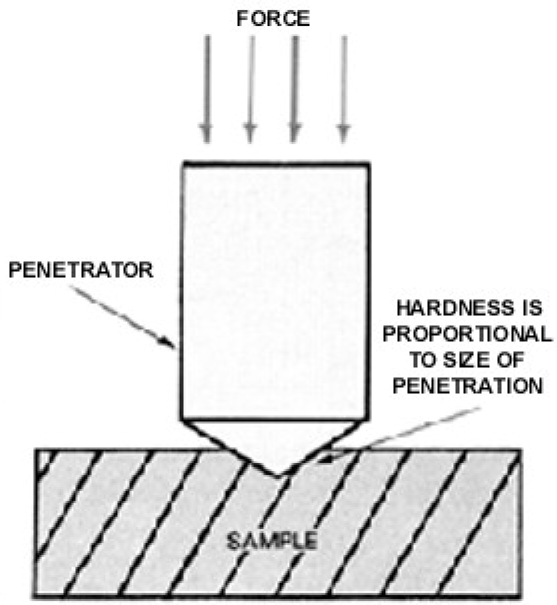
used for dies and for cutting other metal. Barrier material (hard plate) is equally tough and is used in safes to protect critical parts. Hardness must be studied together with several other key properties, including strength, brittleness, ductility, machinability, formability, cracking tendencies, and toughness.

5_3.4.1.1 Testing for Hardness

There are two primary criteria for determining the hardness of a material: **penetration** and **scratch** testing. There are nine recognized methods of testing both the surface and internal hardness of a metal, depending upon the type of material and the information required. In penetration testing, hardness can be measured using a number of different machines, but they all essentially do the same thing: they force a penetrator or sharp-pointed probe against the metal sample. The size of the resulting impression or dent is precisely measured and translated to a hardness rating.

There is no universal standard of hardness; each manufacture of hardness-rating equipment has developed its own units of measure. There is a correlation, however, between the different test procedures. There are many different units of measure, such as BHN, DPH, SHORE UNITS, and KNOOP UNITS. The primary and most accepted tests are the **Rockwell** and the **Shore Scleroscopic protocol**.

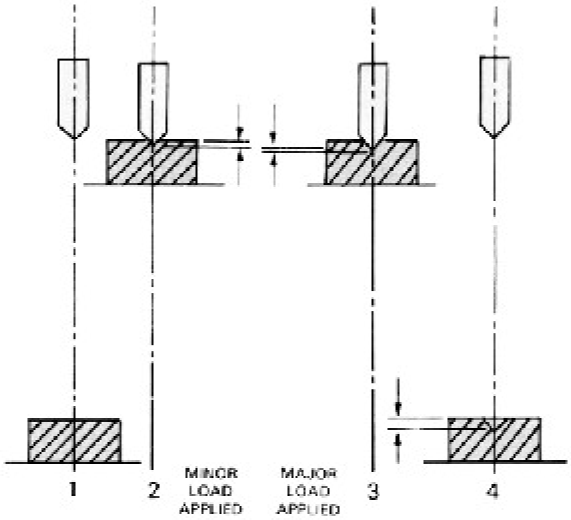
The MOH testing method was probably the first ever used and dates thousands of years. Ten stones, rated in hardness from one to ten, were first selected. Talc, with a rating of 1, and diamond, with a hardness of 10, was used as the limits of hardness measure. Stones with varying hardness between two to nine were then selected. The questioned sample would be scratched or struck with each test stone, starting with the softest. When a scratch could no longer be made, the test material was said to have that hardness.



Perhaps the oldest recognized procedure for testing hardness is the Brinell Test. This involves the application of 3,000 kg. load through a steel ball onto a sample. A calibrated microscope measures the resulting depression.

5_3.4.1.1.1 Rockwell Testing Procedure

Rockwell is the most popular method of testing for simplicity in procedures and accuracy. Equally important, localized surface



imperfections are taken into account in the process that can skew test results.

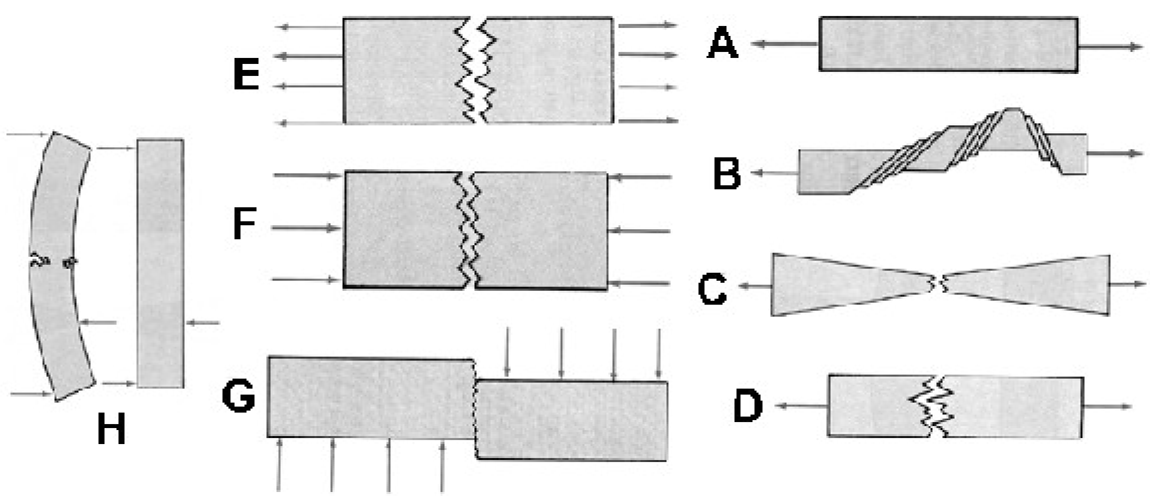
After a sample is placed on an anvil, the penetrator is pressed into the material. First, a minor load of 10 kg is utilized. Then the major load of 60 kg, 100 kg, or 150 kg is applied, depending upon the type of test. As the load increases, the point of the penetrator moves deeper into the sample. The measure of hardness is read from a scale located on the testing machine and is directly correlated to the depth of penetration.

Rockwell has nine different testing scales, achieved using three different penetrators with three differing loads. The penetrators are 1/8" or 1/16" diameter tungsten carbide drillpoints and a diamond point.

For the hardest materials, the 150 kg load and a diamond tip penetrator will be used. Identified as the Rockwell C scale, the hardness rating is written as, for example, 85 Rc. It should be noted that Rockwell also makes superficial-hardness test machines that will only test the surface hardness of a metal. They are often used where measurements are to be made with very thin materials or for testing case hardness.

5_3.4.1.1.2 Shore Scleroscopic Test Procedure

The Shore Scleroscopic technique relies on the use of a light



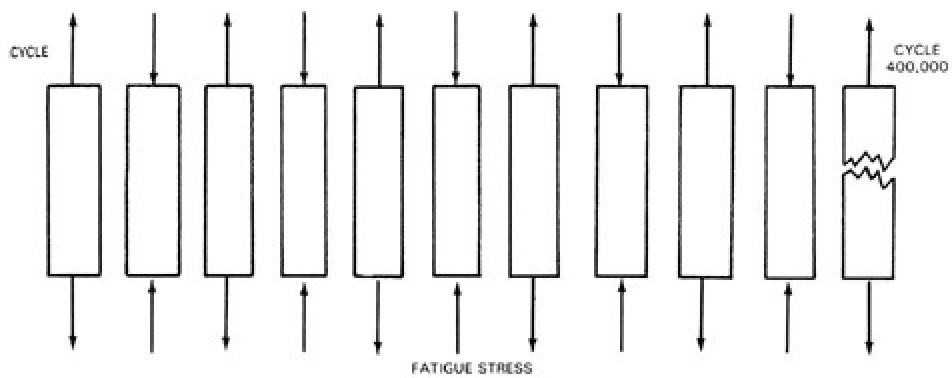
metal ball or hammer that is dropped from a specified height of ten inches, in order to test the "bounce" of the material. The theory is that the hardness of the surface will be proportional to the distance of bounce. In practice, a hammer weighing 40 grains or .001 pound (less than 3 grams), strikes the sample and is caused to rebound. The height of the rebound is measured and translated to "Shore Units." It should be noted that this testing format is not used for evaluating hard plate because it requires a flat, clean horizontal surface.

5_3.4.1.1.3 Sonic Testing

Sonic testing utilizes the resonant frequency of the material, and is quite accurate. A rod of .75 mm diameter is pressed against a sample and electronically vibrated. The resonant frequency of the rod is measured; the higher the frequency, the harder is the material.

5_3.4.2 Strength

The strength of a metal is described and measured in terms of its **tensile(90), stretching or pulling(91), compressive(92), shear(93), fatigue(94), impact(95), flexure or bending(96), and torsion or twisting(97)** qualities. Measurements of these factors are extremely important in the analysis of materials utilized in locks and safes.



Tensile strength is the measurement of the ability of a material to withstand a "pulling apart" force, or stress in tension, and is the most important measure of the strength of a metal. Steel

has a very high tensile strength. The test is utilized by the ASTM in the analysis of padlocks and is described more fully in **Chapter 32.**

Shear strength is the ability of a metal to resist a "sliding past" type of force. A tearing motion or pressure is applied between two edges like a scissors, in order to perform this test.

Fatigue strength is the ability of a metal to suffer repeated loading without failure.

Compressive strength measures the ability of a material to withstand a pressure or squeezing force.

Toughness and impact strength measure the ability of a metal to resist shock.

Flexure describes bending of a material.

5_3.4.3 Brittleness and Ductility of Metals

These two terms denote somewhat opposing characteristics. A material that stretches before breaking is said to be **ductile(98)**, or has high ductility with a corresponding ability to resist shock. Low-carbon steel, aluminum, and rubber bands are said to be ductile. Alternatively, if the metal does not stretch, it is **brittle(99)** and generally will have a low resistance to shock. Cast iron, glass, and uncooked spaghetti are brittle.

5_3.4.4 Thermal and Other Properties of Metals

Thermal properties, **corrosion resistance**, and **wear resistance** are

also important attributes of metals. **Wear(100)** is the ability of a metal to withstand loss of material by frictional scratching, scuffing, galling, or goring. The "wear factor" is directly affected by hardness; the harder the surface, the greater the resistance.

A metal must be able to resist atmospheric deterioration, called **corrosion.** This occurs from destructive agents in the air, such as acids, alkalis, salts, and smoke. They combine with humidity, heat, and ultra-violet rays from the sun to attack the freshly cut surfaces of most non-precious metals. **Corrosion(101)** produces a film on the surface of the metal that can either protect or destroy the underlying material, based upon its molecular structure. In iron and steel, rust is a form of corrosion, and once begun, it is very difficult to arrest. Copper and its alloys, once exposed to corrosive elements, will form a protective film called **verdigris(102)** that will inhibit further corrosion.

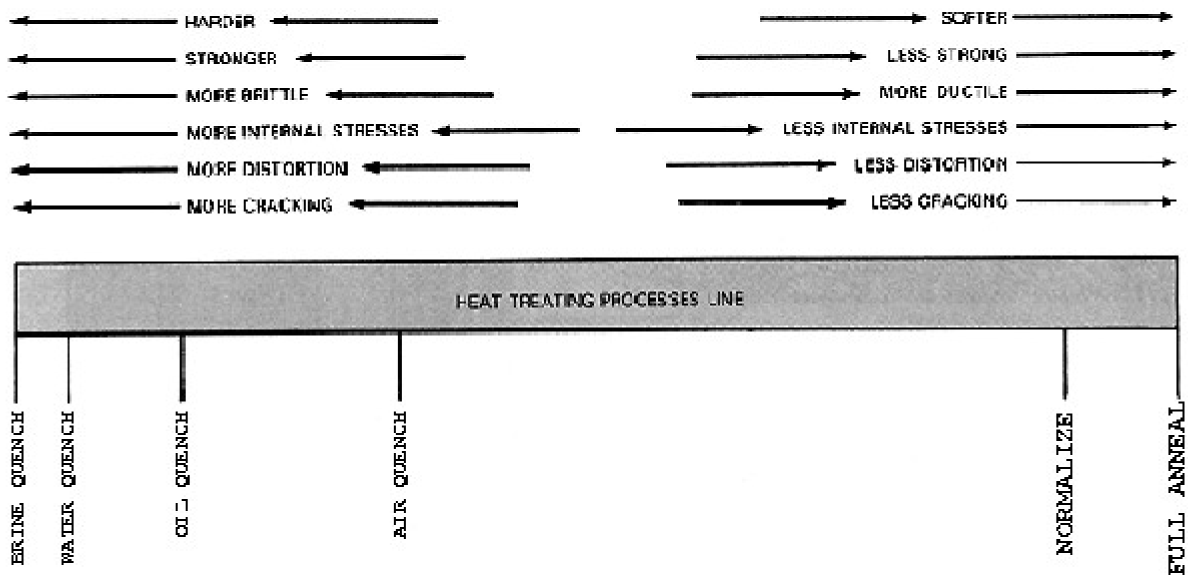
When metals are heated or cooled, their structure changes. If a metal is heated, it grows larger. This property is referred to as the **coefficient of thermal expansion** and is a measure of how quickly the material expands. When a metal is heated to its melting point, it changes from a solid to a liquid. In the case of steel, this occurs at about 3000°F. The molecular structure of the metal allows the heat to travel rapidly across its surface: it is said to have a high **thermal conductivity.** Copper and aluminum are excellent conductors and thus are used to carry heat (from a torch) away from surface materials in safes.

Deformation(103) describes a property of some metals to stretch when tension is applied, just before breaking. The measure of deformation is the increase or decrease in length when a load is applied. A material is ductile if it stretches significantly prior to failure, whereas the metal is brittle if it does not become elongated.

Brittle materials fail with **cleavage(104)**, whereas ductile materials fail during **shear.** Shear failure in ductile materials occurs when atoms slide past each other within the crystals. Shear strength is the ability of a material to resist a “sliding past” type of stress.

Cleavage causes atoms to separate, whereas in shear, atoms slide past each other within the crystals, causing stretch. A shear failure will result in atoms either sliding or twining; the part

will deform and become elongated and thinner. Eventually, a break will occur.



When a material is stretched out of its normal shape, it is often **work- or strain-hardened.** A material that is deformed will work-harden, becoming stronger, harder, and less ductile. Drilling of hard plate, if not done properly, will cause work hardening of the material ahead of the cutting edge, making penetration even more difficult.

5_3.5 Effects of Temperature upon Metals

Any process involving the application of heat and cooling is called heat-treating. This includes **heating**, **quenching(105)**, **annealing(106)**, **normalizing(107)**, **tempering(108)**, and **surface hardening**. Heat-treating affects iron and steel in different ways and depends in part upon the precise quantities of oxygen, carbon, nitrogen, or ammonia that are added, together with the exact duration and temperatures. Heat-treating can both harden and soften a metal.

5_3.5.1 Heat-Treating Techniques

An overview of the various processes relating to the application of temperature to metals can be demonstrated using the example of **tempering** a steel needle. If a needle is heated until it is red-hot then cooled quickly in water, it will break easily but will be extremely hard. If, on the other hand, the needle is heated and cooled slowly, it can be bent like a wire. The needle can be retempered by reheating it to a red-hot state, then rapidly cooling it, then reheating it to a yellow color and then cooling it slowly.

Quenching is a controlled process of cooling that will result in the metal becoming harder. It is achieved by heating the material to a temperature greater than what is called the **temperature transformation region.** Several different quenching methods involve the use of water, air, oil, brine, molten salt, sand, and other materials. Water is the most popular medium for quenching carbon steel, because it can effect rapid cooling. However, water can also cause internal stresses, distortion, and cracking in the metal. Oil, for example, will often be used for cooling critical parts where strength or hardness is not quite so important. Air cooling is used in steel with a high alloy content, such as chromium and molybdenum.

Annealing or normalizing both involve the heating of material to above the critical point, then the subsequent slow cooling of the metal to room temperature. Either process will result in a softer, more ductile, and less distorted material. Annealing occurs even more slowly than the normalizing process and may take several days. There are three methods of annealing: **full**, **process**, and **spheroidizing**. In **full annealing**, the part is heated, then cooled at the rate of 100°F per hour. Annealing will relieve internal stresses without affecting the mechanical strength of the material.

Process annealing is slower and more economical. The part is heated to a lower temperature and cooled more slowly. **Close annealing** requires the exclusion of air to avoid oxidation during the heating and cooling process. Finally, **spheroidizing** is almost

identical to process annealing; the part reaches less critical temperature and has a slower rate of cooling.

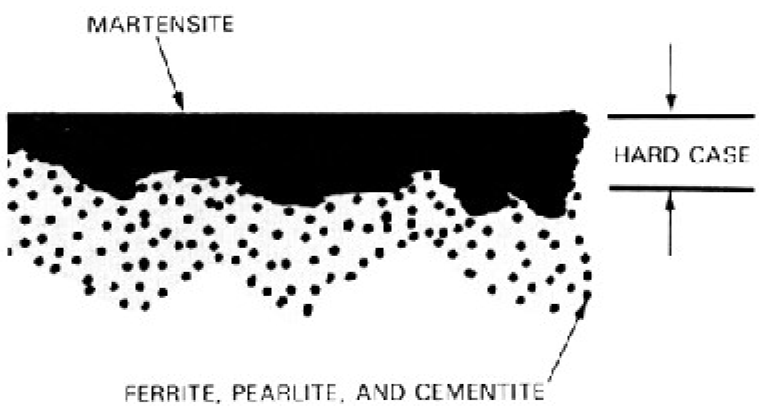
Normalizing is almost the same as annealing, with respect to the time required for cooling of the metal. The material, however, is not submersed in a liquid as in standard quenching. The result does not produce as soft a metal as by full annealing. In fact, the metal will be somewhat stronger, harder, and more brittle than would be obtained in the annealing process.

Both annealing and normalizing result overall in a weaker, softer material, which is less brittle and more ductile. The technique also removes internal stresses, thereby lessening the opportunity to distort and crack. These processes are employed to increase the machinability of parts. Often, after annealing or normalizing, the part is then hardened.

Often misunderstood, **tempering** is a process of rehearing steel after it has been hardened so as to increase toughness and ductility. It is used to partially correct the undesired effects which quenching produces: hardness, brittleness, distortion, cracking, and internal stresses, although it will not cure the problems. **Tempering** is similar to annealing but occurs faster and at a lower temperature. The process first involves heating the metal to a temperature that is just high enough to remove internal stresses, then cooling to actually soften the material. It causes less severe changes than annealing or normalizing. Temperatures between 300°F and 1200°F will produce the desired result immediately after quenching. A higher temperature will result in less hardening of the material and an increase in ductility. Tempering of some tool steels between 200°C-350°C is done to protect against accidental damage from mechanical shock.

5_3.5.2 Surface or Case-Hardening

Surface or case-hardening is another form of heat treating that creates a thin, hard, wear-resistant layer or skin on the outer surface of the metal. For historical reference, see **Chapter 3** of Price. **Case** refers to the layer of hardness or higher carbon content mixed within the skin of the metal during the heat-treatment process. The longer the period of heating, the greater the carbon content of the surface. Case-hardening is a critical process; if excessive heating is applied, the metal will become brittle and crack due to the large grain sizes produced.



Like an apple, the hard outer layer covers a softer internal

material. The outside layer is generally a martensite crystalline structure, while the underlying material is softer and more ductile and is described as ferrite, pearlite, or cementite structures. Thickness of the "case" may vary from 1/8" to .001".

Case-hardening is particularly important in the manufacture of cutting tools and barrier hard plate. Tools must have an extremely hard exterior cutting surface, yet the material cannot be hard throughout or the tool will fracture. The process dates to ancient times when warriors would harden the tips of their spears, allowing armor to be pierced without cracking the point.

Case-hardening only applies to a surface layer; the process will not harden to the complete thickness of the metal. For example, a 1/4" thick plate may have a case of only .025". Thus, there will be a hardened layer on both sides, measuring .025" thick, but the core material will retain its original characteristics. To drill case-hardened metal, one must penetrate two layers of high hardness, plus the softer core material.

There are three basic methods to achieve case-hardening: **addition of carbon** and/or **nitrogen**, or **localized heating**. These processes are also referred to as carburizing, pack carburizing, gas carburizing, liquid carburizing, nitriding, cyaniding, and carbon nitriding.

5_3.5.2.1 Hardening Using Carbon

When carbon or nitrogen is used, the surface is impregnated and the part is heated and quenched. The now carbon or nitrogen enriched surface becomes hard. In the case of nitrogen, however, the gas combines with the steel and forms an extremely hard

nitride compound. The swords of Roman soldiers were hardened through the **carburizing(109)** technique. When temperatures reach the 1700°F range, most low carbon steel will absorb carbon into its outer skin to about 0.050”.

During p**ack carburizing**, the steel parts are packed into heat-resistant containers filled with a carburizing material. Hardwood charcoal, coke, and barium carbonate are often added to the mixture. These materials are sealed and heated in an environment devoid of oxygen, to between 1500°F-1750°F. The steel is transformed during this process to its **austentite state**, which allows it to absorb large amounts of carbon. The material is then quenched to achieve hardening. **Gas carburizing** involves the injection of propane or natural gas, impregnated with vaporized hydrocarbon liquids. Hardening is achieved at about 1700°F. **Liquid carburizing** involves the use of molten salt baths, into which the parts are dipped at temperatures between 1550°F and 1650°F.

Nitriding has many advantages as compared to other case-hardening processes. Harder surfaces, superior wear resistance, minimal warping and distortion, improved corrosion resistance, high resistance to fatigue, and lower production costs are all achieved in the nitriding process. However, nitriding also has drawbacks. It is a very slow procedure and will adversely affect dimensional accuracy of the part due to swelling. Most importantly, machining of the metal is almost impossible.

Cyaniding(110) involves the dipping of the part in a bath of molten cyanide salt. The process is quicker than most others and produces a case of about .005”. Less than thirty minutes is required to cyanide-harden a part, at 1400°F-1600°F. **Carbonitriding** is also known as dry cyaniding, gas cyanitriding, nicarbing, and nitro-carburizing. Nitrogen gas is introduced during carburizing and assists in insulating the part from oxygen. The nitrogen actually increases hardness and resistance to tempering.

Localized heating is employed for medium to high carbon steel. In practice, high temperature is applied in order to heat only the surface, using techniques of **flame hardening** and **induction hardening**. In flame hardening, no chemicals are used, just heat. A direct flame from an oxyacetylene torch is placed in contact with the surface of the material. As soon as it is heated, it is immediately cooled. This method can produce a deep case, up to about 1/4", with a maximum hardness of 50-60 Rc.

High-frequency electrical current produced through a coil is used in the **induction hardening** process, to cause a magnetic field to be induced around the steel part. This will result in a skin effect, causing eddy currents to pass through the surface of the metal, producing heat.

5_3.6 Special Processes for Treating Metals

Metals can be formed and treated through a number of different processes, many of which are utilized in the production of locks and keys. These do not affect the basic molecular structure or attributes of the metal.

5_3.6.1 Surface Treatments

Anodizing(111): The skin of a metal is anodized to create a thin coating or layer of material that will inhibit corrosion and create a hard and abrasion-resistant surface. The technique utilizes an electrical process and is generally employed with aluminum and its alloys.

Dipping(112): Brass castings are often dipped in an acid bath to clean and remove debris from casting.

Electro-Plating(113): Electroplating, based upon the principle of electrolysis, is a technique used to form a thin metal surface or finish upon another metal. Finishes are created for several reasons, including the protection of the surface, to give the effect of a more precious metal and to improve appearance. The process involves passing an electric current from a source metal (the anode) to the target metal (cathode). Both the source and targets are suspended in separate chemical baths. This allows the molecular structure of one metal to be transferred from the source to the target. Electroplating is used with copper, nickel, zinc, cadmium, tin, brass, bronze, chromium, and other base metals. Copper, for example, may be electroplated onto iron and steel to prevent corrosion.

Galvanizing(114) is another surface treatment for iron and steel for protection against corrosion. **Hot-dip galvanizing** is simply a process for applying zinc, generally in a molten state. The procedure is not suitable for most lock parts, because it is almost impossible to produce and control a precise thickness of the zinc.

Sheradizing also produces a protective layer of zinc upon iron and steel by heating the material for several hours, then rotating the metal in a drum while applying zinc powder. The zinc will impregnate the metal, offering excellent corrosion resistance.

5_4.0 Forming, Shaping, and Cutting Metals

There are many operations available for the forming, shaping, and cutting of metals. Those processes pertaining to the production of keys, locks, and safes are detailed here. Cutting operations can include sawing, reaming, tapping, planing, broaching, boring, threading, and drilling. However, only broaching and drilling is relevant in the context of locks and safes. Drilling is discussed later in this chapter.

5_4.1 Broaching

Some cutting procedures involve simultaneous action on two edges or surfaces. **Broaching(115)** is the process of cutting the keyway in a brass plug during the manufacturing process. A broach, in its simplest form, is actually a pointed, sharp die used to remove layers of metal. In order to form a specific keyway, the plug of a lock must be precisely cut with a broach. Designed as a cutting die, it is formed to create the exact reverse of the key blank.

The **broaching tool** is forced or rammed into a solid block of brass. Its purpose is to shear away metal, thus forming a keyway that has the identical dimensions of the broach. The broach will have all of the grooves, angles, ridges, and bullets of the desired keyway. It will appear exactly as would the key blank, except that its surfaces are extremely sharp. The broach actually removes the metal as it is forced into the plug. See **Chapter 16** for sequential illustrations of the process of producing a plug from a block of brass.

5_4.2 Shaping and Forming of Metals

There are many operations that involve the shaping or forming of metal. These include **casting**, **die-casting**, **extruding(116)**, **forging(117)**, **pressing**, **rolling**, and **stamping**.

Casting: This is a method of producing a part to a required

shape, generally by pouring molten metal into molds of sand or metal.

Die-casting: This process requires a metal die rather than sand for the mold. Zinc, aluminum, and brass can be cast and are very popular for the production of lock parts. It is an economical process that allows intricately shaped components to be formed with a high degree of accuracy. Machining is not required after casting. Metals can also be cut, bent, molded, and formed using dies.

Drop Forging: This is a process of shaping metals while they are hot, using a drop hammer. The machine actually resembles a hammer and anvil, wherein the hammer is raised automatically and falls by gravity.

Drop Stamping: In this operation, a part is shaped using a die while the metal is cold. In contrast, a part may be formed through the process of **hot stamping** or **hot pressing** when the metal is heated.

Extruding: Extruding requires the use of a special die in which metal in a plastic or liquid state is forced through a shaped hole. The material is rapidly cooled to retain the shape given it by the die. Aluminum and brass are very suitable for extruding, and many common parts are formed using this process.

Hot Rolling: Metal, while red-hot, is fed between two steel rollers to form a sheet, bar, or plate of specified dimensions.

5_5.0 Specific Metals Utilized in Keys and Locks

A number of popular metals are utilized in the production of locks and keys and will be discussed here. Materials that are used in the manufacture of safes are covered later in this chapter.

Aluminum and its Alloys: Aluminum and its alloys are very popular for key blanks. One alloy **Avional** is used extensively by Silca to make keys that can be stronger than brass and cheaper to produce. The specification for Avional is: silicon (Si) .4 percent; iron (Fe) .50%; copper (Cu) 1.2-2%; manganese (Mn) less than .3%; magnesium (Mg) 2.1-2.9%; zinc (Zn) 5.1-6.1%; titanium (Ti) less than .2%; zirconium (Zr) .25%; and aluminum (Al)

comprises the remainder of the alloy.

Brass: This is an alloy of copper and zinc, with copper comprising between 60-70 percent. There are other materials added. The melting temperature of brass is approximately 1660°-1710° F. Brass may be sand cast, rolled, extruded, drawn, hot pressed, hot stamped, and die-cast. Almost every part of a lock can be made of brass. Metal content for brass keys is typically: copper (Cu) 57.5-60%; iron (Fe) .45%; nickel (Ni) .3%; zinc (Zn) the remainder of the mixture.

Bronze: Bronze is an alloy of copper and tin, with 90 percent or more copper. This metal can be rolled and drawn.

Copper and Copper Plating: Copper is an alloying agent in certain brasses and bronzes. Copper, with nickel and chromium, is used for plating non-ferrous metals as a primer. Copper also provides an excellent binder for nickel plating.

Gunmetal: This is an alloy of copper and tin. It is a bronze, although lead and zinc may be added. Gunmetal is considered superior to brass in lock making. It is harder and more expensive, resistant to corrosion, and generally is only used in external parts which are subject to environmental conditions.

Malleable Cast Iron: Cast iron may be made ductile through a special process of annealing, described elsewhere in this chapter. Lock bolts and shackles of padlocks have often utilized malleable cast iron because of economy and convenience.

Manganese Bronze: A small amount of manganese can be added to brass to increase strength. It is used for padlock shackles.

Nickel: Nickel is an alloying agent and provides a protective finish when plated to another metal.

Nickel Silver: This is an alloy of nickel, copper, and zinc. It is often mistakenly described as brass, where in actuality, some of the zinc is replaced by nickel, thereby making the alloy tougher than brass. Nickel silver is utilized in many factory original keys for added strength.

Phosphor Bronze: A very small amount of phosphor is added to bronze, which has the effect of making it a very strong, springy material. It is used extensively in making non-rusting springs for pin tumbler locks.

Spring steel: Steel, having a higher than normal carbon content, is used for making springs, lock picks, and other parts.

Stainless Steel: Chromium and nickel are added to iron to produce this corrosion-resistant metal.

Steel used in Keys: Steel is still used for some keys. The metal content for steel keys is typically: (C) carbon .13%; (Mn) manganese .9-1.3%; sulfur (S) .24-0.30%; silicon (Si) >/= .05%; lead (Pb) .04-0.10%; and iron (Fe) the remainder of the alloy. Lead will be eliminated in keys within a few years due to environmental and health concerns.

Tenite: A plastic material used in the production of Mosler dials.

Zamak: Zamak is used for making a variety of lock parts, and is composed primarily of zinc (95.5%), aluminum (4%), copper, lead, tin, magnesium, cobalt, and iron. The material has good casting qualities, good tensile strength, and can be sanded, filled, drilled, and tapped. The melting temperature of zamak is approximately 787° F.

Zinc and its Alloys: Zinc is also the base metal for die-casting alloys. Intricately shaped components can be made using zinc alloys. Zinc has three uses in lock-making: (1) for use in die-casting, (2) as a protective coating of other metals, and (3) as an alloying metal for use with various brasses.

5_6.0 Metallurgy and Safe Development

5_6.1 Introduction

The anti-burglary safe maker faces many difficult problems, both in the selection of materials and in the mechanical design of the safe. In contrast, the fire safe maker must offer minimal resistance to forced-entry while providing protection against the effects of heat upon the contents. Each type of safe has markedly different requirements and demands, from the standpoint of the choice of metals, how they are treated, and what they will guard against.

In the Middle Ages, underground cellars and buried vaults with doors constructed of hardwood with thin iron plates were used for

storing valuables. Then, chests made of iron plates riveted together and secured by iron bands were developed by the Germans and Dutch. Cast and wrought iron, and later steel alloyed with manganese and laminated with copper, was popular. The problem with virtually all of the early safes, whether made of rolled iron, cast iron, or steel, was that they were easily fractured by concussion. Innovations in safe technology would come primarily from England and the United States during the nineteenth century. See **Chapter 33** for a more detailed discussion of the history of safe development.

5_6.2 Early Development of Burglary Safes

Many approaches in the design and use of materials for burglary safes have been tried. The main problem has been finding or creating metals which were hard enough to resist drilling and cutting, yet tough enough not to fracture under percussion or pressure. Chubb, a pioneer in safe development, early on determined that they should make safes out of layers of hard and soft plate, comprised of high carbon steel, welded and rolled between layers of iron and mild steel. The high carbon steel would offer resistance to cutting instruments, while the softer material would add toughness. There were often five or more sandwiched layers.

Other techniques involved the use of cast metals such as speigeleisen, which could be sandwiched between outer and inner layers of other metals within the safe. The cast metals could be solid blocks of chilled iron that were grooved, keyed, or bolted together and were often a foot or more in thickness. Joints were then covered with forged bands. In 1860, Chatwood, an English safe maker, took two sheets of iron, and poured molten metal between them. This produced an extremely hard center that would cause a shattering or flattening of drill bits. This presented a far better solution than obtained from using multiple iron sheets and was successful in resisting cutting and torching; the two most common methods of attack. If copper sheets were then placed between steel plates as a heat sink, the steel would be prevented from reaching its melting point upon the application of heat from a torch.

Later, Chubb, in its high-security safe door, utilized ten layers of metal. The door was comprised of a five-ply drill-resisting steel; three sandwiches of softer steel protected two of these layers. Concrete and hard mineral chips (an anti-blowpipe material) were also used. Siemens steel, copper, and another

five-ply layer of steel, together with proprietary alloy steel, were also employed. Finally, two more layers of Siemens were added. In 1882, it was discovered that steel containing one percent carbon and thirteen percent manganese would effectively deter sawing, drilling, or filing. The metal was heated to about 1900°F, and quenched in water. It was used in the outer shells of safes and in prison bars and was known as manganese hard plate.

5_6.3 Specific Metals Utilized in Safes and Safe Locks

Many materials are utilized in the construction of safes and safe locks, based upon requirements of strength, machinability, cost, wear, and other factors.

5_6.3.1 First Outer Layer

The doors and walls of safes offer a wide divergence in penetration resistance, depending upon whether the safe is rated as **fire** or **burglary**. If burglary, the specific rating, i.e., UL tool (**TL**), torch (**TR**), or explosive (**TX**), will relate to the type and thickness of metals used. Generally, the outer layer of most safes is iron, steel, poured aluminum, concrete, or other materials. Plastics will also become more prevalent as special polymers are developed such as used in the Chubb Planet safe. Typically, ½″ to 5″ of mild steel or other material is utilized as the first barrier against drilling and other forms of forced-entry. Often, a sandwich of hard and soft materials is found, acting as a heat sink and frustrating attacks by drilling, explosives, torches, lances, and other techniques.

5_6.3.2 Hard Plate Barrier Material

Behind this first layer of metal is the real protection for internal locking components. It is called hard plate or simply barrier material and consists of ¼″ or thicker plate that is a specially created and treated metal alloy, having a Rockwell C rating approaching 80. This hard plate protects critical parts and functions and will always be found in front of and covering combination locks and relockers.

5_6.3.3 Internal Moving Parts

Boltwork, locking bars, gears, and other locking surfaces are

generally made of steel, stainless steel, or other hardened materials. Softer metals, which can be machined to high tolerances, are used in all moving components associated with locks and some relockers. Zamak and brass are popular.

5_6.3.4 Internal Lock Parts for Safes

Many different metals are used for internal lock parts, mechanisms, and for special purposes. These will be briefly detailed. Copper is used as a heat sink, generally in sandwiched layers, to frustrate attack by torch. Brass, steel, aluminum, plastic, delrin, acetal, nylon, and celcon are all used in the combination lock wheel pack. These soft materials are chosen for their special characteristics, needed to maintain reliability of the lock. Brass is also utilized for many internal lock parts, including some wheels, casings, cams, levers, relock triggers, and bolts.

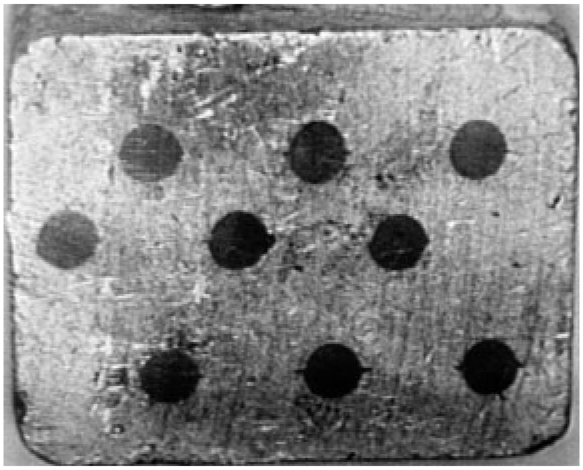
Materials are selected based upon the following criteria:

- **Resistance to corrosion and development of micro-organisms and biological growth (green film) in wet climates;**
- **Self-lubricating features;**
- **Resistance to radiographic imaging and penetration;**
- **Impervious to chemicals, oils, grease, or solvents;**
- **Ability to produce to high tolerances;**
- **Does not conduct electricity (not subject to electrolytic action).**

5_7.0 The Penetration of Safes: Barrier Materials and Hard Plate

The following sections describe barrier materials and hard plate in the context of penetration of safes and vaults.

5_7.1 Basic Construction Technique



All modern safes follow the same fundamental pattern of construction, although the basic configuration, reduced to its primary elements, is quite constant for most containers. Depending upon the security classification and manufacturer, differences in design can include:

- **More material;**
- **More layers of a given material;**
- **Sandwiched layers of different materials;**
- **Heat sink or ducting materials;**
- **Ball bearings;**
- **Steel pins;**
- **Stone chips;**
- **Specially designed alloys to frustrate penetration.**

Let us first examine the components of a "typical" low to medium rated security safe. The door is made of 1/2" mild steel. Welded behind the door is 1/4" hard plate to protect access to the combination lock, followed by a 1/8" lock mounting plate, upon which the lock body is actually affixed. The mild steel first barrier presents little difficulty for the proper drill rig. In larger, higher security safes, this 1/2" outer skin may be several inches thick. In addition, there may be added copper layers in critical areas to draw heat away from barrier materials. If a copper layer is encountered, it will make attack by torch very difficult.

Regardless of the security rating or the number of layers of metal between the outer surface of the door and the lock mechanism, the principle is the same: **the barrier material is the primary protective shield against penetration.** As will be seen in the chapters dealing with safe construction, there are many sophisticated ways to add penetration resistance. The major safe manufacturers have concentrated their primary research efforts on the barrier material or hard plate, rather than other technologies. Each manufacturer has developed different metallurgy to protect its safes, and thus, each material will differ in its penetration resistance. Hard plate can take many forms from case-hardened steel to laminates and can be any thickness and composition. Generally, all barrier materials will have a Rockwell C rating between 70 and 85 or higher.

5_7.2 Definitions

There are a number of terms associated with barrier materials. These are important to an understanding of their properties and construction techniques.

Carbide chips are welded on the surface of some hard plate (and are placed on the tips of drill bits). They make drilling very difficult because the bit cannot "bite" into the metal without breaking.

Carbide pins or balls are a very popular technique of protecting hard plate from drilling. An anti-drill, closely spaced array is pressed into the plate or is free-floating. Stainless steel rods incorporated within aluminum alloys such as aloxite are equally effective. Chubb has been using this technique for many years.

Hard plate or **alloy Hard plate** is a combination or amalgam of one or more metal plates and particles or other materials. These are sandwiched between the lock body and the safe door to create a hard barrier to resist forced-entry. Depending upon the manufacturer, varying amounts and ratios of chrome, tungsten, carbon, nickel, and other metals will also be used in the production of hard plate.

Hard plate, in its many forms, is metal that has been specially treated and hardened. **Tempered hard plate** will have a smooth surface. Unpainted, there will be traces of discoloration, with reds, blues and greens. Hard plate can be **included** or **non-included.**

Hard plate is generally exposed to 1500°F-1600°F for about four hours, then cooled in oil to obtain a maximum case hardness. The

individual characteristics of the steel being hardened will determine time and temperature applied, for a desired hardness rating.

Inclusion materials are found within alloy hard plate for added drill resistance. Alloy hard plate is known for its "inclusion materials" and is often referred to as **included hard plate.** Generally, included hard plate is high carbon alloy steel. In addition, a layer of bronze, epoxy, ceramic, or other material may be poured over the metal skin. Inclusion composition may contain small chips or pieces of tungsten carbide, carbide chips, carbide dust, ceramics, aluminum oxide nuggets, ball bearings or other materials. These inclusions may also have varying spacing or gaps in materials to make drilling even more difficult.

The combination of surface deposits and inclusion materials within the metal can create a very irregular and rough outer skin, with non-uniform and hard internal layers. Varying surface dimension and materials will wreak havoc with drill bits.

Laminated hard plate is made up of interleaved layers of hard plate, soft steel, copper, and other heat-conducting materials.

5_7.3 Manufacturing Hard Plate

Many manufacturers produce their own patented hard plate or barrier materials; each is given a special name. Thus, there is Maxaloy**tm**, Kimloy**tm**, Lockmasters**tm**, Aloxite**tm**, Alchronite**tm**, and Relsom**tm**. Each manufacturer uses different techniques, including the addition of carbide chips, nuggets, aloxite, concrete, or other materials within the mix or welded to the surface. Layers of plates, iron laced with hard studs, hardened suspended discs which are free to revolve and other techniques may be employed in the production of hard plate. They all have the goal of preventing, delaying, or increasing the danger of penetration by drilling, explosives, thermic lance, and other sophisticated methods. All hard plate is different, even within the same manufacturing batch.

Hard plate can also be poured into a form. Maxaloy, for example, contains coarse cobalt, cemented tungsten, tantalum, and titanium carbide grains in a high-strength matrix. This amalgam is poured into a form, in the shape of a pan. The hardness of this particular material exceeds the top reading of 86.5 on the Rockwell C scale. Mosler pours Relsomite in this same fashion.

The approach Diebold has taken utilizes "envelope" technology, “including” carbide chips within a stainless steel matrix, poured into two pans. When the metal has cooled, the two layers are joined together with ball bearings within a matrix of epoxy. An outer layer of ceramic may also be encountered in drilling certain Diebold products. Chubb utilizes a variety of approaches, including poured aloxite and hardened nuggets, pressed bearings, and other techniques discussed in later chapters. Steel balls, used by Chubb, may be either loose or pressed. If loose, they are suspended in oil.

5_8.0 Metal Cutting Principles

5_8.1 Introduction

This section outlines the principles that apply to metal cutting, with the emphasis on drilling theory of hard plate. The section first details the development of materials used for the production of tools during the twentieth century, including some of the more exotic high-tech compounds. The physics and chemistry of metal cutting are then explored, again with the emphasis on how a drill interacts with the work surface. Special attention is given to the production of chips, how they occur, and why they are so important. Understanding how metal is cut is particularly important for the evidence technician in order to aid in the investigation of the forced-entry of safes and vaults. The discussion is of equal significance for the safe, vault, and container specialist.

5_8.2 Tool Materials in the Twentieth Century

The development of more sophisticated materials can be directly traced to certain periods in the twentieth century and special technical requirements connected with such developments. The following events set the stage for staggering advances in chemistry and metallurgy that have occurred during the second half of this century.

- **The introduction of the automobile around 1910;**
- **World War I and the recognition of the value and subsequent use of aircraft for both military and civilian purposes;**
- **Second World War, with the development of the**

chemical, petrochemical and polymer industries.

Factors, including the birth of the nuclear industry, the need for improved machine tools for use in automated production, jet engine manufacture, the space program, and national defense also contributed to current technology. Finally, environmental concerns, energy costs, and the price of labor and materials have all had a tremendous impact upon technological advances.

5_8.2.1 Cutting Tools

The development of advanced materials for use in the production of cutting tools have resulted from the tremendous demands placed by a highly technical society and the rapid changes which have been brought about. As has been noted previously, the development and refinement of materials used in cutting tools has required the integration of many disciplines, including physics, engineering, metallurgy, and chemistry. Tools are available in hundreds of different alloys and are rated and classified by the following criteria:

- **Structure;**
- **Properties;**
- **Performance;**
- **Composition;**
- **Ability to resist temperatures and stresses;**
- **Interaction of the tool and the work surface.**

A tool is evaluated in terms of initial cost, tool-cutting costs, tool life, cutting speeds and feeds. This is especially important in the case of drills used for penetrating barrier materials. Until the first use of metals, naturally occurring products such as wood, bone, and rock were the only materials available for cutting. Prior to the turn of the twentieth century, copper, iron, and steel were the only metals available.

In terms of a time line of material and tool development, there have been many significant advances after 1900. Before World War II, high-speed steel (1900), cast alloys (1910), super HSS (T-15) (1920), and sintered WC (K-type and P-type) (1940) were developed. Around 1950, M-40 series HSS, ceramic, and synthetic diamonds made their debut. Shortly after 1960, TiC, improved sintered WC, cermets, and coated carbides were introduced. In the seventies, polycrystalline D and CBN and powder metallurgy (P/M) high-speed steels were developed. In the 1980s and 1990s,

extremely complex polymers and ceramics have been patented and are being used for special tools.

5_8.3 Tool Material Classifications

Within the last quarter century, tools have been divided into two major groups: **high-speed steels** and **cemented carbides.** Other groups of materials are **carbon steels**, **cast cobalt-based alloys**, **ceramics**, and **diamond.** Materials are chosen for use in tools depending upon many factors, including operating temperature, feed, speed, and the hardness of the material being cut or drilled. Many metals, such as HSS, will lose their hardness once heated above their tempering temperature. Others, such as tungsten carbide, titanium carbide, cast alloys, ceramics, and cermets will recover their hardness at room temperatures.

5_8.3.1 Primary Measurements for Cutting Materials

Three primary measurements are employed to evaluate cutting tool materials: **high-temperature** physical and chemical **stability** (**HTS**), **abrasive wear resistance** (**AWR**), and **resistance to brittle fracture** (**RBF**). As has been noted earlier in this chapter, rarely can all three criteria be optimized; a compromise is always required. A high HTS material will become more brittle or have a low RBF. If it is made more abrasion resistant or high AWR, it will become more brittle or low RBF. These relationships are true over broad classes of materials, including high-speed steel (HSS), tungsten carbide (WC), and titanium carbide (TiC).

5_8.3.2 Toughness and Hot Hardness

The properties of materials with respect to toughness and hot hardness are inversely proportional. Thus, the following nine material classifications are shown in order of toughness. Carbon steel is the least hard but most tough.

(Most Tough)

- **Carbon steel**
- **High speed steel**
- **Cast alloy**
- **Tungsten carbides**
- **Cermets**
- **Titanium carbides**

- **Ceramic (Al_2O_3)**
- **Polycrystalline diamond and cubic boron nitride**
- **Single crystal diamond**

(Most Hard)

As we move from carbon steel to diamond, the strain or stress required to cause fracture decreases. All of the materials, with the exception of single-crystal diamond (extremely brittle), have a two-phase structure: a softer continuous phase, which separates very hard particles. As a material becomes harder, the space between hard particles becomes less.

5_8.4 Different Tool Materials

Hundreds of materials are utilized in the production of tools that are employed for cutting other metals. These are described below.

5_8.4.1 High-Speed Steel and Alloying Agents

As the Industrial Revolution came into full force in the nineteenth century, carbon steel tools were not cost effective in meeting the increasing demands of factory output. Tools were needed that could cut more steel at lower cost; thus, the introduction of high-speed steels. Robert Mushet of England was the first to use alloying elements to improve cutting tool design in 1868. Prior to that time, lathe tools were forged from steel containing 1% carbon, .2% manganese, and the remainder iron. These had a low hot hardness (hardness at elevated temperatures). The result was that prior to 1868, tools could not be used at high speeds. Production of this material also required water quench that invariably caused fracture.

Mushet introduced 2% carbon steel, with 5.5 percent tungsten, 0.4 percent chromium, and 1.6 percent manganese. One advantage to this mixture was the ability to harden without quenching the metal. It also allowed higher cutting temperatures. This steel was used until about 1900. In 1901, a metal was developed which would double the cutting speed of the Mushet alloy and was to be known as high-speed steel (HSS). HSS did not signal the development of a new metal but rather the introduction of a new heat-treatment for existing steel.

The inventors of HSS, F.W. Taylor, and M. White, noted that if tools were heated quickly to a temperature of 845°C-930°C, just short of the metals melting point prior to quenching, significant improvements in hot hardness would occur. By 1906, the optimum formula (at that time) was determined for high-speed steel tools: C, .67%; W, 18.91%; Cr, 5.47%; Mn, .11%; V, .29%; and Fe, the balance.

Many changes in the composition of HSS occurred, which allowed much higher cutting speeds. In addition, the abrasion resistance of the metal was changed through the addition of vanadium. By 1910, the tungsten content had decreased to 18%, chromium to 4%, and vanadium to 1%. This was the well-known HSS 18-4-1, which would be the standard High Speed Steel for the next forty years. In 1912, cobalt was added to improve the red-hot hardness of the metal.

By 1920, there were three high-speed steels in common use, known as T-1, T-7, and T-4. In 1923, a fourth super high-speed steel was developed, called T-6. Today, the standard M2-HSS, which displaced the original T-1, has the following composition of alloying agents: .8% C, 4% Cr, 2% V, 6% W, 5% Mo. Current HSS will cut up to 120 times faster than the original material. The steel developed by Taylor and White is still popular and is one of the two primary metals used for cutting.

During the 1970s, further advances were made in the development of HSS which created materials with a smaller carbide size and more uniform distribution of carbides. HSS made possible the cutting of steel at approximately four times the rate of carbon steel. The properties result from precipitation hardening within the martensite structure. Toughness and high temperature strength has allowed this steel to survive for almost a century. High-speed steels cannot be used for cutting hardened steels, found in barrier plate within safes. This results from the loss of strength and the changes in the permanent structures when heated above 650°C. The most significant advance in the metallurgy of high-speed steels has been in the development of coatings by CVD and PVD processes.

5_8.4.2 Powder Metal (P/M) High-Speed Steel

High-speed steels can be created through powder metallurgy, which involves a very fine powder stream, produced by atomization of molten steel being broken into tiny droplets. This molten flow solidifies within a fraction of a second to a fine-grained

structure. Through this process, carbide particles are more evenly dispersed than in traditional methods of steel production. Powder metallurgy produces superior structure, resulting in lower failure rates and the ability to manufacture steels with higher alloy contents.

5_8.4.3 Spray Deposition Coated Tools

Like powder metallurgy, a fine spray of molten metal is produced that is then sprayed onto a solid substrate, itself molten. Coating high-speed steel tools involves the formation of hard layers on working surfaces, the primary purpose of which is to reduce friction or wear. Coated carbide tools appeared about 1969. Originally, a thin film of TiC (.0002), TiN, Ti, or HfN was applied to steel-cutting carbides. There are three popular coatings: TiC, Al_2O_3, and TiN. Some tools have several coatings to reduce brittleness inherent with such processes. Two processes, called **chemical vapor deposition (CVD)** and **physical vapor deposition (PVD)**, involve the creation of a very thin layer of metal carbides on the tool surface.

Generally, coated-tools are not suitable for machining high-temperature alloys. They are most useful in high-speed cutting on ferrous alloys of all types, including stainless steel. They can reduce cutting forces, produce greater cutting speeds, and may increase tool life from 2 to 100 times.

5_8.4.4 Cast Alloy Tools

Non-ferrous high-temperature alloys, with significant amounts of cobalt, chromium, and tungsten, were developed about 1915 by Elwood Hayes. The materials were not heat-treated but cast and therefore were known as cast alloy tools. By 1925, they were common. Tools made of cast alloy retain their hardness at high temperatures.

5_8.4.5 Cemented Carbides

Cemented carbides have many unique properties that have led to their use in drills and other cutting tools. Carbides, especially tungsten and molybdenum, are rigid and strongly bonded compounds. Until they reach their melting point, no major structural changes are experienced. Thus, their properties remain stable and unchanged by heat treatment, in contrast to steels that can be softened through annealing and hardened by rapid quenching. Cemented carbides are sometimes included in the

category of ceramics, and thus have often been referred to as **cermets** or ceramic metal.

Although the hardness of carbides will actually drop rapidly as the temperature increases, they remain harder than steel. They are especially well suited as cutting tools because of their stability within a wide range of thermal treatments. Carbide particles and cemented carbide alloys constitute fifty-five to ninety-two percent, by volume of the structure, in contrast to ten to fifteen percent of hard carbide particles in high-speed steels. Cemented carbides are often characterized as brittle materials, almost like glass and ceramics. They are actually capable of a great deal of plastic deformation before they fail.

During the 1960s, there was an increase in the quality of carbide tools; they were made less brittle through improved binding and sintering techniques, coupled with smaller carbide size. These tools are made of milled tungsten carbide powder, mixed with a sintering material and pressed, to provide a homogenous mixture. Traditionally, steel-cutting tools were made in one piece; however, cemented carbides have been produced to form tool tips or small-brazed inserts used for cutting. They are generally less tougher than high-speed steels and require the tool edge to be formed differently. It will be recalled that the rake angle on steel tools is generally as high as +30°. In contrast, the rake angle on carbide tools is rarely greater than +10°, and is often a negative.

5_8.4.5.1 Cemented Tungsten Carbide

Tungsten carbide, with its many alloys, is used extensively in drill bits for the penetration of barrier material. It was originally developed in 1896, when a French chemist mixed iron, charcoal, and sugar with cobalt. The first tungsten carbide tools were brought to the United States from Germany in 1928. These were actually made of finely ground tungsten carbide particles, sintered together with a cobalt binder. With improvements, they became quite popular during World War II.

Drill bits made of WC will withstand higher temperatures than the material being drilled and will generate a great deal of squealing. The chips thus produced are blue-black in color and quite hot. Several bits are generally required to make a hole through most hard-plate material. Note that carbide drills **cut** the material in contrast to diamond tip drills, which **grind** through the metal. There are two types of Tungsten Carbide: one

for machining gray cast iron non-ferrous metals and abrasive non-metals (ISO-K type), and one for machining ferrous metals (ISO-P type).

5_8.4.5.2 Titanium Carbides

Titanium carbide (TiC) tools were introduced in the 1960s in an effort to improve upon tungsten carbide tools. The material is more oxidation resistant, available at lower cost, and quite popular.

5_8.4.6 Ceramic and Cermet Tools

Ceramic cutting tools were first used in England, Germany, and Russia, and were introduced in America in the mid-1950s. This technology uses finely divided aluminum oxide, or alumina that has been sintered, without binders or other additives. These substances have high hardness and melting points. Tool tips consist of fine-grained alumina with high relative density and with less than two percent porosity.

Although the room-temperature hardness of alumina and cemented carbides is about equal, alumina has several advantages, including the retention of hardness and compressive strength at temperatures higher than is available with carbides. They also have lower solubility in steel than any carbide, up to the melting point of the steel. However, toughness and strength under tension are lower than with carbides. Alumina-based tools will cut steel up to four times faster than conventional cemented carbides or TiC-based alloys, yielding greater metal removal rates. Tools made of alumina, however, have not been particularly successful for use in high-speed drills.

In the 1980s, advancements were made in alumina technology, with the addition of up to 25 percent FiC whiskers, one to two micrometers in length, which were randomly distributed in the alumina matrix. This increased the metal's fracture toughness value. Cermet tools are popular for the high-speed machining of hard cast irons and steels, where there is limited mechanical shock encountered. Tools produced with ceramics are more brittle than carbides but also harder.

5_8.4.6.1 Sialon

A special group of ceramics, called **sialons**, has been used since 1976 for cutting tools. This material has high hardness, bend

strength, and a low coefficient of thermal expansion, providing good resistance to thermal shock. The cost of these tools is high.

5_8.4.7 Cubic Boron Nitride (CBN) Tools

Cubic boron nitride (CBN) is the next hardest material to diamond. It has many similar, but not identical properties and is harder than any metallic carbide. CBN can be used for cutting hardened steel at high speeds without rapid wear as encountered with diamonds. A thin coating of CBN or polycrystalline diamond is also popular on tools made of sintered tungsten carbide substrate with a cobalt binder. Introduced in 1973, these tools are made by placing small grain-size diamond or CBN on the carbide surface. They work best on non-ferrous alloys, fiberglass, silicon-aluminum alloys, graphite, and other highly abrasive materials.

5_8.4.8 Polycrystalline Diamond

The hardness of diamond is related to and is the result of its crystal structure. Diamond tools are the hardest known, but very expensive. They have a much lower wear rate, with longer life than carbides or oxides. Where there is a high-abrasion potential resulting from the hardness of the work surface, diamond will perform well. Diamond cutting tools are up to five times harder than cemented carbides, or alumina. Rates of abrasive wear can vary by a ratio of 1:80. The use of diamonds for drill bits is limited due to the inability to create sharp edges in the tool. Another drawback is that diamonds are easily chipped.

5_8.4.9 Other High-Technology Materials

Limited application, high-cost materials have been developed for special purposes. For example, tools made of columbium (niobium), known as UCON (trademark of Union Carbide) contain columbium, titanium, and tungsten, and are diffused with nitrogen at 3000°F. The material is extremely hard, yet ductile.

5_8.5 The Cutting of Metals

5_8.5.1 Introduction

There are three primary metal cutting operations: turning,

milling, and drilling.

Turning(118), with a lathe, uses a single-point tool to remove unwanted material during the process of revolution.

Milling(119) produces flat and curved surfaces, using multipoint cutting- tools. There are three basic milling machines: plane-milling machine, face-milling cutter, and an end-mill.

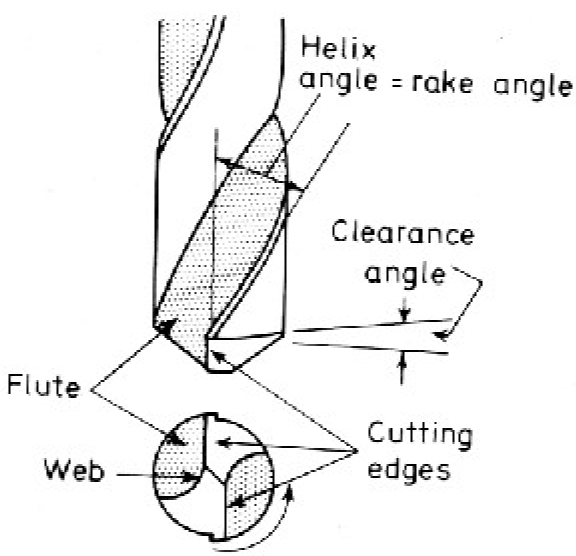
Drilling(120) produces either rough or precise holes in metal parts. It can also be a preliminary process to reaming, boring, or grinding.

5_8.5.2 Making Holes by Drilling

This section will summarize the theory of drilling holes in metal. Cutting soft non-metallic materials requires "fine" cutting edges, such as found in a knife. Generally, a wedge-shaped tool is forced symmetrically into the material to be cut and actually severs it. In contrast, the penetration of metal by drilling requires a tool with a cutting edge that will withstand the stresses encountered during the cutting process. Metals and alloys, except very low melting point materials, will be impervious to "fine" cutting edges.

A cutting tool, such as a drill, must take the form of a large angled wedge, which is forced asymmetrically into the work surface in order to remove a thin layer of metal from the thicker composite. This layer of material must be thin enough to enable the tool and surface to survive the stresses imposed, yet the cutting edge must have a sufficient clearance angle so that it will not make contact with the work surface. Thus, for example, a high-speed steel drill bit will have the following characteristics:

- **The point is in the center of the bit;**
- **The cutting edges are parallel to each other and of equal length;**
- **The point is at a 45° angle to the cutting edges;**
- **The heel is lower than the cutting edge on both sides.**



Generally, the included angle of the cutting edge varies between 55°-90°. This will allow for chip withdrawal through an angle of at least 60° as the removed layer moves across the rake face of

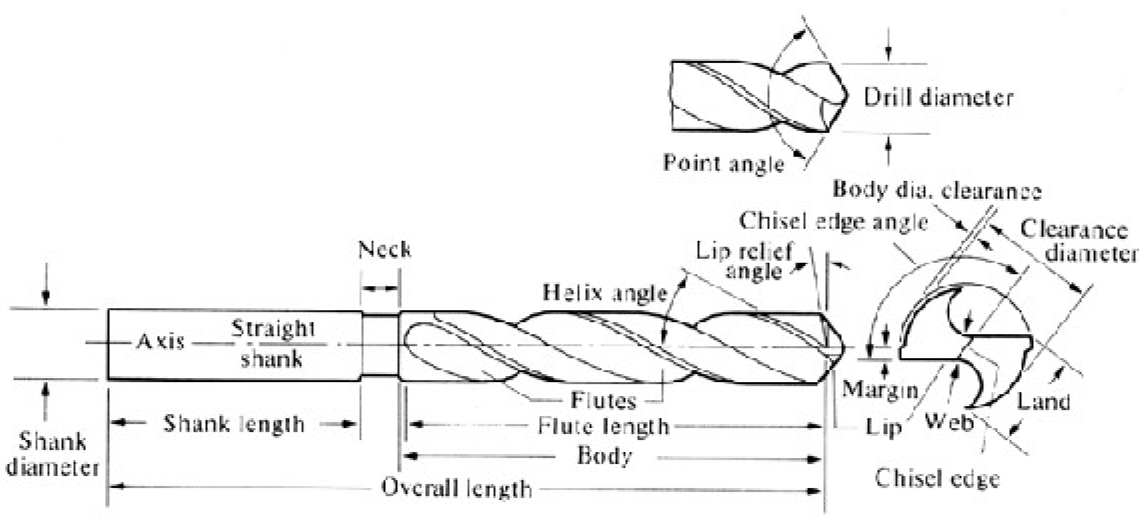
the tool. A great deal of energy is needed to deform the metal into chips and move them across the tool face. The chip or removed surface is a waste product and may seem to the reader to be insignificant to the drilling process. However, the transfer of energy required for the formation, movement, and removal of chips, and the problems associated with the rate of metal chip removal and commensurate tool performance, are of critical importance. **They are the essence of drilling theory and are given special consideration here.**

There are many different kinds of drills beside the common two-flute twist bit. These include flat drills, drills with one, three, or four flutes; and core, shell, and spade drills. The different materials used for making drill bits are described elsewhere in this chapter. Information about drilling barrier materials is also presented in **Chapter 35.**

5_8.5.2.1 How a Drill Cuts Metal

Our discussion will focus on the two-flute twist drill. It is probably the most common and is representative of the problems associated with most drilling operations. A twist-drill is a complex cutting tool, generally used in a drill press or drill rig. There are two cutting edges or **flutes**, which produce **chips**. Forming part of each flute is the **rake**; its orientation is controlled by the **helix angle** of the drill bit.

The product of drilling is a chip that slides up the flutes and is carried away from the center of the hole by the **web region** of



the bit. Each flute (cutting edge) has a variable **cutting angle**, **inclination angle**, and **clearance angle** along the cutting edge. There are actually four operations performed in the drilling cycle:

- **A small hole is created in the material being drilled by the rotating web;**
- **Chips are formed by rotating cutting edges or lips;**
- **Chips are carried from the hole by the helical flutes that are an integral part of the drill shaft and create a "screw conveyor";**
- **The drill is guided in the hole already produced by the margins.**

The two critical operating variables in any drilling operation are **speed** and **feed**.

5_8.5.2.2 Drill as a Complex Cutting Tool

The drill is said to be a complex cutting tool because there are a number of conflicting requirements in the geometrical design of its web, flutes, and helix. Each must be somewhat compromised to produce the required result.

To illustrate, a **small web** is needed to reduce the required thrust placed on the drill in order to pierce; yet, a **large web** is desirable for greater resistance to chipping and torsion rigidity. However, the same requirement for torsion rigidity has an impact upon flute design.

Large flutes provide a greater area for chip transport; they can also cause a loss of rigidity. Thus, another compromise must be reached. Finally, a **greater helix angle** will cause chips to be removed more quickly but will also reduce the strength of the cutting edges. The helix angle will vary with the radius to any particular point on the cutting edge.

5_8.5.2.3 Drill Performance and Design

Most critical to the cutting process is the design and computation of the **helix angle**, **point angles**, **web thickness**, **clearance angle**, and **drill diameter**. These criteria will determine drill performance. While the manufacturer will control the helix angle, the user can alter the other characteristics. The following can be said regarding the effect of altering drill design, with respect to web thickness, rake angle, point angle, helix angle, and other parameters.

5_8.5.2.3.1 Web Thickness

An **increase in the web thickness** will strengthen the cutting edge near the point, with a smaller increase in the rake angle. There is no significant effect on the periphery of the drill. Because structural failure at the drill point is common when drilling harder materials, greater web thickness is required.

5_8.5.2.3.2 Rake Angle

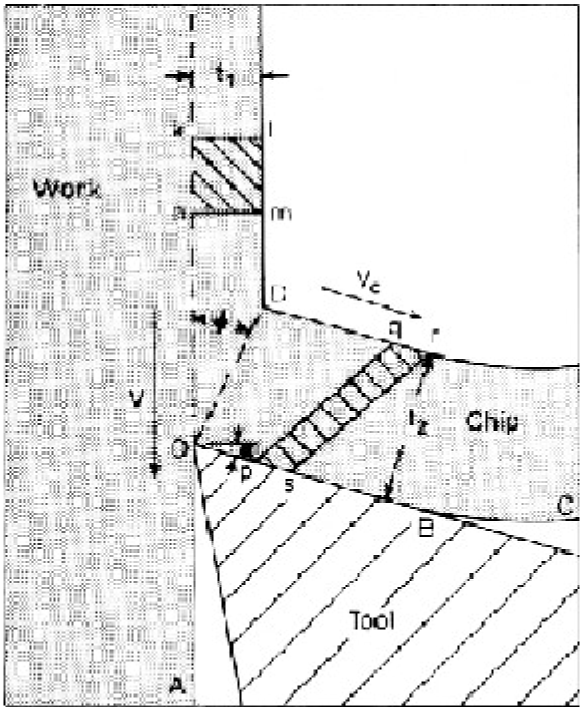
A rake angle increase will lower cutting and feed forces but will also reduce the strength of the tool edge. Negative rake angle tools provide the strongest cutting edge and thus are used for cutting harder grades of carbides and other tough metals.

5_8.5.2.3.3 Point Angle

Increase in the point angle will have a significant impact at the center of the drill and a corresponding increase in the rake angle. The effect is to offer better cutting at the point of the drill, but less support to the cutting edge. A small point angle can be used when cutting soft materials such as aluminum, because less cutting force is required. For drilling hard materials, a large point angle is desirable, because failures occur at the center of the bit.

5_8.5.2.3.4 Helix Angle

While changes in point angle and web thickness is largely irrelevant at the periphery of the drill, a change in the helix angle will have its greatest effect there. An increase in the helix angle will allow freer cutting but provide reduced support across the cutting edge, particularly at the areas away from the center of the drill.



5_8.5.2.3.5 Overall Drill Design Parameters

Drill design will dictate a small helix angle, large point angle, and thick web for drilling strong materials such as high-temperature alloys and stainless steels. Generally, standard drill design will correspond to the following parameters: helix angle = 28°-32° (soft and hard metals); point angle = 100°-118° (soft metal); 135°-140° (hard metal); clearance angle = 8°-12° (soft metal); 5°-9° (hard metal). The chisel edge angle is an approximate measure of the clearance angle of the drill.

The web thickness, which is actually the metal that connects the flutes, represents a lessening of the diameter of the drill as the drill size increases. The design of the web is quite complicated. If a drill has a web thickness greater than actually needed, then the required thrust force will also be greater. If the feed rate is too high, a failure may occur through the web. Generally, a drill is slightly tapered toward the shank (.0005”-.001") to allow clearance of the drill body in the finished hole. Drill performance and long life also require that all of the cutting edges do equal work: both their length and height must be the same. If the lips are asymmetrical, inaccurate cutting and short life will occur.

5_8.5.3 Chips: The Product of Metal Cutting

Perhaps the most important aspect of metal cutting involves the formation and transport of chips. These are the waste product of the cutting process, are controlled by the cutting tool, and, together with their shape, size, and design, are generally the prime concern of tool designers and manufacturers.

Chips are formed by shearing at the point where the cutting portion of the tool meets the work material surface. Depending upon the work surface, chips tremendously vary in size, shape, and density. A great deal of energy is expended at the point of shearing and chip transport, and some materials will fracture under this stress.

Chips may be continuous or discontinuous, depending upon the structure and ductility of the work material. Generally, continuous chips are produced in softer metals. Chips may be studied by forensic technicians, for example, at a burgled safe in order to determine certain characteristics of the cutting-tool. The analysis of chips, including cross section, thickness, and formation, may yield information about grooves in the tool rake face and thus the design of the tool.

5_8.5.3.1 Contact Between Work Surface and Tool

The actual degree of contact between the cutting tool at the shearing plane will determine how a chip is formed and the stresses related thereto. In fact, the coefficient of friction between the cutting surface and the work surface is an important consideration in chip formation. In reality, work surfaces are

never entirely flat, and thus the surface of the cutting edge does not make complete contact with it. As noted by Trent, the contact area can be very small, in some cases as little as one percent of the apparent area of the sliding surfaces.

When materials of different strengths come into contact during the cutting process, the force that is required to move the cutting tool across the work surface equals the force required to shear the weaker of the two materials across the entire surface area.

The conditions that exist at the interface point between work surface and cutting tool are extremely significant. Research indicates that during the cutting process, the work surface and cutting surface become bonded to one another. The strength of this bond can differ or can change based upon factors including the tool and work material, cutting speed, and feed. In areas of bonded contact, the tool and work materials have effectively become one piece of metal. The point at which the work material and cutting material become interlocked is referred to as the **condition of seizure.**

5_8.5.3.2 Treatment of Work Surface

The treatment of the work surface will increase the force required to form a chip. Chip thickness will be inversely proportional to **shear angle.** Thus, where the shear plane angle is very slight, the shearing force can be up to five times greater, in comparison to where the angle is 45°. Shear plane angles will vary, from 5°-45°.

Many forces are encountered during the cutting process on the shear plane. The force required to form a chip depends upon the **shear yield strength** of the work material under cutting conditions. Shear yield strength of the work material will vary greatly. For example, the strength of nickel-chromium-vanadium steel is almost six times that of magnesium and almost twenty times that of lead.

In metals such as copper, aluminum, iron, and nickel, cutting forces are high, because the area of contact between the rake face and the material is high. Correspondingly, when the shear plane angle is small, thick strong chips are created at slow speed. This explains why pure metals are traditionally difficult to machine. High ductility results in high contact area.

Contact area will decrease with certain types of metals. When cutting magnesium, titanium, hardened steel and hard plate, chips will be much smaller and thinner. In fact, forces will decrease as the cutting speed is raised, because there is less contact area. Temperatures will also rise as the speed increases.

5_8.5.4 Tool Life and Failure

In the simplest of terms, the material it must pierce, its metal composition, and the skill of the operator will determine the life of a drill bit. Many complex factors affect drill failure. These include:

- **Changes in tool geometry caused by plastic deformation under compressive stress;**
- **Diffusion wear;**
- **Attrition wear;**
- **Abrasive wear;**
- **Fracture;**
- **Thermal fatigue;**
- **Wear under sliding conditions.**

Tool forces generally rise as wear increases on the tool. This is because the clearance angle is destroyed and the contact area is increased.

5_8.5.4.1 Changes in Tool Geometry: Wear and Deformation

In order for the tool to be effective and survive over extended use, the cutting edge must be accurately controlled and can be extremely critical in maintaining tool dimensions. Tool geometry is thus very important and must be maintained within a few tenths of millimeters to prevent burs, chips, and rounded edges. The action of cutting during drilling modifies the shape of the cutting edge, so that at some point the tool will cease to cut efficiently or effectively or will simply fail. Determining when a tool fails to perform satisfactorily may be evidenced by fumes, noise, vibrations, a change in tool shape, generation of chips, or other indicators.

Critical changes in tool geometry may be very small, with a microscope required to observe them. Such changes are referred to as wear and deformation. **Wear** generally means the removal of

small amounts of metal, such as found in abrasions. **Plastic deformation** involves conditions of seizure and geometry changes. **Deformation** is not considered as wear, because no material is actually removed form the tool surface. Generally, deformation occurs along the tool edge and is due to stresses and temperatures. It is rarely uniform in dimension. Deformation causes tool damage when working with harder materials and limits the ability of high-speed drills to penetrate hardened steel.

Tools may also be worn by metal and carbon atoms from the tool diffusing into and being carried away by the stream of chips flowing from the work surface. **Diffusion wear** occurs from 700°C-900°C and is accelerated by high temperatures and rapid flow rate. Tool surfaces may also fail due to **attrition** at relatively low cutting speeds and temperature. Large microscopic fragments may also be torn from the tool surface; in effect nibbled away. Attrition is in fact a slow form of wear.

Abrasive wear occurs because particles are present in the work surface that is harder than the martensite matrix of the tool. Wear will be greatest where sliding occurs, which is at the tool-work interface. In summary, drill bits can fail due to plastic shear at high temperatures, deformation under compressive stress, diffusion wear, attrition wear, abrasive wear, and sliding wear. The most common drill failures in small bits (<1/16”) are **breakage**; **wear** is the cause in large bits. Drills will generally break due to too great a thrust load, or torque.

5_8.5.4.2 Forces Encountered During Drilling

Major forces are encountered by the drill during the process of cutting. Drills with small rake angles experience increased stress on the contact area of the rake face. This force is compressive in nature and can be calculated by dividing the cutting force by the contact area. The compressive stress experienced by the tool correlates to the shear strength of the work material. Large contact areas will result in high forces.

The properly designed cutting tool will have a calculated distribution of compressive and shear strength. Unless properly engineered, tools will fracture or disintegrate in very short cutting time from stress and temperature. Up to ninety-nine percent of the force exerted during cutting is converted to heat in the chip, the tool, and the work material. Temperatures at the tool-work interface increase with cutting speed. This rise in temperature sets a practical limit to cutting speed for higher

melting- point metals and their alloys.

The point of highest temperature is at the **flow zone**, where the chip is seized to the rake face of the tool. Temperatures of 1000°C or higher can be encountered at this point. Solving the problems of increased temperatures during cutting has probably been the most critical design challenge over the past hundred years. It has spurred the development of new high-temperature materials.

5_8.5.4.3 Cutting Lubricants

Cutting lubricants may be very effective in preventing seizure at low speeds between tool and work surface and thus can greatly reduce forces inherent in the process. They reduce the seized contact area and, thus, the corresponding forces which act upon the cutting tool. Lubricants are not effective at higher cutting speeds.

5_9.0 Penetrating Hard Plate

This section provides information necessary to an understanding of the mechanics of drilling hard plate. Additional discussion is presented in **Chapter 35**, specifically from the perspective of the safe and vault technician.

5_9.1 Introduction

Drilling through mild steel and even tool steel is a great deal simpler than boring through hard plate due to the complex physics and metallurgy involved in the cutting, heating, and cooling processes. Even the observable physical results are quite different from drilling other steels: very few chips come out of the hole, and what is produced is extremely fine-grained. If more than 1” of hard plate is encountered, it may be considered as drillproof. Often, several layers of different alloys will be found with a combined thickness exceeding 1”. This combination can frustrate drilling and the effects of temperature from a torch.

There are three critical and equally important factors to consider when drilling hard plate: **speed**, **pressure**, and **stability**. Their proper combination will cause the metal to become hot enough to actually melt or anneal in order to allow the drill to remove material from the hole. It does not take

muscle to drill through barrier material; rather, it takes knowledge and skill.

5_9.2 Drill Bits for Penetrating Safes

Different types of bits are required for penetrating the various layers of metal within a safe. A thorough analysis of drills is presented in **Chapter 35**.

5_9.2.1 High-Speed Steel (HSS)

Mild steel is the first barrier layer on safe doors. Although this metal may be one-half to several inches thick, it is pierced using a high-speed steel bit with a positive rake flute. An HSS bit is also used to penetrate the last layer of steel to which the lock body is attached. These bits are run at high RPM and are designed to bore through relatively soft materials. They are not suitable for use with harder materials found in security barriers. High-speed steel bits are always positive rake and will generally have carbide tips. The flutes will slice away material at the work surface.

While soldered flutes are encountered in cheaper drills used for penetrating mild steel, they will not withstand the heat of drilling hard plate. Scratching the metal surface between the flutes and shank of the drill can easily make a determination that flutes are soldered or brazed. If gold in color, they are brazed; if silver, they are soldered. Once through the mild steel outer skin of the safe, a quite different type of bit is utilized, designed for high temperature and the stresses encountered when drilling hard plate.

5_9.2.2 Drills for Hard Plate

Drills for hard plate were first introduced at the end of the nineteenth century. They have always been designed to work when red-hot, often using carbide chips and cobalt for the drill point. Generally, these drills have a negative rake to avoid damage to the cutting edge. Regardless of the tip design, the drill must be harder than the material to be penetrated. In the alternative, the surface and structure of the hard plate must be altered.

Bits used for drilling barrier materials are specially made to allow for unknown and uncontrollable variances in the following parameters encountered during penetration:

- **Temperature;**
- **Required rotation speeds;**
- **Drill pressure;**
- **Stresses and shocks from the movement of bits;**
- **Changes in drilling angles;**
- **Density of the hard plate.**

The proper bit must be selected based upon the type of metal to be drilled. Depending upon the composition of the material, several bits may be required to drill through one hard plate, while the same job may be accomplished using only one bit on a different occasion.

The actual drilling process can be a great deal more complicated than encountered with mild steel. For example, **drilling and punching** may be required, rather than simply running the bit at high speeds with pressure applied. In hard plate, drills will stop penetrating as they become dull. Then it may be time to utilize a sharp punch in the partially drilled hole. Repeated blows to the punch are made in an attempt to fracture or dimple the material in order to give the flutes of the drill a place to bite. A sharpened piece of drill-rod, flame tempered until straw in color then immersed in oil, can be used for this purpose.

5_9.2.2.1 Chips

Very few chips are produced during the hard plate drilling process. Those that are ejected are extremely fine grained. Crime laboratory technicians should search very carefully for the metal powder produced by such drilling, and look for a match with clothing, hair, tools, skin, and any other materials with which a suspect may have come into contact.

5_9.3 Operating Conditions

Three essential actions must occur in the penetration of any metal when using a drill: **cutting by the flute edges**, **cutting action at the web**, and **extrusion by the web**. Each of these is in turn affected by **torque**, **thrust**, **feed**, and **drill diameter**.

5_9.3.1 Feed

Feed rate is dependent upon the size of the bit. Flutes can only transport a certain chip volume, which is closely related to the diameter of the drill. Thus, for standard drills, the formula **f=d/65** provides the standard, where **f** is the feed rate and **d** is the drill diameter. The result is expressed in terms of IPR. (inches-per- revolution). Recommended speeds for high-speed steel bits are increased by 50 percent from standard drill bits.

5_9.3.2 Speed and Feed

Drill speed and feed rate will vary, depending upon a number of factors. These include:

- **Chip volume;**
- **Material structure;**
- **Cutting fluid effectiveness;**
- **Depth of hole;**
- **Drill condition.**

Drilling speeds and pressure will change, depending upon the material. Slow speeds begin at about 500-2000 RPM, moderate speeds of about 1500 RPM, and high speeds greater than 5000 RPM. The pressure applied to the drill motor ultimately controls drill speeds. If high pressure is required, a **drill rig** is mandatory to provide stability of the bit.

5_9.3.3 Forces: Torque and Pressure

Drill forces determine how a hole is produced. Torque and thrust are dependent upon point angle, number of cutting edges, feed, drill sharpness, and cutting fluids. Drill speed, clearance, and small changes in flute shape will be of little importance. Application of incorrect pressure during drilling will result in broken bits, with the potential of sealing the hole. Bits generally fail when breaking-through the hard plate, so special care and expertise are required to gauge the progress and location of the drill within the material.

5_9.3.3.1 Pressure and Drilling Technique

There are two accepted techniques for penetrating tempered hard steel. The first involves running a drill at a slow speed with controlled pressure. The second requires high speed, between 4000-5000 RPM, coupled with high pressure.

Just how much pressure to apply during the drilling process is difficult to precisely state. Essentially, sufficient pressure is applied to begin cutting the outer surface of the hard plate. Listening to the drill motor offers an indication of progress. Obviously, the larger the drill, the more pressure that is required. Each material demands slightly different drilling technique. For example, when drilling aloxite (a soft aluminum-based material), low RPM and a great deal of pressure is required. If a diamond tip drill is used, low RPM with light pressure is employed.

It must always be remembered that making a hole through hard plate can be dangerous. A great deal of pressure must be applied during the drilling process. If a drill fails, pieces can fly outward, causing injury. In addition, if a drill rig breaks loose, the operator is at risk. If an amateur attempts to drill a safe without the proper tools or knowledge, he may be injured in the process. Evidence technicians should be vigilant for such signs.

5_9.3.4 Temperature

The creation of high temperatures during the drilling process is critical, especially with tungsten carbide tips. Annealing of the metal occurs around the hole and makes the steel softer and thus easier to cut. High-speed drilling requires heat; the process is called red-point drilling. The drill tip actually becomes cherry red in color and will work best in that condition. Once drilling begins, it cannot be stopped without the danger of heat-treating or work-hardening the metal, with the consequence of making subsequent penetration more difficult.

5_9.4 Drill Rigs

Hard plate cannot effectively be pierced with a handheld drill motor. Rather, drill rigs that attach to the front of the safe are required. Such apparatus allow constant pressure to be applied at a uniform angle. See the discussion in **Chapter 35.** There are three basic types of rigs: the **lever**, the **pressure bar**, and the **magnetic drill**. Each is designed to allow the controlled application of pressure in order to maximize drill motor control.

5_10.0 An Alternative Method of Cutting: The Thermic Lance

5_10.1 Introduction

Another form of cutting tool is available for the non-precise penetration of any metal. Information is provided about the thermic lance in this section and in **Chapter 35**. The burning bar or thermic lance presented a new and dangerous challenge to safe makers. Although these devices became popular in the 1960s, they were present in the U.S. in the 1930s, and the basic principle was known since the 1880s in England and Europe. The lance relies upon the principle that a metal, brought to a burn in an environment of pure oxygen under pressure, will generate a tremendously high temperature. As the material melts, the metal itself acts as a flux to speed up the intensity of the reaction and subsequent burning of the target metal.

The lance will virtually melt any material, including iron, steel, concrete, and granite. The high temperatures generated by these devices will destroy the molecular structure of any metal, including high-density barrier hard plate. The development of the thermic lance, as described in the Brower patent (**4182947(121)**, **4069407(122)**), provides a superior means of cutting metal and other materials. The system allows for a lightweight, readily adjustable, easy-to-handle tool. An arc can be developed in any non-explosive atmosphere, including water.

5_10.2 Development of the Lance

Developed for use in the shipyards and initially described as a burning bar, exothermic lance, or mini-lance, the first device was about ten feet long. It was actually a pipe filled with steel wool, aluminum, and magnesium wire or rods that were connected to a source of oxygen. An oxyacetylene torch was used for ignition. The original devices were large, awkward, and too dangerous to be considered as a reliable tool. Locksmiths began using the lance after the Second World War.

Today, the lance is handheld, compact, relatively safe, and can be transported in a briefcase. The active "pipe" is 18" long and ¼" in diameter. The lance operates on oxygen, and will cut through any barrier material in seconds. The early lances had three serious drawbacks:

- **Too dangerous to use because they were difficult to control;**

- **Destructive to anything lying near where they were operated;**
- **Could only be used outdoors due to the high temperatures, gasses, and smoke produced.**

Today, these arguments have been met and solved by technology and training. Safe technicians have come to realize that the lance, such as supplied by Broco, is a safe and effective tool. Proponents point out that a thermic lance may be the only method of entry into a particular safe. Further, a safe technician may use over one hundred dollars in drill bits to penetrate some doors, whereas the lance may do the same job in under a minute and costing only a few dollars.

5_10.3 Theory of the Thermic Lance

The active element of the lance is a consumable burning rod in the form of a hollow tube that forms the outer casing. Measuring approximately 18" to 36" in length, it is constructed of a relatively thin-walled, lightweight, electrically conductive steel. The tube is generally covered and protected with an insulating non-conducting material such as plastic, epoxy, vinyl, acrylic, or urethane. The purpose for the insulation is to prevent side arcing to the target material.

Within the burning hollow tube are many metallic rods or fibers. Some of these small-diameter rods will be made of steel or other ferrous materials, and some will be made of non-ferrous metals or alloys. Typically, steel and aluminum wires are placed in clusters, in a ratio of from 3:1 to 10:1, although it appears that the optimum ratio is 7:1. Metals other than aluminum may be selected, including magnesium, titanium, or their alloys.

5_10.4 The Broco System

The **Broco system** consists of few components, all of which can be carried within a briefcase. A pistol grip holder that receives a rod through its center allows for the transmission of oxygen from a connected hose and the conduction of an electric current for ignition. The holder is connected to an oxygen source through a standard regulator. A 12-volt battery and a striking plate are also required. A current is passed through the holder and rod tip and is used to generate a spark at the distal end of the rod to initiate burning.

In operation, oxygen is fed through a valve in the holder to the tip of the rod. Although other gasses will work, oxygen is most popular. Oxygen flow is directly related to cutting action and is controlled by the operator through both the internal valve and regulator attached to the oxygen source.

5_10.4.1 The Function of Oxygen

Oxygen performs two primary functions. It provides an oxidizing envelope at the tip of the rod, which aids in the complete combustion of materials and blows away slag created during burning. In addition, the oxygen initiates and maintains a continuous thermic process at the tip of the rod. The oxygen elevates the temperature to the white heat range and thus provides a gaseous cone for the ionized arc to form.

Low current is required to start the burn. A power source is not needed once ignition occurs, although if the current is maintained, the burning rate occurs fifteen to twenty percent faster. The arc, in conjunction with the oxygen, ignites the rod and creates a gaseous cone instantly. The melting of the binary metallic system of rods creates a eutectic.

Oxygen passing into this melt causes an exchange and reformation of Al_2O_3Fe- in the correct ratio. Continuous burning will occur so long as the oxygen flow is present. In actual operation, the end of the burning rod is moved to the target area, and melting, burning, or cutting begins. The rod is consumed at the point of burn to create a lava-like melt and subsequent flow of molten material.

Five cubic feet of oxygen is typically required to burn an 18" x 3/8" rod. The pressure is varied based upon the target material; the rate of oxygen flow is in part dependent upon whether the material is to be pierced, cut, or gouged. Typically, a forty-five second burn can be achieved using an 18" rod. Generally, 1” of rod will cut 1” of steel.

5_10.4.2 The Physics and Chemistry of Burning with a Lance

Burning in any form occurs when focused energy, in the form of heat, contacts a solid surface. The lance allows a concentration of energy in a small region of material at extremely high temperatures. This reaction produces such high temperatures that they cannot be removed at a fast enough rate through the ordinary

processes of heat transfer, such as conduction, convection, and radiation. This will result in the creation of a highly excited region, generally referred to as a **dense superheated plasmic cone**. The thermic lance creates a thermitic reaction cone at the point of burn.

Chemically, the classic thermitic reaction consists of eight moles of aluminum plus three moles of magnetic iron oxide. The reaction when completed produces four moles of aluminum oxide and nine moles of molten iron, as shown in the formula $8Al+3Fe3O_4$ --> $4Al_2O_3$ + 9Fe. The rod, when ignited using the aforementioned mixture, creates an enormous quantity of heat, approximately 758,000 calories per gram molecular weight. The target material is essentially vaporized, because the heat thus generated cannot be dissipated in any other manner.

5_10.4.3 Advantages Over Oxyacetylene

The system has many advantages over oxyacetylene. Most importantly, the thermic lance will cut virtually any material. A fine, precision cut is not possible but rather an irregular one is produced with localized high temperatures. The lance offers almost twice the temperature generation of oxyacetylene. No fumes, smoke, or poisonous gas is produced, unless the material being cut has been specially developed to emit such special gasses.

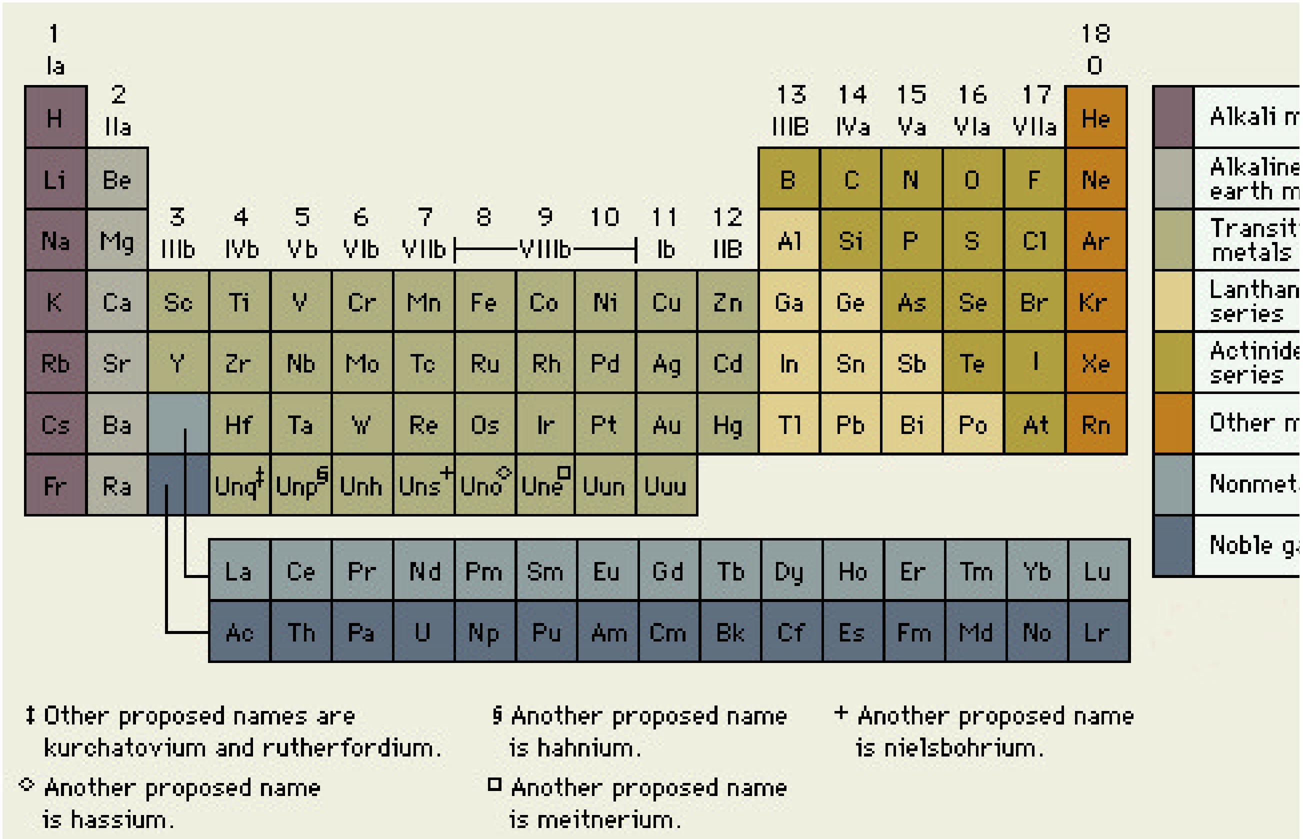


Figure LSS+501, Periodic table, courtesy Microsoft Encarta, 1998.

For complete data on any particular element, see **webelements.com.**

PART B: Systems

Key and Keying Systems

Chapters in Part B present detailed information regarding keys, and keying systems. The materials focus on issues specifically relating to standards, production, generation, and copying of keys, as well as the unique characteristics of keys for each primary type of lock. Specialized keying systems and high-security keys are presented in the next six chapters. The following topics are covered in detail elsewhere in this text:

- **How keys work in locks (Chapters 13-14-15-16)**
- **Producing keys for different kinds of locks (Chapters 13-14-15-16)**
- **Criminal investigations and evidence derived from**

keys (Chapters 24-25-26-27)
- **Decoding and producing keys from locks (Chapter 31)**
- **Evidentiary analyses of keys (Chapters 24-25-26-27)**
- **Impressioning locks to produce keys (Chapter 30)**
- **Investigation checklist regarding keys and crimes (Chapters 24-25-26-27)**
- **Non-metal, alternative forms of keys (Chapters 5)**
- **Picking with rocker and special keys (Chapters 29)**
- **Surreptitious entry utilizing keys (Chapters 24-25-26-27)**

For the criminal investigator or crime scene technician, important evidence about an offense may be revealed from keys left at the scene, found on suspects, or used in the commission of the crime. A locksmith may also be asked to testify as to his findings or conclusions when called to the scene of a burglary to open, repair, or replace broken locks or safes. It is thus equally important that the locksmith and investigator be attentive to detail, making detailed notes as to observations.

A great deal of information can be **derived from keys.** For example, the manufacturer, type of mechanism, and its possible physical location may be determined. Whether it is likely that the key fits a public locker, safe-deposit box, residence, hotel room, post office box, vending machine, or other area may in some cases also be learned.

Motor vehicles can, in some instances, be traced and identified by their keys, either through the number stamped on the key, by decoding, or by actually fitting it to a specific lock. Even the make and model of a vehicle can be ascertained in certain cases. For example, the General Motors VATS anti-theft system was initially utilized on the Corvette and Cadillac. Vats keys are easy to identify and decode.

Master keys are often stamped with "Master," "M," "GM," or some other similar designation and often can be identified from the pattern of depths. Post office keys can be readily identified, and their mere possession may lead to other fruitful areas of inquiry. In certain cases, a question should arise as to why a certain person, suspect or victim has a particular type of key in his or her possession. A juvenile, for example, may be found with several tubular keys, primarily used for vending machines and alarm locks.

Unauthorized keys may have been obtained from such areas as schools, hospitals, dormitories, and other large complexes. Possession may be linked to recent or continuing losses, the compromise of information, shrinkage of inventories, and so on. Again, their possession should be carefully questioned. A detailed investigative checklist is presented in Chapters 24-27, providing a comprehensive analysis for the investigation of crimes involving the possible use or compromise of keys.

CHAPTER SIX: KEYS

The Development of Keys

Master Exhibit Summary

6_1.0 History of Keys

This chapter shall begin with a simple, yet fundamental question: What is a key? The answer is equally simple: any object or device that allows the mechanism of a lock to be actuated to the locked or unlocked position. Keys have taken many forms throughout the past four thousand years, from Chinese finger rings, to early pin tumbler wooden keys, to modern metal keys incorporating sophisticated integrated circuits. They all,

however, perform essentially the same function: to open locks. Keys have come to symbolize responsibility and authority; most inhabitants of civilized societies carry them.

Although the ancient Greeks contributed to lock development, the Egyptians are credited with conceiving the first significant locking principle. It will be recalled from **Chapter 1** that the Greeks developed a form of key to move a crossbar mounted across the inside surface of a door. It replaced earlier, intricate rope locks. This "key" was extremely primitive and consisted of a large semi-circular blade measuring more than one foot in length. It had a long handle, often inlaid with semiprecious metals, and was tapered to a blunt point. The size of a farmer's sickle, the hook-shaped key was inserted through the hole in the door.

The Egyptian mechanism, in use some four thousand years ago, appears to be the first true mechanical locking device as we understand the concept today. This lock was made entirely of wood and the bolt was hollowed out to allow insertion of a key. There were metal pins on the end of the key that would mate with and raise wooden tumblers within the lock. When the tumblers were raised to clear and slide the bolt, the lock could be opened. Although this object, which resembled a toothbrush was the first real key, it had little similarity with anything we know today. Keys for the Egyptian locks were large, cumbersome, and heavy, mirroring the design of those first devices.

The Romans merged Greek and Egyptian designs producing door locks that used small keys. Although the Romans utilized the pin tumbler principle, they are credited with the introduction of wards. Until the use of metals during the Roman period, keys were only made of hardwood and measured up to three feet in length. They generally offered little resistance to duplication.

Roman artisans were already used to working with metals and began producing keys and locks in iron and bronze. These craftsmen recognized that the smaller the keyhole, the less likelihood that the lock could be picked. As the warded lock developed, the shape and design of the keys became extremely complex and intricate, with many angles, often creating a maze-like pattern. Even with the small, complex key designs, blacksmiths realized that only a few different "tryout keys" were required to open all of the warded locks.

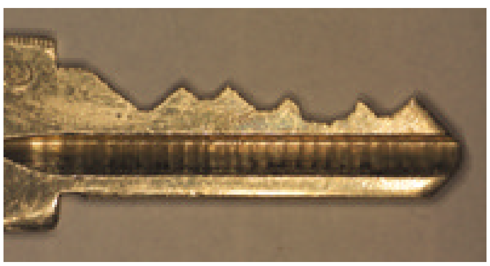
Although warded keys became works of art, the problem of skeleton keys remained. This shortcoming would not be solved until the

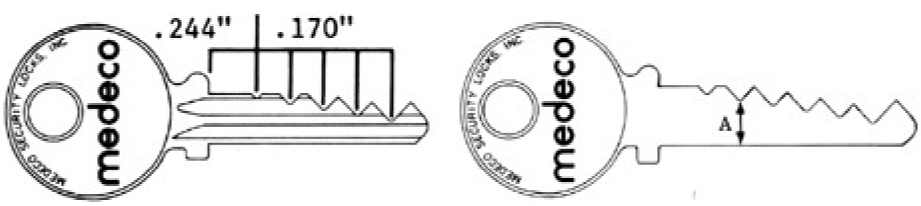
introduction of the lever lock during the Renaissance, when keys began to resemble those in use today. During the nineteenth century, the lever became the most popular locking mechanism in England and the continent. These required small keys and offered a high degree of security. While the lever lock is still extremely popular in Europe, the pin tumbler became the lock of choice in the United States in the latter part of the same century and continues so to this day.

6_2.0 Terminology and Basic Definitions

The following terminology and definitions are common to all forms of locks and keys. Definitions relating to specific types of locks will be found in subsequent chapters.

Back Cut Key: A key having one or more angles cut so as to cause the tumblers to seat in the valley or root and prevent removal of the key from the lock. Too steep an angle will cause back cutting. Generally, a combined angle of 90°-120° is required to prevent back cutting.





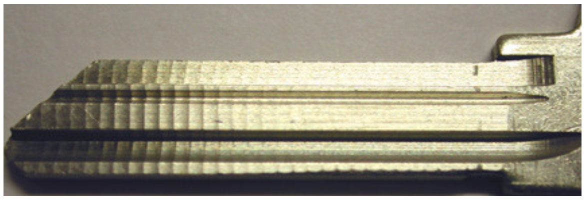


Figure LSS+601, a back cut key. Note the angle of cut of the fourth tumbler position from the shoulder

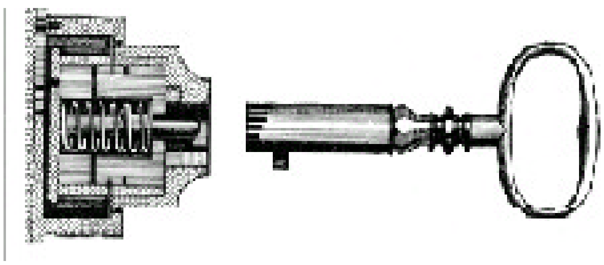
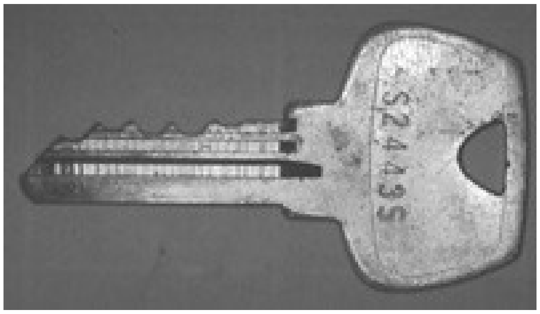


Bitting or Bit: That part of the key that enters the lock and meets the wards, levers, discs, or tumblers.

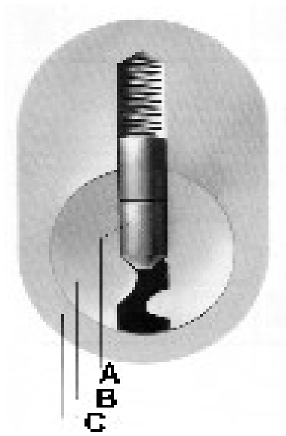
Blank Key: A key corresponding to the correct keyway that may be cut to any pattern of depths.



Bramah Key: This term refers to a tubular key design, introduced and patented in England during the latter part of the eighteenth century. The Bramah lock remained incapable of picking for almost fifty years until 1851. The unique design of the key that fit the Bramah lock in some respects resembled the modern axial pin tumbler key that was introduced by Chicago Lock and other American companies.

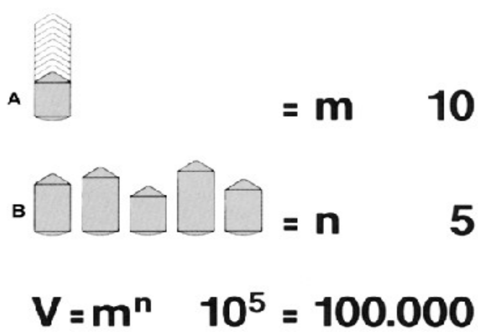
Change or Guest Key: The change or guest key refers to one that is coded to open only one lock, in contrast to a master key, which is coded to open a number of locks within a locking system. It provides the lowest individual level of keying. The term "change key" is also used in conjunction with "combination locks." See **Chapter 34**.

Codes of Keys: All manufacturers of locks will define precise measurements for each different depth and spacing assignment for each kind of lock and keyway they produce. The unique combination of depths for each individual lock will thus have a code number that will correspond to the exact design of the key. Keys may then be produced solely from these codes. The photograph shows a factory original Sargent code cut key. The code, 24435 is read from shoulder to tip, and directly correlates to the key cuts.



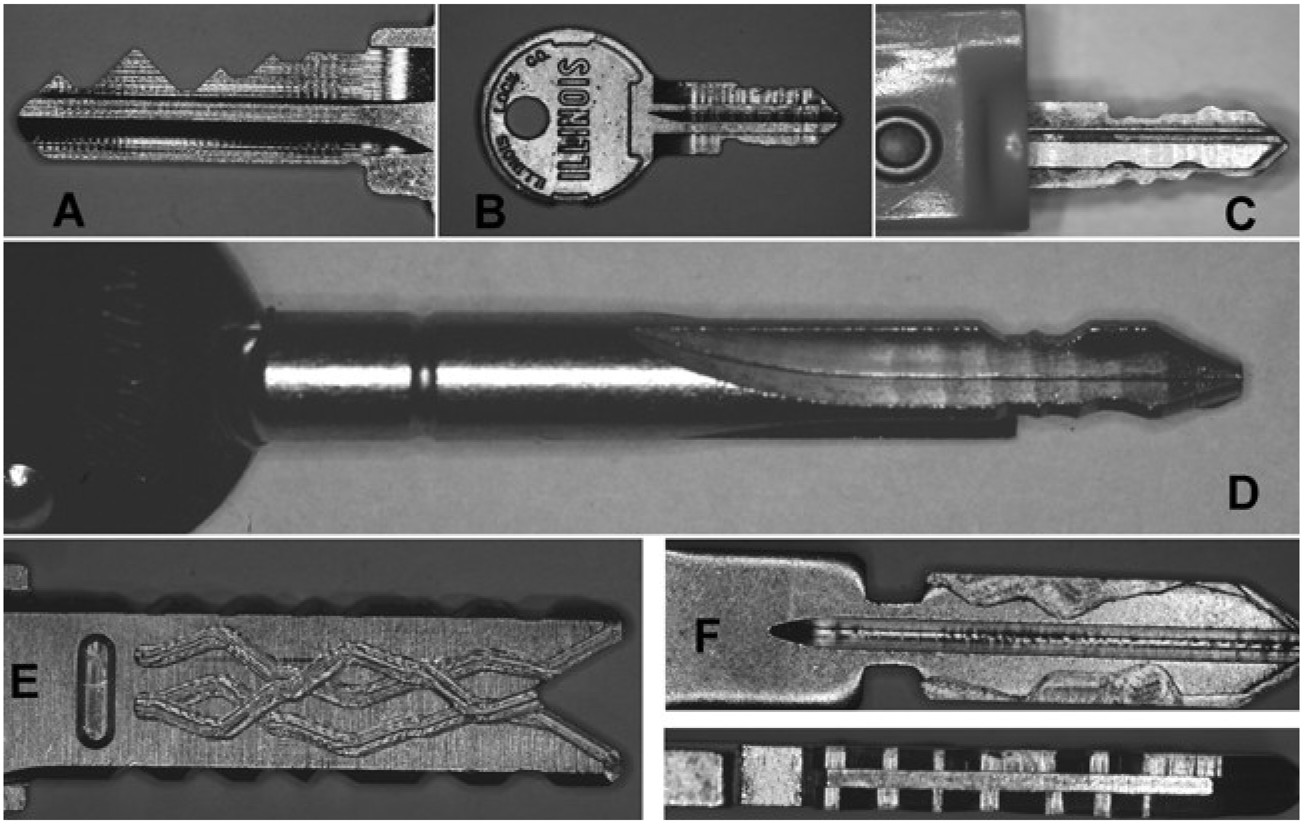
Corrugated Keys: These keys have longitudinal grooves running the length of the bitting surface. They are used for warded padlocks and certain specialized wafer locks, such as produced by Schlage and Winfield.

Cylinder Key: This term generally refers to a key for a pin tumbler, mortise cylinder lock.



Depth Gauge: A depth gauge is a device that allows the decoding of the various depth cuts of a key. A key micrometer or specially designed gauge may be utilized for these measurements. HPC manufactures both instruments. The HKD-75 will decode all popular blanks. A key is inserted and read by a **floating stylus**, which is linked to a **pointer** that moves across the correct datacard.

Depth Keys: A depth key provides precise bitting information for a particular keyway and series of lock. Keys can be decoded and replicated using depth keys, for they will provide exact depth and spacing data.



Detainers: The term will be utilized throughout this text when referring to pin tumblers, discs, wafers, levers, wards, or other components which inhibit movement of the plug, cam, or other moveable locking device within the locking mechanism. It may be recalled that the term "detainer" was originally used in **Chapter One** in describing the development of locking principles. All modern mechanisms operate on the theory of two or more detainers that must be raised to a precise point (shear line) in order to allow the lock to open. In the photograph, the pin tumblers represented by "A" are split, comprising an upper pin (driver) and lower pin. This illustrates the double detainer theory of locking; the pins must be raised to the proper height so that the split is positioned precisely at shear line. If the pins are above or below this division, the plug is blocked from rotation and the lock cannot open.

Differs and Differing: The English term "differing" refers to the number of different possible realistic or effective combinations and numbers of change keys which are possible for a given lock. Differs are calculated by taking into account the number of wards, levers, pins, or discs, as well as the design of the keyway and tolerances of the locking components. In the illustration, "A" signifies the number of depths available for each tumbler, and "B" equals the number of individual pins.

Double-Bitted Key: A key that is cut on two sides or surfaces. They are most often found in wafer locks.

Flat Key: A key made from sheet metal, produced without grooves, generally used in warded or lever locks.

Key: A device or object which is inserted into a particular lock or group of locks, causing the internal mechanism to align in a predetermined order, to allow actuation of a locking or unlocking mechanism.

Key Changes: See Key Differs. The term describes the number of effective changes possible for a particular lock.

Key Control: Manufacturer key control describes the keys that can or will work in one lock or a group of locks. It encompasses (1) the number of differs or change keys effectively available, (2)

the maximum possible number of changes, mathematically, (3) keying alike all locks, and (4) master keying or complex keying locks. Security key control relates to policies and procedures designed to inventory and restrict keys and access to locks by unauthorized persons.

Key Cuts: Any cuts made on the bitting of the key.

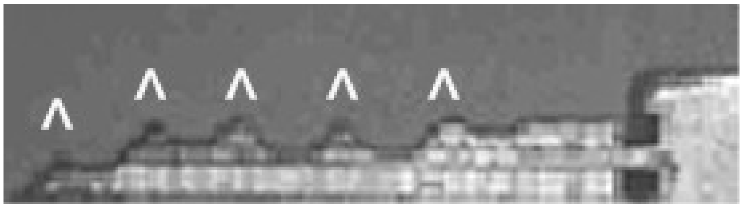
Sidewinder or Laser Key: A form of key having depth cuts on three or four surfaces. Mercedes (right photograph), Volvo (left photograph), and BMW automobile locks utilize these keys. The term "laser key" came into use because locksmiths believed that the bitting design was produced by a laser cutting system.

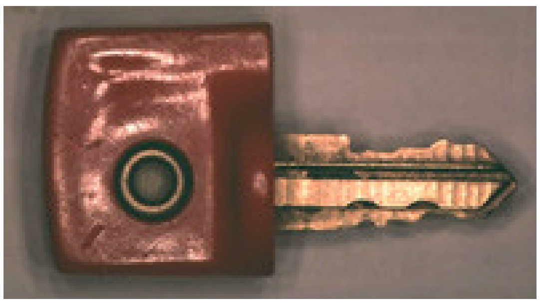
Figure LSS+602 lasertrack keys utilized in Volvo (left) and Mercedes (right). Wafer sliders move along the contour of the surface.

Single-Bitted Key: A single-bitted key has cuts on one side or surface. Most keys are single of this design.

Skeleton Keys: Skeleton keys are used to open warded locks. They can be identified by the removal of a large portion of the bitting. In effect, the keys are made to bypass all of the fixed wards.

Steeple: This describes the convergence of the peaks of the angled cuts between valleys of the bitting. Generally, the steeple at the tip of the V cut is pointed. In the photograph, the bitting is shown, with indicators above each steeple.





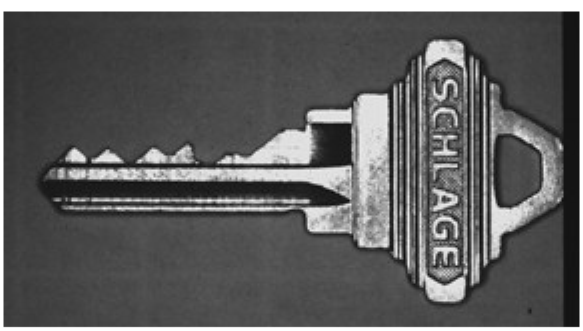


Figure LSS+603, bitting of key showing steeples.

Triple-Bitted Key: A conventional key that is cut on three sides or surfaces.

Tryout Keys: Multiple sets of keys have been designed with special depth and spacing patterns. When manipulated correctly within a lock, they may align the tumblers to shear line and simulate the correct bitting. Based upon tolerances, just a few tryout keys can open many locks.

Valley of Root of Key: The portion of the bitting which forms the bottom of each cut is referred to as the valley or root.

6_3.0 Basic Classification of Keys

6_3.1 Introduction

Although no worldwide standard system has been established, keys

can in fact be identified as belonging to certain primary groups based upon recognized parameters. A basic classification of keys is thus possible based upon: materials, mechanism or function, bitting, and keyway. A fifth parameter, size, may also be utilized, although the size of a key will not in and of itself provide absolute information as to what type of mechanism the key operates.

6_3.2 Materials

Six basic materials are utilized in the production of keys, primarily dependent upon the type of lock, manufacturing process, cost, and function. Keys are generally made in brass, steel, iron, nickel silver, aluminum or aluminum alloy, and zamak. Plastic and other polymers are also being utilized to a limited extent. A more thorough discussion of material content is provided in **Chapter 5**.

6_3.3 Bitting

Above the keyway, or as an integrated part of it, is that section of the key that encounters and acts upon the detainers in the lock. A properly designed key will allow enough bitting surface to provide for a sufficient number of different tumbler depths. This will allow for many differs. The bitting of a key refers to cuts, depressions, holes, indentations, build-up, or removal of material, affecting one or more surfaces of the key, to mate with discs, tumblers, pins, wafers, levers, wards, or other detaining devices. Keys may have bitting on one, two, three, or four sides or surfaces as shown.

6_3.3.1 Surface Cuts and Active Components

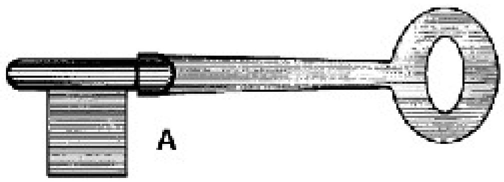
Many keys will have bitting on more than one surface, but not all surfaces are actually active. Thus, for many automotive and dimple locks, while the key is cut on two sides, there is only one actual set of tumblers within the lock. This design will allow the key to be inserted into the lock with either vertical orientation for the convenience of the user. Keys for many dimple locks will be cut on four or six surfaces, but the lock will only have two or three actual sets of tumblers for the same reason.

6_3.4 Keyways

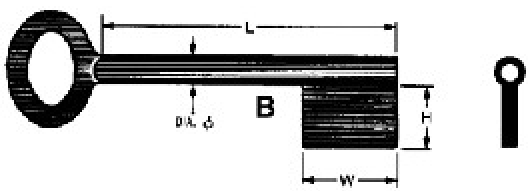
Keys may be classified by the keyways they fit. Keyways may range from flat (no wards) to extremely complex. Major key catalogs, produced by Silca, Ilco, and other manufacturers always include keyway profiles for every blank. There are a number of design parameters involving keyways that are detailed below.

6_3.4.1 Mechanisms or Function

Keys are classified based upon the type of lock they are designed for or their function, in the case of specialty keys. Within this sub-grouping are the following categories:

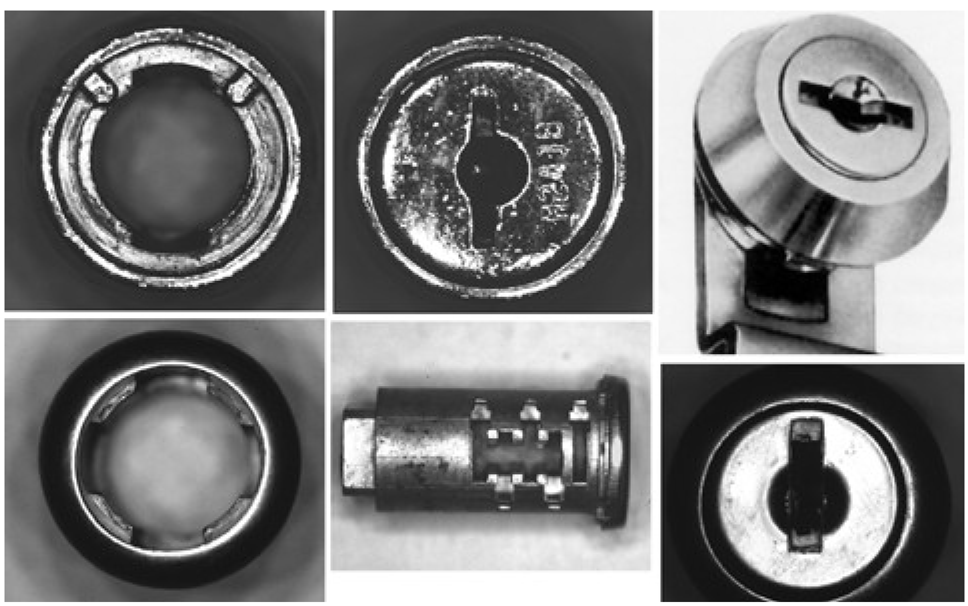


6_3.4.1.1 Axial (tubular)



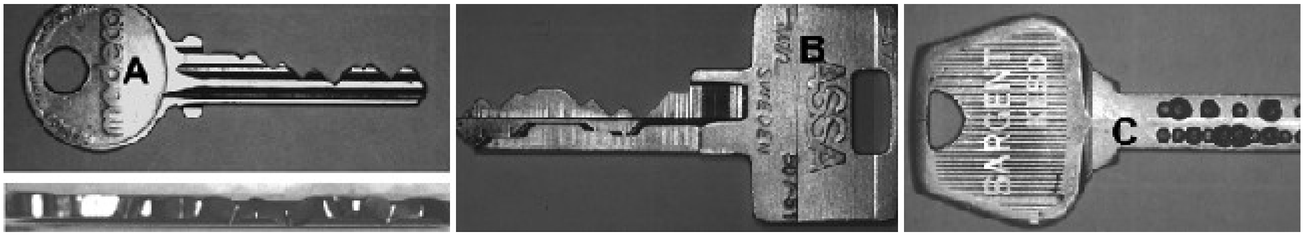
Tubular keys are primarily used in cam locks for vending applications. They were made popular by **Chicago Lock Company** and their Ace design.

6_3.4.1.2 Bit and Barrel Keys



These keys are used with warded locks. They are essentially identical, except that a barrel key will have a hollow shank, and often do not have shoulders.

6_3.4.1.3 Cam Lock



Cam locks are used in a variety of applications, primarily in vending, utility, control, and furniture. Wafer and tubular cam locks are the most popular configurations.

6_3.4.1.4 Cylinder, Special, and High-Security

This category encompasses pin tumbler locks, modifications in pin tumbler design such as sidebar and high-security cylinders, like ASSA, Medeco, Ikon, Sargent Keso, and DOM, and other unique keys. Included within this category will be sidebar rotating tumbler (Medeco), dual-sidebar (Schlage Primus, ASSA, Ikon), and dimple

keys (Mul-T-Lock, Sargent Keso, KABA, and DOM).

6_3.4.1.5 Flat Steel Keys

Flat steel keys are utilized in many applications, including safe-deposit, warded padlock, luggage, electric control, lighting control, cash box, and other low-security, low-cost applications.

6_3.4.1.6 Safe-Deposit

Safe-deposit lever locks use flat steel keys. They are generally made of brass, nickel silver, or zamak.

6_3.4.1.7 Specialty

Within this grouping can be found certain high-security designs, especially European, as well as stamped keys for locks offering little to no security. Keys may be grouped in this category as well as cylinder, special, and high-security.

6_3.4.1.8 Vehicle

There are many different kinds of locks utilized in motor vehicles throughout the world. The original Briggs and Stratton sidebar design is perhaps the most popular. It was introduced in the United States in 1935 and is still used today. All General Motors products that utilize this sidebar design have a key that resembles a wafer lock. There are, however, many different kinds of keys for motor vehicles.

Within the past twenty years, many different locks have been introduced for cars to provide a greater measure of security against picking and decoding. Perhaps most popular is the sidewinder key, utilized in Mercedes, Volvo, Honda, Lexus, and BMW cars. This lock, until 1991, was thought to be virtually impervious to picking and **decoding**.

6_4.0 Key and Keyway Patterns

Along with the basic classification parameters defined above, there are a number of other considerations involved in the design of keys, keyways, and locks.

6_4.1 Physical Dimensions

Several factors contribute to the well-designed and practical key. Each can affect security and can be altered or controlled by the manufacturer, including:

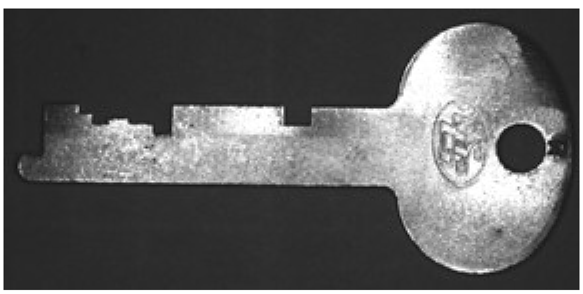
- **Length;**
- **Width;**
- **Height;**
- **Thickness;**
- **Number and shape of grooves forming the keyway;**
- **Width and depth of the bitting;**
- **Production materials utilized;**
- **Keyway design;**
- **Detainer mechanism.**

6_4.2 Design Parameters and Rules

In order for keys to operate properly in any given lock, certain design rules must be observed. These rules will affect:

- **How many tumblers, wafers, discs, levers, wards, or other detainers are incorporated within the lock.**

The length of the key, from the shoulder to the tip, will determine the number of possible detainers that may be spaced evenly across the various surfaces of the key.



- **Where the detainers seat or are positioned on the bitting of the key. Depending upon the type of detaining mechanism, the cut key will appear differently with respect to spacing, depth of cuts, and the angles associated with each depth-cut.**

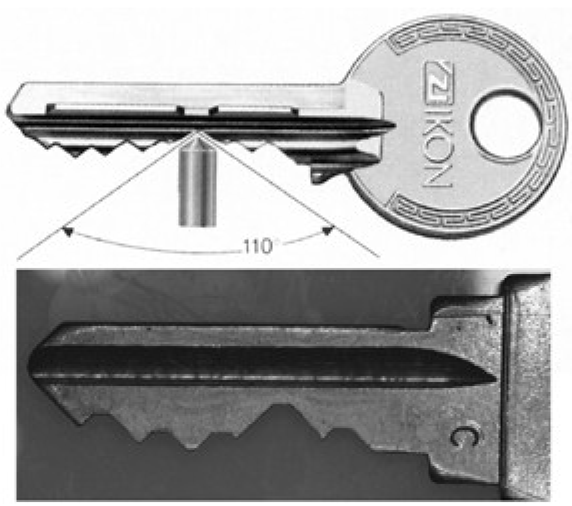
- **The number of available depths for the detainers. The number of different tumbler depths available in**

any lock is first a function of the dimensions of the active portion of the keyway, which allows differences in the bitting levels of the key. The actual number of depths will control how many different keys can be produced for a given keyway. This parameter is called differs.

- **Design of each depth-cut. The design of each individual depth-cut is controlled by three parameters: the angles on each side of the cut, the depth of the cut, and the width of the cut at the root. Standard terminology for these parameters has been developed within the industry.**

A V cut refers to the overall dimensions and design of each depth-cut. There is no standard actually established, although in practice, a 90°-120° composite cut angle for pin tumbler and wafer locks is established. This means that the composite angles of the V cut must be between 90°-120°. This will insure proper operation and prevent back cutting. The root or valley of the cut refers to the bottom of the cut where the tumbler, disc, wafer, or other detainer makes contact. The root may be a sharp V, a flat, or a radius.

6_4.3 Differs

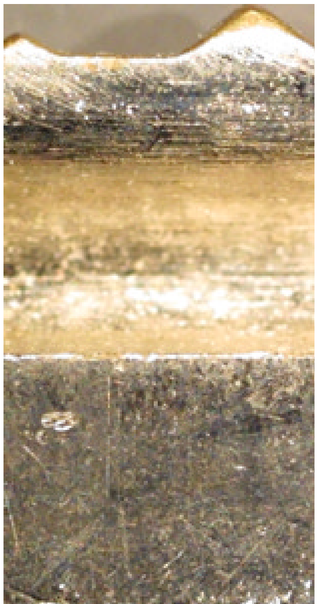


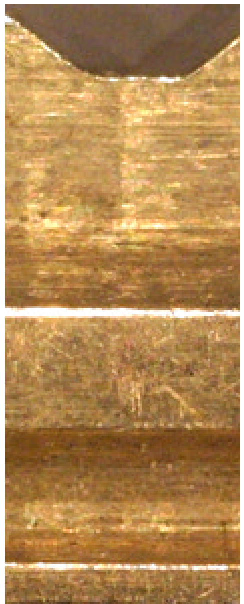
The number of **differs** is mathematically based although not absolute. Minute changes and tolerances are not relevant in determining the number of possible combinations; many factors are taken into account in determining the actual number of differs. Claims by manufacturers should be examined critically, especially with respect to a high number of possible combinations for a given lock.

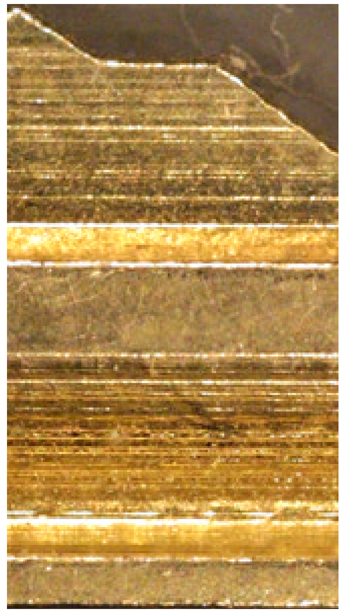
Often, there are realistic mechanical restrictions as to how a key can actually be cut, which will in turn control the maximum

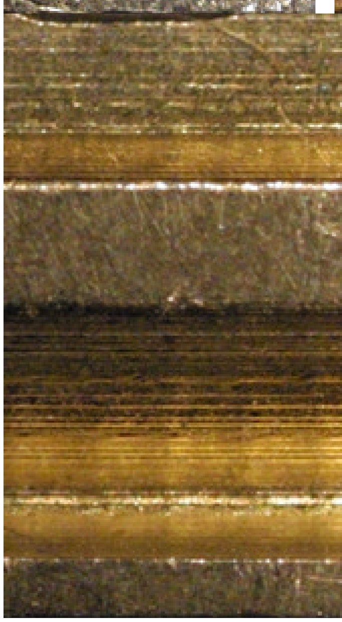
number of different keys that can be made to fit a given keyway and lock. The number of combinations may be increased by complex lock design, utilizing, for example, **magnetic** and mechanical locking action or standard pin tumblers combined with sidebar action. **Master keying** will reduce the number of possible combinations or differs in most locks, unless specially designed with **master rings**, sidebar action, or other schemes.

6_4.4 Keyway and Depth-Cut Design

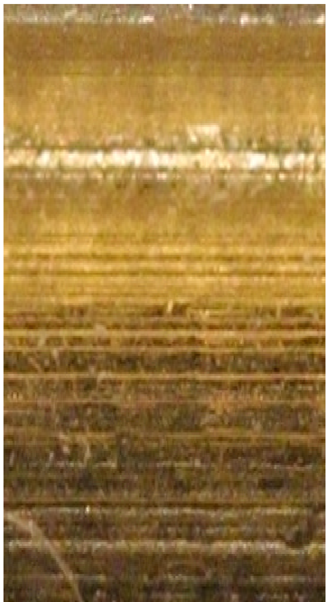


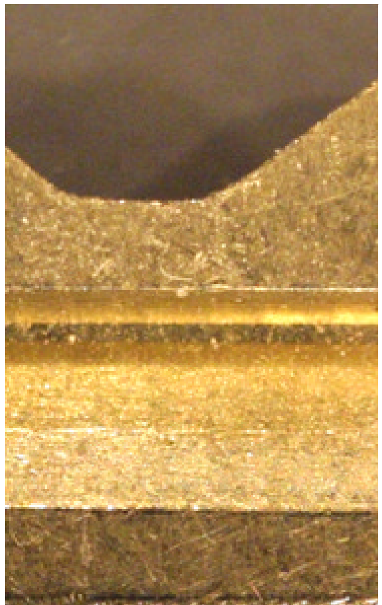




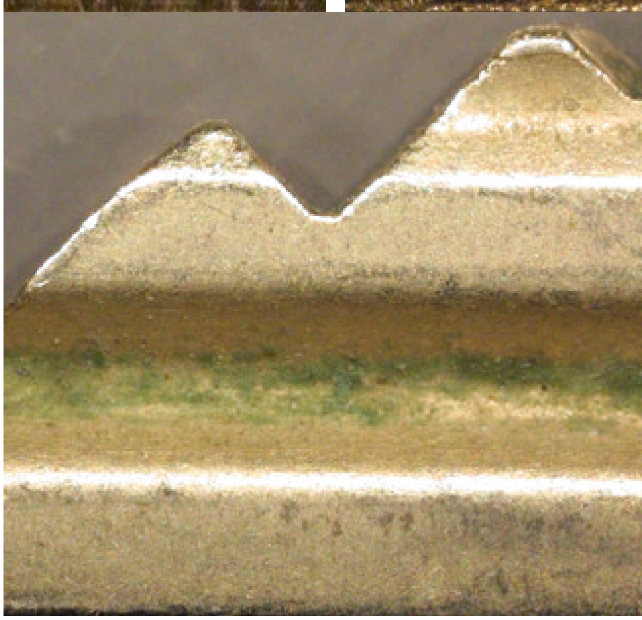


A keyway constitutes the opening into the lock through which the key enters. By varying the keyway, the manufacturer can control which blanks will operate the lock to the exclusion of all others. This illustration shows the interaction between the bitting angles for each cut, and the tumblers. The properly designed key must provide for each tumbler to properly seat at the root of each cut. The ramp angles that form each cut must allow for a smooth entry and exit of the key. Too sharp an angle will present an obstacle to the tumblers, or will prevent removal of the key.

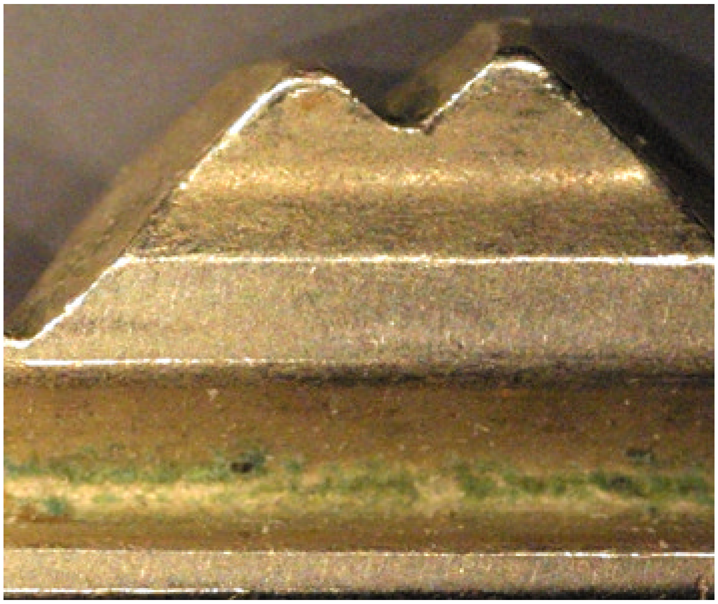




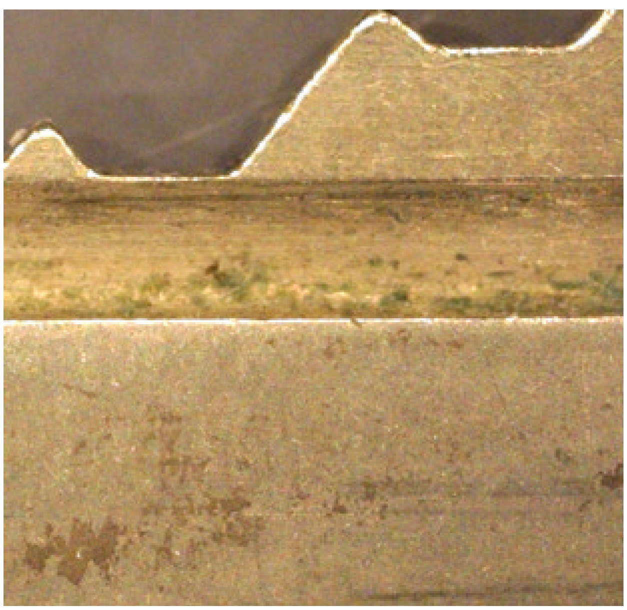
Keyways have many different patterns of wards, which are in fact projections from either side of the opening. Their purpose is to block entrance into the lock except by the key blank having the corresponding ward pattern. Thus, for every projection of a ward within the plug, there must be a corresponding depression or absence of material upon the key.

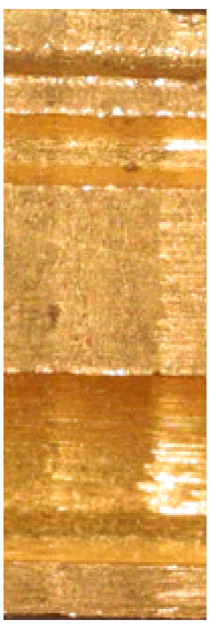


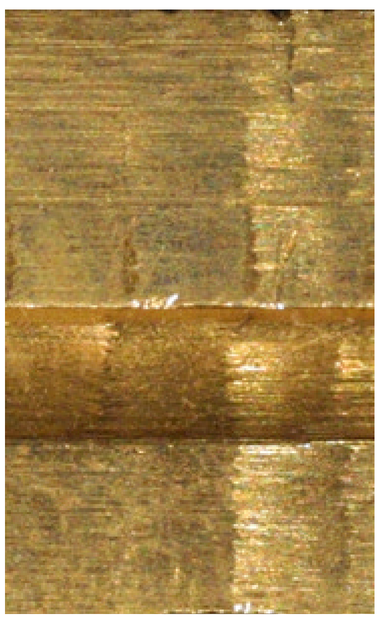
Wards may have many different shapes. Thus, they may be square, round, angled, flat, wedge-shaped, or other similar design.

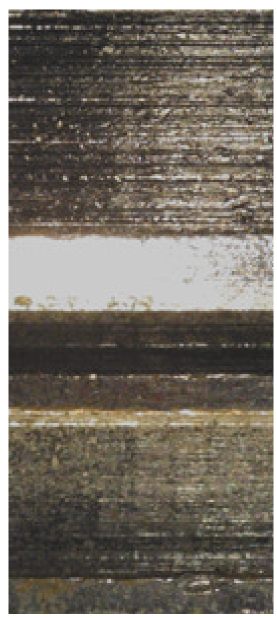


There are in fact five primary keyway design variations: left angle, right angle, square, V, and round. Varying angles are utilized in forming these shapes, and thus, an infinite number of groove patterns can be generated. In the photographs below, several different ward patterns are shown.









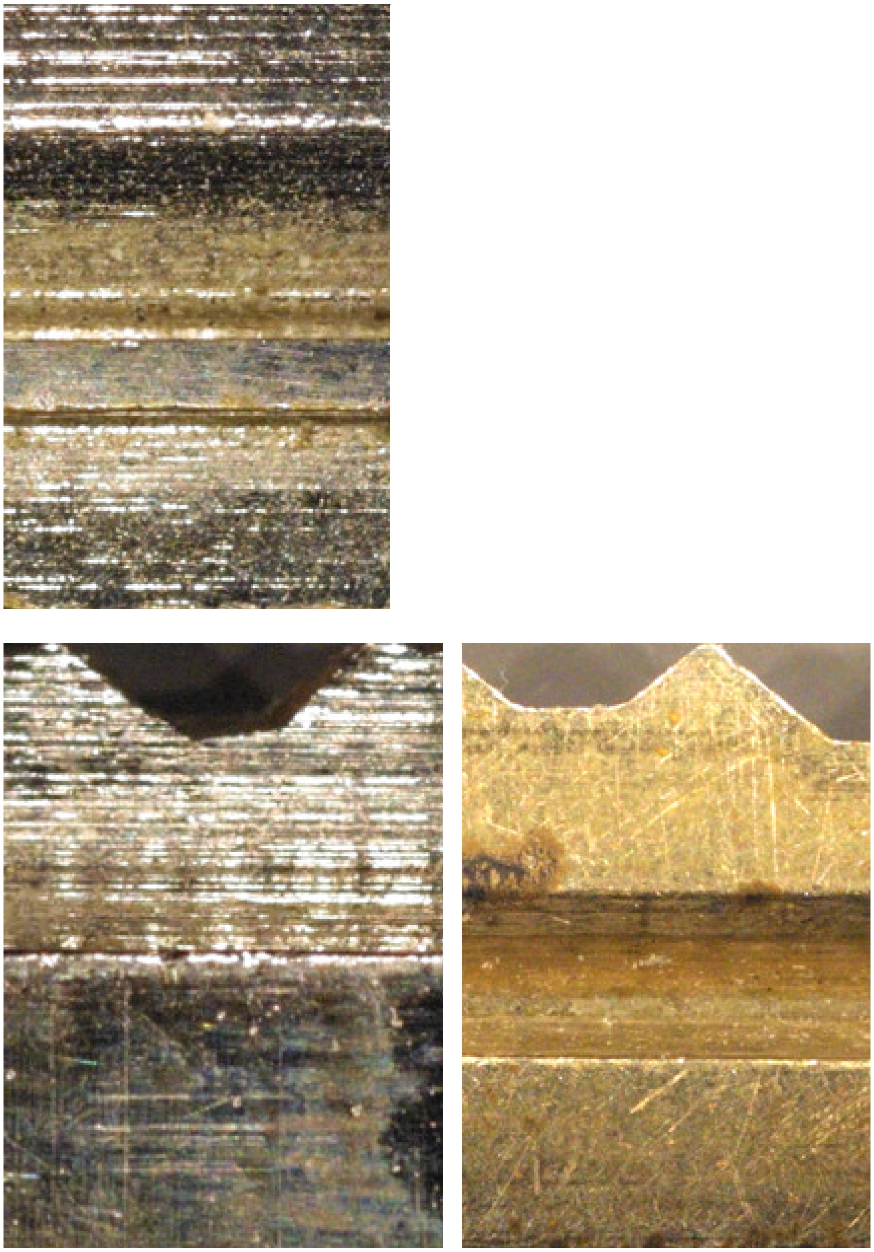


Figure LSS+604 Keyway ward sections take many shapes and forms.

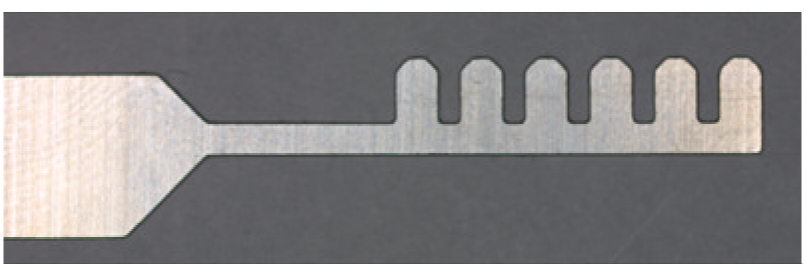
When producing a new lock, the manufacturer will first determine the design of the keyway. Functionally, the keyway will reject all but the correct key from entering the plug. Different keyways provide the primary means to allow the production and use of billions of locks throughout the world. Without keyways, there would be no security against keys for one lock opening many others.



Each manufacturer will develop different keyways from that of its competitor. In this way, a manufacturer can be assured that a customer will purchase only his locks for a specific keying system. Otherwise, there would be no master keying options, because different blanks would be required for different locks within one system. Although many keyways may appear identical, there are always slight differences between vendors. Keyways form the basis of key control and are essential in complex master key systems.

6_4.4.1 Restricted Keyways

A manufacturer may also designate certain keyways as restricted. Generally, key blanks for restricted keyways may not be obtained by the public. They may be available only on a direct basis from the manufacturer or from licensed locksmiths. In certain cases, restricted keyways are designed for a specific customer and will not be used in locks that are sold to any other location. The post office and other government agencies have restricted keyways from Yale and other manufacturers, which will never be used by anyone else.

6_4.4.2 Anti-Picking Keyways

Paracentric keyways are designed to frustrate lock-picking, because they have wards that extend over the imaginary vertical centerline. The design of the keyway can prevent the pick from easily moving within the plug. Paracentric keyways will also prevent a picking technique called wedging, using a comb pick. There are some very complex paracentric keyways in high-security locks, which make picking almost impossible. One covert entry specialist utilizes a very fine saw to cut away difficult wards within the keyway, prior to picking. Although it may be effective, this procedure is not recommended.

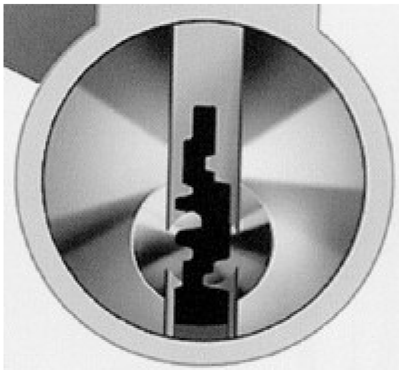


Figure LSS+605, a John Falle Comb pick. Paracentric keyway.

Figure LSS+606

Note how the wards cross the centerline to frustrate picking.

6_4.4.3 Keyways and Complex Keying Systems

Manufacturers will define a certain keyway group for large and complex master key systems. Thus, a keyway configuration may allow for a grand master keyway, with several sectional and individual keyways. In these types of systems, blanks for the higher keying level will always work in the sublevels. Thus, a grand master key will fit the keyway of every lock in the system. A **sectional** master will fit locks within that section but not other locks. Greater security is obtained in this type of a system.

6_4.4.3.1 Schlage Everest

The Schlage Everest cylinder employs a patented design that provides for an under hang in the keyway that interacts with a corresponding channel that runs the length of the key. As shown in the photograph, the raised portion near the tip of the key controls a spring biased check-pin in the plug. Unless the pin is raised by the channel, it will prevent rotation, even with the correct bitting values. The author does not consider this cylinder to be suitable for high security installations, but rather of another level of access control or equivalent form of restricted keyway. The locks are not difficult to pick with the correct tool, manufactured by Peterson. Although the key design is patented, it can be replicated to bypass the check-pin using the Easy entrie profile milling machine, or by simply producing a blank that bypasses the undercut portion of the keyway, in combination with the Peterson ET-1 tool, or even a spring steel

tyne. See the discussion relating to master key security in **chapter 31.** Picking technique using the Peterson tools are discussed in **chapter 29.**

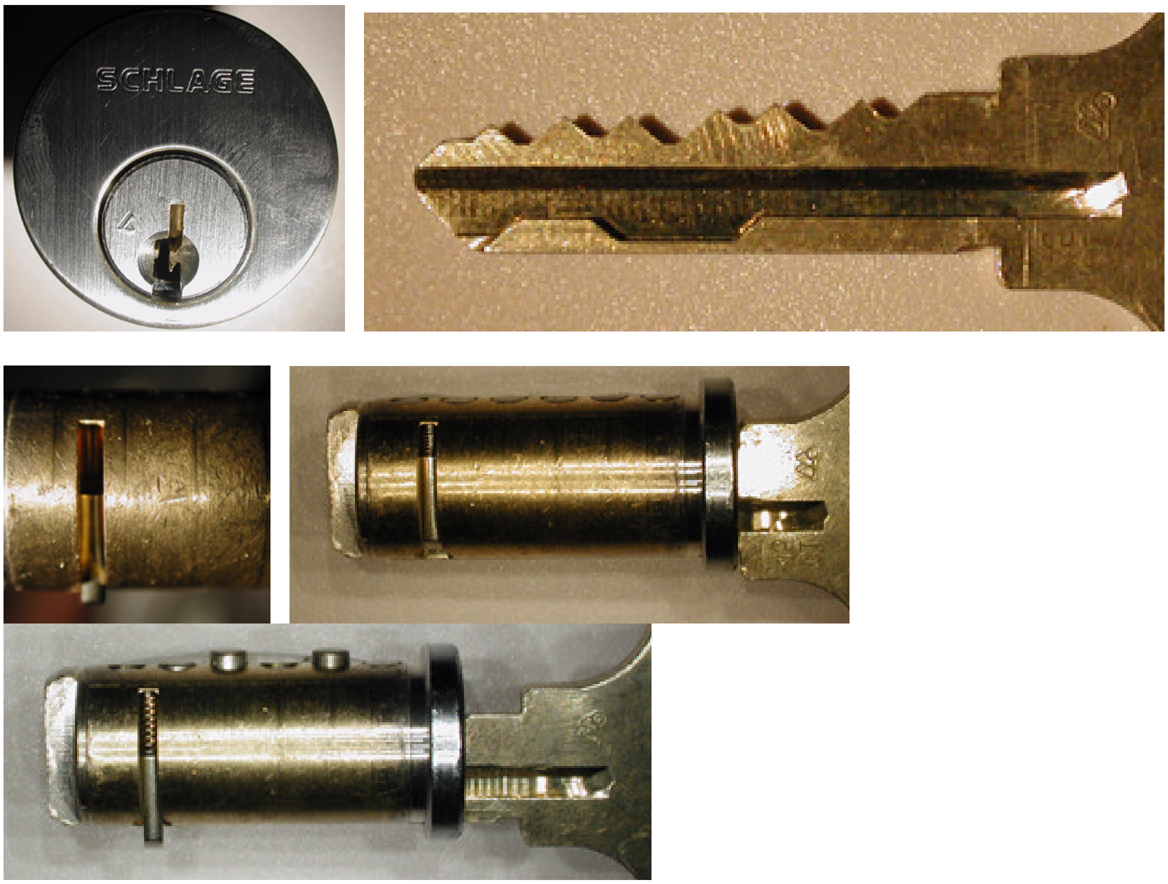

Figure LSS+610 Schlage Everest utilizes a unique keyway design that incorporates a check-pin that must be lifted by the corresponding channel on the side of the key. In the photograph of the plug and keyway, note the undercut on the right side of the keyway that prevents a key that does not have the corresponding channel. The check-pin is shown in a locked and unlocked state. Schlage supplies the blanks for this cylinder, and thus can control duplication of keys. It is a relatively simple matter to bypass this function.

6_4.5 Identification of Keys and Blanks

The procedure for the identification of a key will generally require:

- **Basic classification of the type of lock or general purpose of the key blank, from the shape, size,**

appearance, and metal;

- **Identification of the manufacturer from the keyhead shape, name, or identifying number or symbol;**
- **Identification of the specific keyway.**

To complete identification and matching with a known key blank sample, the length, width, thickness, and keyway should be compared on a side-by-side inspection. To compare keyways, examine the known and suspect key at the tips. A method for the computerized identification of keys was patented by Yanovsky in 2001 (**6175638(123)**). This shadow acquisition device allows the accurate analysis and storage of information regarding key blanks. A more complex and sophisticated system has been developed by Silca and is fully described in this text.

Figure LSS+607, examples of markings on a Sargent KESO key, and a Sargent LA sectional keyway series. Noted on the KESO there is an indirect code number and master key system number. On the Sargent LA keyway, the direct code 334874 appears. The key can be duplicated from this number.

The grooves of the suspect key must correspond perfectly with those of the known key. Be certain to physically compare all surfaces for a match. Some blanks are so similar that the shapes of the grooves on all sides must be carefully examined.

It may be important to learn what type of lock a specific cut key

will operate. The following indications may be helpful:

- **Length and height of the key;**
- **Number of tumbler cuts;**
- **Type of tumbler cuts (round, square);**
- **Shape of the cuts.**

Information can be derived from a key blank reference source, including:

- **The manufacturer;**
- **Code numbers;**
- **Coding system;**
- **Cross-references to the same blank produced by another vendor;**
- **Coding system used for a particular lock.**

A good key blank catalog, produced by ILCO or Silca, is a requirement for identification. These listings will contain 1:1 photographs of virtually every key blank and a keyway profile. The catalog will also contain cross-references to other vendors, allowing the identification of keys, regardless of the brand name that appears on the blank.

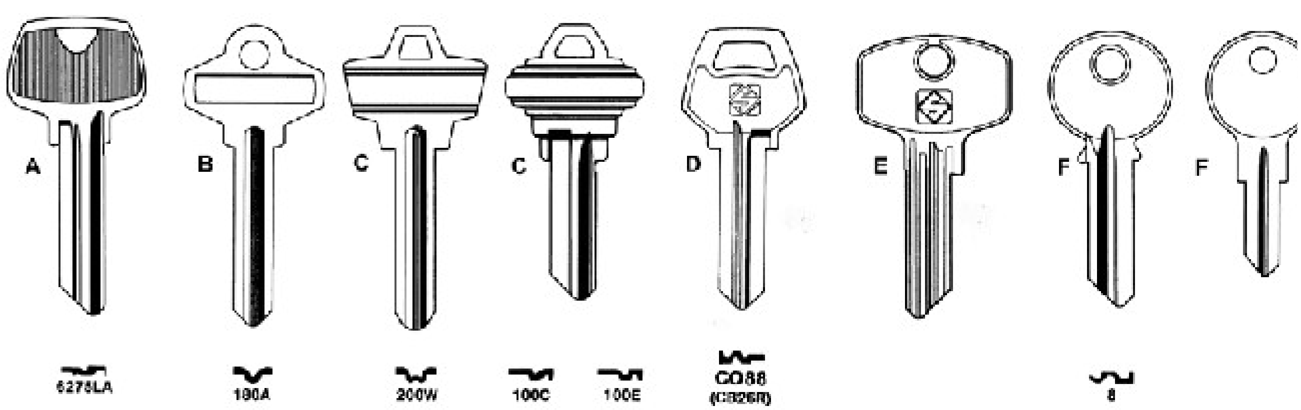
LSS+608, examples of blanks with distinctive markings to identify the manufacturer. Note the Ilco and Silca logos, and the identifying blank numbers. The Ilco blank identifies both the blank number (999) and the OEM (Yale) blank number Y1.

6_4.6 Identification of Keys and Manufacturer

Each lock manufacturer may offer hundreds of different key and keyway designs for their products. Multiplied by the thousands of lock vendors throughout the world, key blank identification can become difficult. Yet, there is no international standard for the design or classification of blanks. The identification of keys to a specific manufacturer, however, in most cases is not difficult.

There are a number of key blank manufacturers throughout the world whose business it is to produce blank keys, on an OEM basis, for many different lock makers. Perhaps the largest international supplier is Silca, located in northeastern Italy. This company produces more than 200,000,000 key blanks a year, for hundreds of different lock manufacturers. Silca has a state-of-the-art automated manufacturing facility that can generate a blank for any lock. Silca, as with all other suppliers, has a unique logo and key number that they stamp on each blank that they produce.

To identify a certain manufacturer from a key blank, we are concerned with several criteria. These include:



- **Name on the bow;**
- **Shape of the bow;**
- **Identifying numbers on the bow;**
- **Size of the key;**
- **Shape and design of the grooves that form**

the keyway;

The name inscribed on the bow may identify the manufacturer if the key is an original, supplied by the manufacturer of the lock, or by a company who produces original keys for the manufacturer under contract. However, just as often, the name on the key will be that of the company that produced the blank but not the lock. Thus, a blank with the name and logo of Silca would indicate that the key, not the lock, was manufactured by Silca. In this case, however, there would also be a number, which can then be correlated to the manufacturer.

6_4.6.2 Shape of the Bow

A primary method of identifying the lock manufacturer is the shape of the bow or keyhead. Essentially, every manufacturer has chosen and trademarked a unique shape for their keys. There are, however, neutral heads produced by a number of key makers. These generic shapes do not reveal anything about the manufacturer. A product number will identify the original lock vendor. There is an interesting **discussion** in Price's treatise found elsewhere in this Infobase, regarding the design of bows.

6_4.6.3 Identifying Numbers on the Bow

There may be as many as three different numbers on the face of a key and a name or logo. These numbers can identify the blank to the original manufacturer. They can also provide the code of the key, which will relate to the actual tumbler combination of the lock. Numbers may also indicate an office identifier or other internal designation.

6_4.6.4 Size of the Key

The size of the key may offer a clue as to what type of lock it fits. Thus, small keys for pin tumbler mechanisms, for example, may indicate that they fit a padlock or cam lock.

6_4.6.5 Keyway

The design of the keyway will often provide the best clue in identifying the lock manufacturer. All manufacturer catalogs will have pictures of both the keys and keyways. Once the search is narrowed as to one manufacturer, it is usually a simple matter to match the key to the proper keyway. Caution must be observed, however, for the keyways of many manufacturers are quite similar. In fact, often they are so close that the keys for one keyway may operate a slightly different design.

6_4.6.6 Production of Key Blanks

Several companies manufacture blank keys, including Independent, Curtis, National, and Silca. Although many lock manufacturers still produce their own original keys, there is a trend to contract with other vendors, such as Silca, to make their original keys. Many key blanks for different locks appear very similar and may be almost identical. Often, a blank for one keyway will operate in another. Thus, investigators should carefully examine suspect keys and consider the possibility that a blank has been selected that does not appear to be the correct one for a given lock. Blanks can also be milled in order to fit different keyways.

6_4.6.6.1 Milling or Alteration of Blanks

In large systems, restricted blanks often cannot be easily obtained by unauthorized individuals or criminals. In such instances, sectional keys that have been lost or stolen can be modified to fit other keyways. Simple milling of blanks to alter the longitudinal grooves can allow access to other keyways.

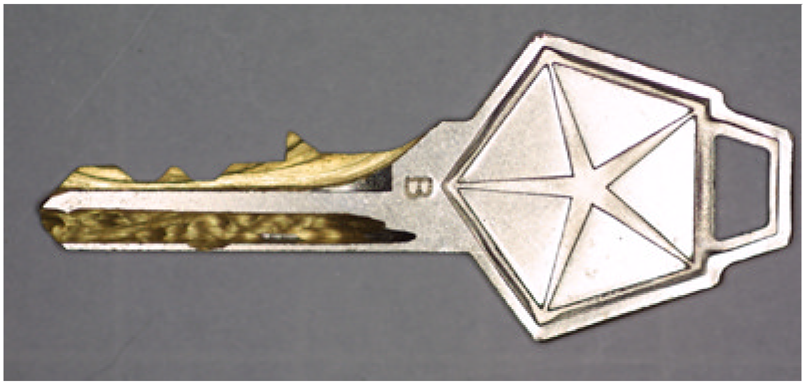


Figure LSS+609, a Chrysler automotive blank that has been milled to open computers in a major bank center.

CHAPTER SEVEN: BLANK KEYS

Processes and Materials for Producing Blank Keys

Master Exhibit Summary

7_1.0 Introduction

There are a number of different processes involved in the production of keys, depending upon the material, function, classification, cost, and tolerances required. This chapter will briefly outline the procedures required during the manufacturing process. For an excellent discussion of early key-making, the

reader is directed to **Chapter 20** in the Price text, contained within this Infobase.

Conversation with Chuck Murray, Kaba-Ilco, regarding keys and their production.

7_2.0 Materials for Key Blanks

Most keys are cut from dies, utilizing strips of brass, nickel silver, aluminum, or steel. In some cases, keys are hot or cold pressed or forged. This is usually the case for iron, soft steel, or zamak blanks. Most cylinder keys are made from brass or nickel silver, although nickel silver blanks are usually of superior quality and strength.

It is desirable to utilize dissimilar metals as between keys and locks, because similar metals wear more quickly when placed in contact with each other. Brass is a popular material for key production, because it is a self-lubricating metal, thus reducing wear.

7_2.1 Iron and Steel Keys

Iron or steel is preferred for the production of car keys, flat keys, and keys requiring extraordinary strength. Thus, Winfield Lock Company utilizes steel keys for their popular hotel room dual-keyway cylinder locks because of the high torque required to actuate the bolt. Brass or nickel silver would likely break in this application.

7_2.2 Brass Keys

Most OEM domestic cylinder keys are made of type #58 brass. Almost all blanks sold in hardware stores, gas stations, and places offering duplicating services are made of brass.

7_2.3 Nickel Silver Keys

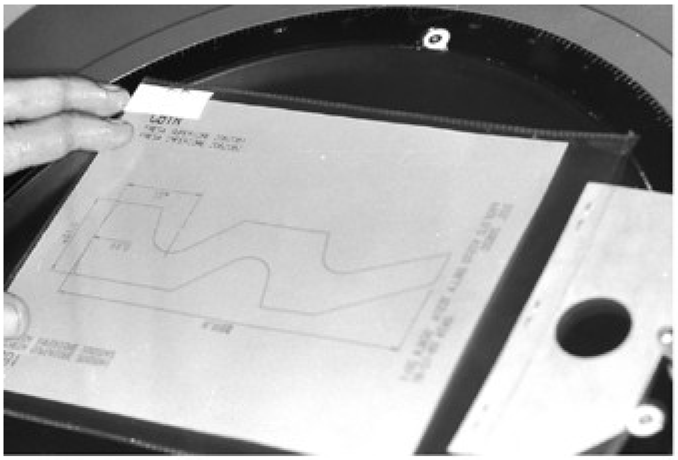
Virtually every high-security cylinder and many OEM blanks are made of nickel silver due to their strength. They are superior to brass in this regard.

7_2.4 Aluminum or Avional Keys

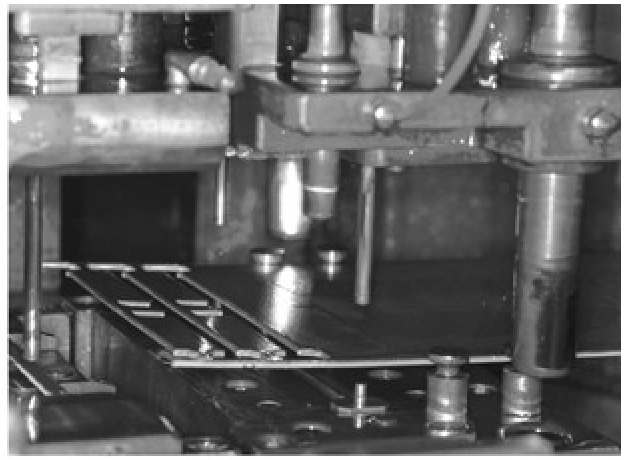
Silca manufactures blanks in Avional, an aluminum alloy. These keys are lighter and stronger than brass and may be produced in many colors. Some manufacturers make keys in plain aluminum. They are not particularly popular with the consumer, however, because of the ease with which they break.

7_2.5 Zamak Keys

Keys are also produced in Zamak for poor-quality locks, such as used in mailboxes. Metal content for zamak is a mixture of zinc, copper, and aluminum.

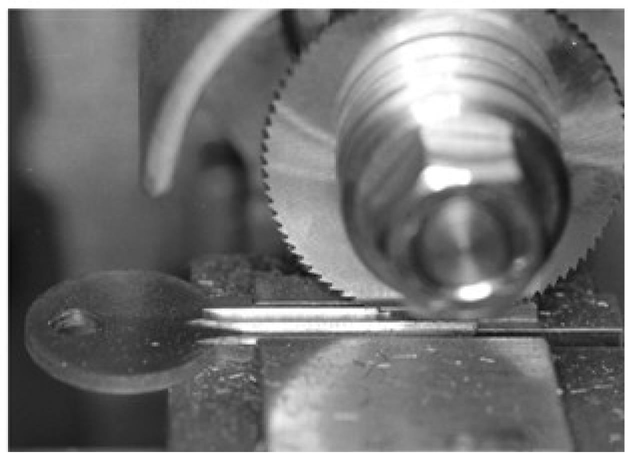


7_3.0 Manufacturing Techniques



Silca is probably the largest and most sophisticated blank manufacturer in the world. Their production facility is among the most automated in the industry. Every phase, from design to final production, relies heavily upon computers. A blank for a pin tumbler cylinder is produced in the following manner at Silca. First, precise measurements are taken from sample blanks and keyways, obtained directly from the lock manufacturer. These measurements are plotted on a computer using special auto-cad programs that translate the dimensions to an exact facsimile of the keyway and, thus, the key. The required data and cutting instructions are then fed to computer-controlled milling machines for production of tool steel dies and coinage stamp dies. What previously required many weeks of work by highly skilled machinists now takes less than two days.

Once the dies are created, production materials are chosen. Then, long rolls or sheets of brass, nickel, aluminum, or steel are fed into a cutting die. This die will produce the required blank key shape, thickness, length, and keyhead design. This flat blank will then be fed into an automated milling machine, which will cut the required grooves on each surface, to form a keyway.



Once the keyway is milled into the blank, the key is "coined" with the proper logo, numbering, and any other required identifying information. The key may also be run through a plating process, to add strength and inhibit corrosion. In some cases, rubber or plastic covers may also be bonded to the head of the key. Other production processes for different kinds of keys may involve **pressing**, **stamping**, or **forging**. Pieces may also be

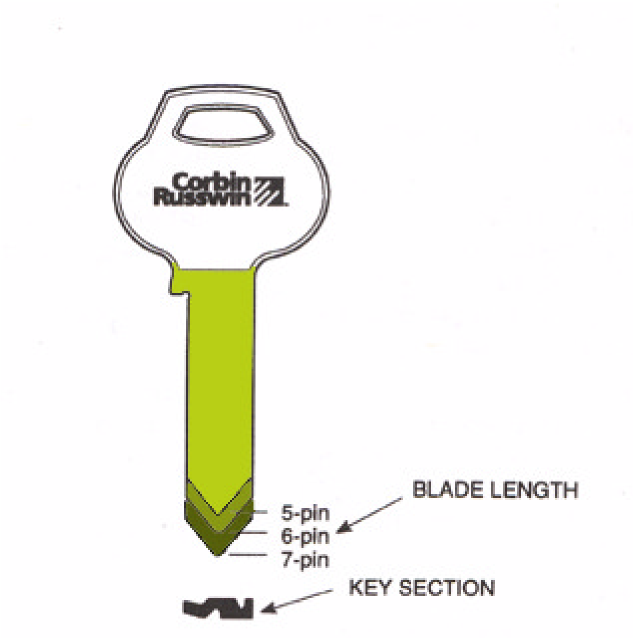
welded in place as in the case of certain warded or bit keys. An excellent description of early key and lock making and the different processes involved in forming of metals is provided by Hobbs in **Chapter 11** of his text.

7_4.0 Knockoff Keys

Many poor-quality blanks are being produced in the Orient and sold in the United States and other countries. In addition, counterfeit knockoff blanks are being sold as factory original. Thus, for example, just because the name Schlage appears on the face of the blank does not mean that the key was actually produced by Schlage. So also, original blanks are copied from those manufactured by Silca, Ilco, Curtis, and others.

Knockoff blanks can be identified by their poor quality in workmanship, tolerance and profile errors, higher lead content, and keyway misalignment problems. The thickness and composition

of metals used in such keys are often inferior to the factory original.



In addition, original logos are often copied imprecisely or are slightly changed to avoid copyright infringement. Many keyways are patented, and thus, the unauthorized production of blanks for certain locks, such as Medeco, violates both copyright and patent laws of the United States and other countries.

7_5.0 Design Considerations for Keys

With the exception of combination and electronic-based mechanisms, all locks require some form of key for their operation. The main function of the key is to transmit locking or unlocking motion to the bolt mechanism. In order to operate properly, the key must be designed to complement the inherent mechanics of the particular lock. That is, each different locking mechanism will dictate the design of the key, based upon the exact interaction between detainers and the bitting.

There are generally recognized design principles as well as a number of specific identifiable attributes of keys. These apply primarily to keys for wafer and pin tumbler locks. They insure proper mechanical operation and are detailed below. There are three primary components to any key:

Key section: The key section or keyway is a function of broaching. Different keyways are created for every cylinder by each individual manufacturer.

Blade length: The length of the blade must be correct for a five, six and seven pin lock.

Bow shape and marking: Each manufacturer defines the shape of bows for various products. Most key head designs are protected by copyright.

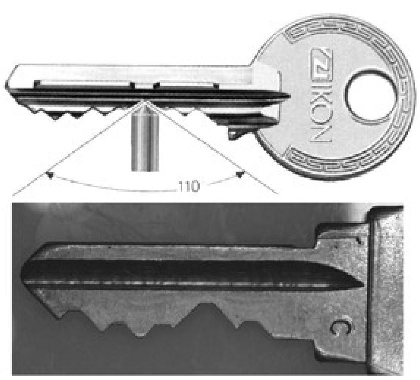
7_5.1 Smooth Edges

All edges on the bitting surfaces of a key as well as all grooves forming the keyway must be evenly contoured in order to make proper contact with tumblers and glide smoothly into the lock.

7_5.2 No Crooked Cuts

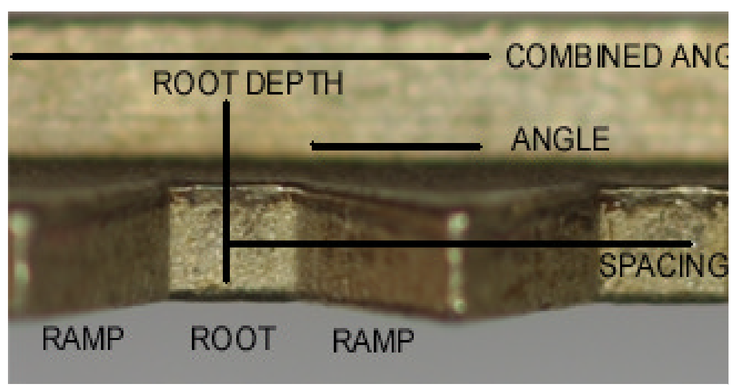
All depth cuts in the bitting surface should be oriented at a 90° angle to the root. Valleys should be symmetrical to each other in their positions, and each alternate valley slope or ramp should be parallel to valley slopes on each side.

7_5.3 Cuts not too Narrow or too Wide



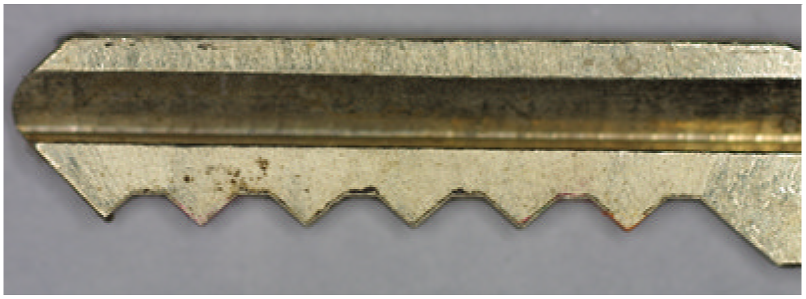
It is extremely important that each depth-cut be centered in the proper position with respect to all other depth cuts. Errors in spacing can result in faulty operation of the lock. If a cut is too narrow, tumblers will not seat at the root but rather on the ramps or valleys of the key. This will result in the tumbler not resting at the correct position with respect to shear line. If cuts are too wide, there will be interference with adjacent depth cuts, causing tumblers for those cuts to rest at the wrong position.

7_5.4 No Sharp Corners or Burrs

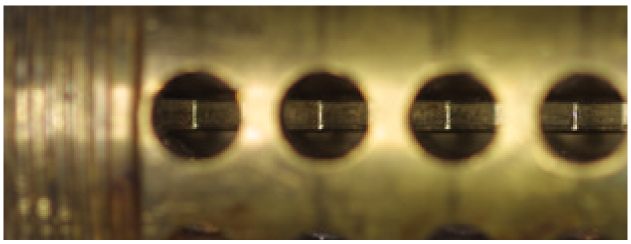


There can be no sharp corners or burrs on the surface of the key which will catch tumblers on insertion or removal. The convergence of ramp angles between cuts is called steeples. A symmetrical point will be formed, resembling an isosceles triangle having two equal sides and angles.

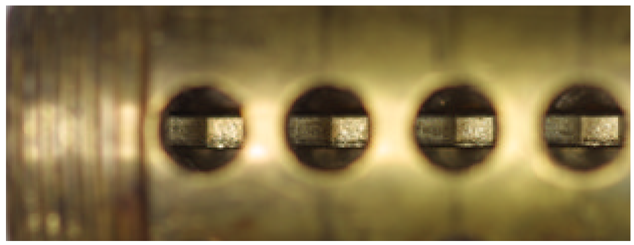
7_5.5 Proper Angles and Valleys or Flats



Proper cutting angles must be maintained for each depth-cut. Generally, 90°-120° total for both angles is considered acceptable. If the angle is improper, keys will not raise and lower tumblers smoothly and may cause the key to hang up in the lock. In the illustration **LSS+701a,** the Ikon key shows a combined angle of 110°.



LSS+701a. Proper key design requires that ramps and root form a combined angle of 90°-110°, as shown in the Ikon and Schlage keys above.



LSS+701b, This photograph shows the prope of a pin tumbler key. Note the symmetrica angles. Spacing is defined as center-to-c distance between cuts.

LSS+701c. This code-cut key shows the symmetry of each cut.

LSS+702a. A key must be properly positioned so that each cut is precisely centered under its corresponding tumbler. In this photograph, there is mis-alignment between chamber and the location of each depth cut.

LSS+702b. In this photograph, proper alignment between each cut and corresponding chamber is shown. Note that the root is positioned at the center of each chamber, thereby allowing the tumblers to seat properly in each root.

7_5.6 Bow

The part of the key that does not enter the lock but allows it to be held for operation by the user is the bow. Its design does not affect the operation of the key, but it should be configured so that it does not interfere with its use, either.

Figure LSS+703 Key bow.

7_5.7 Shoulder

The shoulder of the key must be designed so that it makes contact with the plug, so as to stop the key from forward movement at precisely the correct position. Care must be taken that spacing for the first cut is the proper distance from the shoulder.

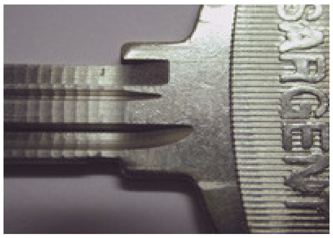


Figure LSS+704 Shoulder of key

7_5.8 Depth and Spacing

The distance between the center of one valley or V cut to the center of the next valley or V cut must be correct in order for all tumblers to set properly. A **micrometer**, such as manufactured by HPC can be used to measure precise distances between cuts, from the flat portion of one to another. The illustration shows a depth and spacing for a Yale pin tumbler lock. There are six spaces and nine depths.

DEPTHS					
0	.320	4	.244	8	.168
1	.301	5	.225	9	.149
2	.282	6	.206	0	
3	.263	7	.187		

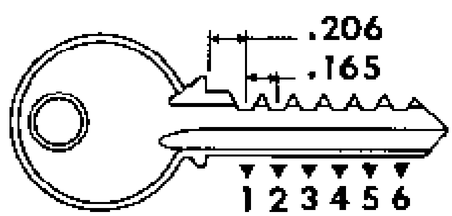

Figure LSS+705 Depth and Spacing diagram

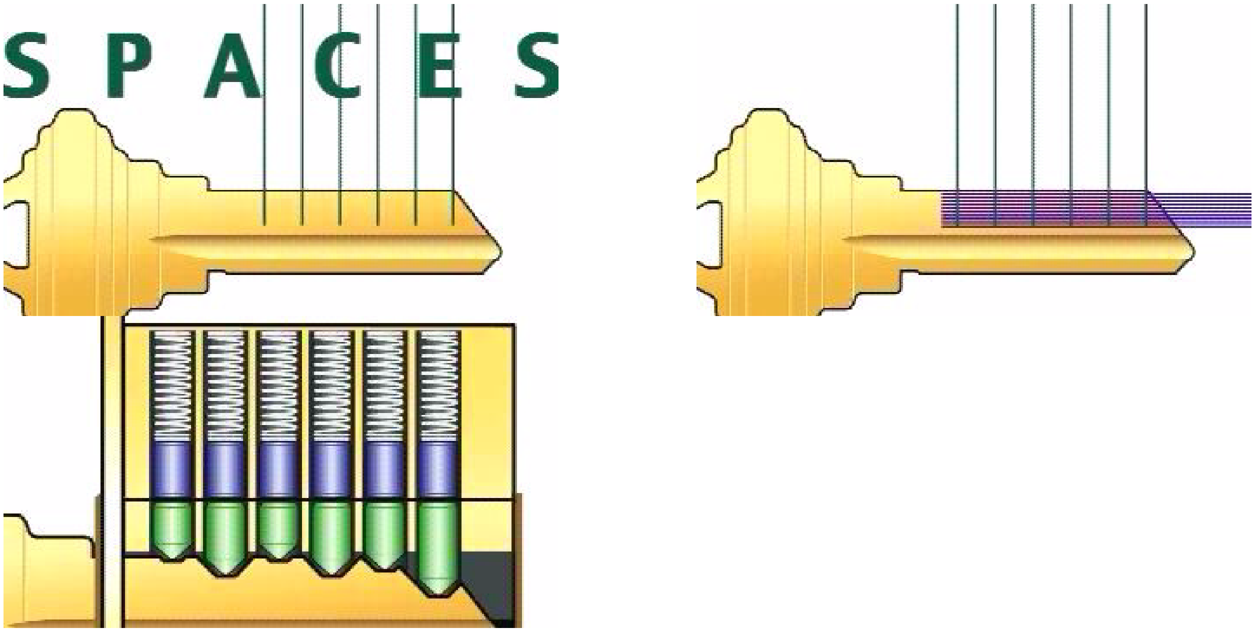
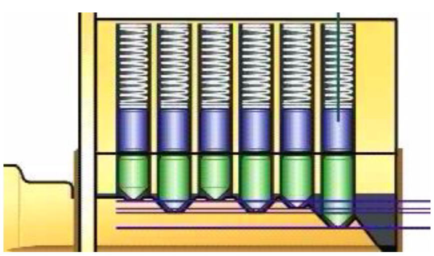
It is interesting to note that a patent was granted to Simon in 1931 for a process of marking key blanks to readily display depth and spacing data on the surface of a key (**1795318(124)**).





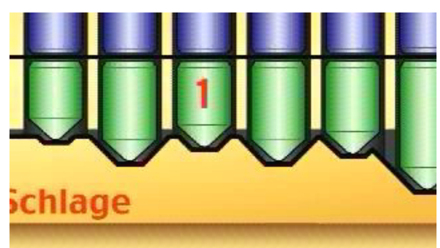


Figure LSS+706 A diagram showing the vertical (left) and horizontal (center) division of the bitting surface of the key, and how the tumblers interact with each position. The spacing between cuts precisely corresponds with the position of the chambers. Courtesy of HPC Interactive Learning Series.

7_5.8.1 Depth of Bitting

The depth of the bitting surface will determine the number of available differs. Keyway design and the structural integrity of the key will be factored into this parameter. Keys that provide for very deep cuts are subject to fracture resulting from the application of excessive torque by the user. In the above illustration, the Yale key has nine depths that range from 0.320-0.149 inches.

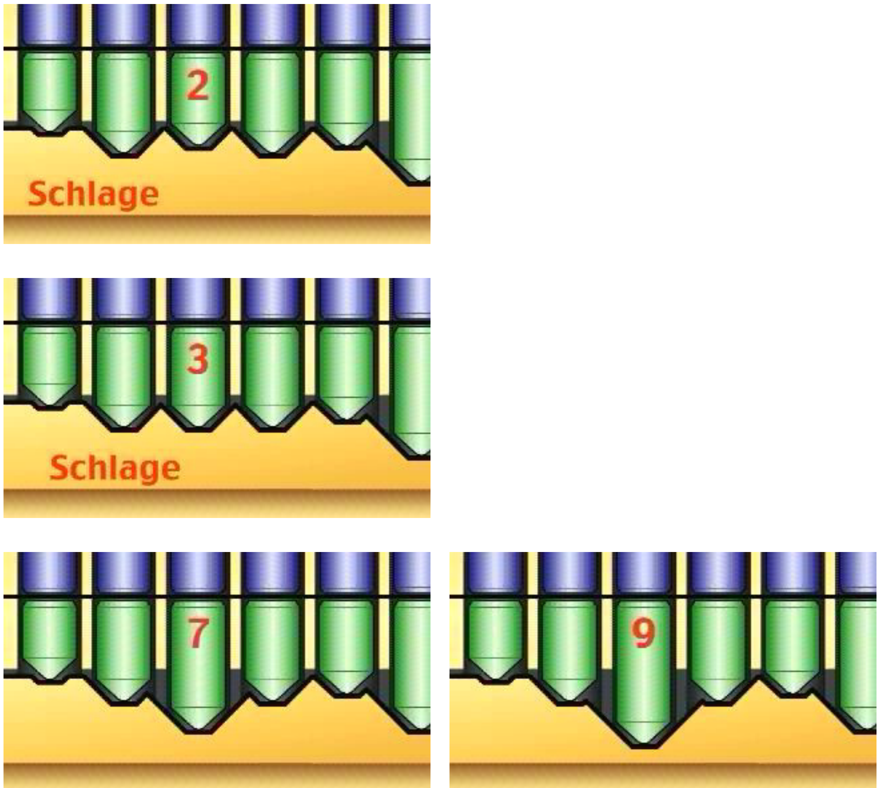

Figure LSS+707 These diagrams show an example of different pin lengths utilized by Schlage. There area total of nine depths available. The first photograph shows the relationship between each pin chamber and pin depths. Courtesy of HPC Interactive Learning Series.

7_5.8.2 Proper Depth Combination

The manufacturer must determine the maximum allowable difference between depth cuts adjacent to one another. Thus, a number 1 cut often may not be placed next to a number 9 or 0 cut because of the sharpness of the angles thus created. If the angle is too steep, the tumblers will not lift properly, and the key may be difficult or impossible to insert or remove. A key is “back cut” if the ramp angle is so steep as to prevent a tumbler from rising as it is withdrawn. In such a case, the tumbler is actually trapped within a valley, formed by acute angles.

8_1.0 Introduction

Keys can be produced by hand or machine cutting. They can be duplicated or generated through casting, impressioning, and decoding techniques. A detailed discussion of these procedures and the required tools, including key machines, is presented in this chapter. Specific bitting combinations can be derived from another key by disassembling the lock or by code. See **Chapter 31** for a detailed discussion of decoding techniques and procedures.

8_2.0 Tools Required for Hand Cut Keys

In order to produce a hand cut key, certain tools, including files, decoders, measuring devices, and key machines, are recommended. These are summarized below.

8_2.1 Files and Miscellaneous Tools

The files listed below are suggested for use in cutting keys by hand. See **Chapter 4** for information regarding each type of file, and its proper use.

- **Warding files (for flat keys, warded and lever locks):**
- **4" warding file**
- **6" warding file**
- **Rat-tail file: 4" and 6"**
- **Triangle file**
- **Swiss file set**
- **Pippin Swiss pattern file**
- **Fine, slim taper file**
- **Clamp or vice to hold key**
- **Vice grips**

8_2.2 Decoding and Measuring Tools

Many decoders have been patented over the past one hundred years for measuring depth and spacing on keys. See an early mechanism invented by Phelps in 1902 (**709240(125)**).

The following instruments and tools are utilized for decoding source keys:

HPC SKM-2D Direct Reading Key Micrometer: This instrument is used in key duplicating and decoding for determining precise measurements of spacing and bitting.

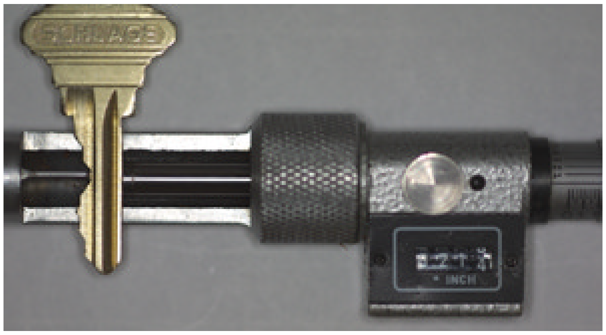

Figure LSS+801 The HPC key micrometer will directly read depths of bitting.

HPC GMTD-5 Decoder Gauge: This set of five gauges is utilized to decode General Motors sidebar locks. With pressure applied to the sidebar, the tumblers are raked to the aligned position. Then, each gauge is inserted into the lock so that the depth of the tumblers can be read.

HPC Key Decoder HKD-75: This is an extremely valuable instrument and should be a part of every tool kit. The handheld decoder allows the reading of virtually every wafer and pin tumbler key in the United States, simply by inserting the blank into the device and directly reading the depth of each bitting position. The unit is supplied with over 110 **reference code cards** for more than sixty locks, detailing blanks, depths, and spacing information. The data thus derived can be fed into the HPC 1200 and a key can be produced by code in seconds virtually anywhere.

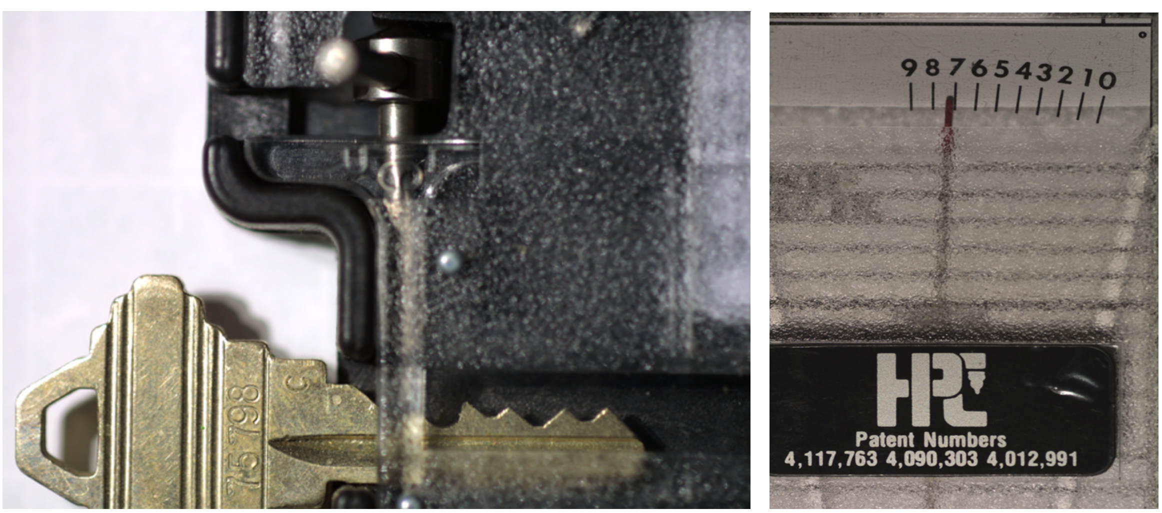

Figure LSS+802 HPC Key decoder. This tool will read all major key blanks and their bitting surface.

HPC Tubular Pin Tumbler Lock Depth Gauge: This tool is utilized in conjunction with tubular lock picks to "read" the position of the feeler pins within the pick after the lock has been opened. It will allow production of a tubular key by code.

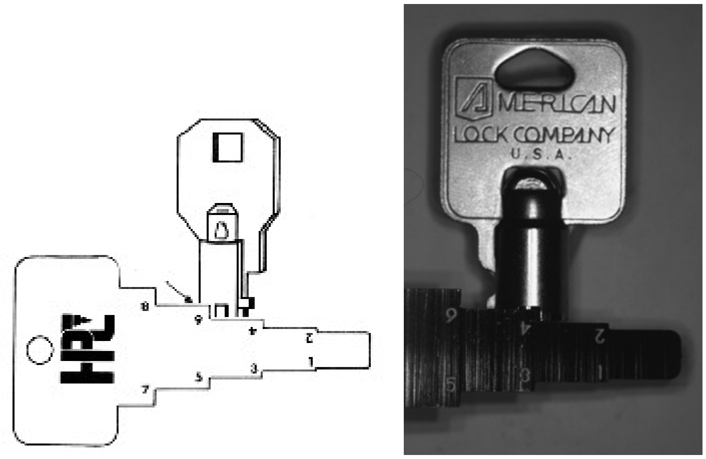

Figure LSS+803 An HPC axial decoding tool (and exploded view) for measuring the depth of each cut. This tool is also shown in Figure 31-7.

Many decoders have been developed specifically for automobile locks. See, for example, Leversee (**4638567(126)**) who invented a decoder for Mercedes-Benz locks in 1987.

8_3.1 Key Cutters

The original code-cutting key machine was developed in 1926 by the Independent Lock Company (ILCO). Today, many companies produce machines and cutters. They range in price from under two hundred dollars to over twenty thousand dollars depending upon complexity. The author utilizes cutting machines produced by the two leading manufacturers in the world: HPC and Silca. These companies offer a series of manual, electric, electronic, and laser-guided cutters that can duplicate or produce virtually any modern key. Each machine has its application; the serious locksmith or law enforcement agency may purchase more than one based upon specific needs.

8_3.1.1 Hand-Operated Key Cutters

There are a number of handheld key cutters that do not require electricity and which are extremely versatile for use in the field. The following three cutters are highly recommended:

- **HPC 1200PCH Manual Key Cutting Machine**
- **HPC TKM-90 Tubular Key Cutter**
- **A-1 Security Manufacturing Pack-A-Punch**

There are two versions of the HPC 1200: one unit is solely mechanical and the 1200CM is motor-driven. The 1200 will produce any wafer or pin tumbler key by code, using punch dies. The machine is extremely simple to use, compact, and can be taken anywhere. It is particularly suitable to field operations. The HPC TKM-90 (above left photograph) is a handheld cutter for tubular keys used in axial pin tumbler locks, such as the Chicago Ace. The A-1 Pack-A-Punch can be used to code-cut most automobile keys as well as Schlage, Best IC, and Kwikset. The punch features interchangeable cutting dies and code wheels. It is ideally suited for producing keys in covert operations and is described more fully in chapter 31, regarding the decoding of master key systems.

Figure LSS+821 The HPC 747XU tubular key duplicator will copy virtually any axial pin tumbler key. It can also be used to generate keys from an HPC tubular pick.

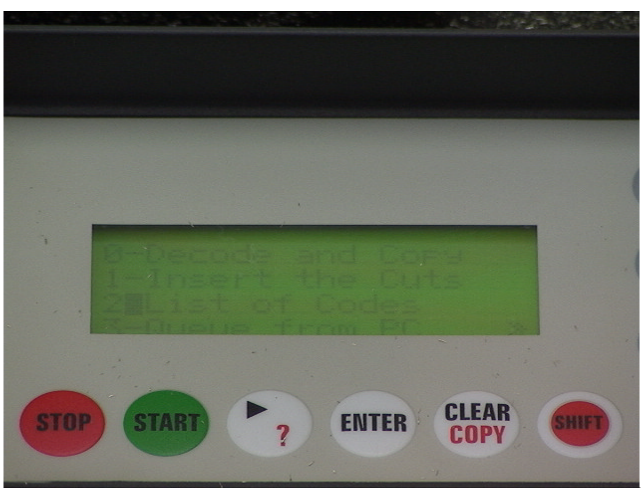
8_3.1.2 Motor-Driven and Computer-Controlled Key

Machines

All motor-driven and computer-controlled machines perform the job of cutting keys in similar fashion. The essential difference is logic, control, and the complexity of their databases. However, the job of actually cutting keys is relatively simple. The HPC 1200CM is the motor-driven version of the 1200PCH. The real distinction between this model and its predecessor is that it can cut Medeco keys and it requires less work to operate. The 1200CM has become one of the most popular key machines during the past ten years, although HPC has introduced the second generation "Blitz" version, and their new third generation machines.

Figure LSS+822 The HPC 1200 CM key duplicating machine (left) is one of the industry standard duplicators. The 1200CMB (center) is the second generation Blitz that provides enhanced options and allows cutting of a variety of high security keys. The HPC Premier Speedex 9160MC is a manual duplicating machine that will handle both large and small keys.

Figure LSS+825 The HPC 1200PCH mechanical punch cutter (left) can be utilized anywhere. The Drill Mill is an extremely clever key cutter that utilizes a drill motor for the driving force for the cutting wheel.



The HPC CodeMax and the BlueSHARK (described below) are the premier machines produced by HPC. The CodeMax is an extremely sophisticated, computer-controlled device, which is capable of cutting virtually any "standard" key by code. Data for hundreds of different blanks and codes are preprogrammed at the factory. The machine can also be set for custom configurations. The CodeMax is compact, easy to operate, and price-competitive. The BlueSHARK will replace the CodeMax, in terms of functionality and simplicity.

Figure LSS+826 The Codemax was one of the original HPC computerized code cutters.

The Silca **Quattrocode** is probably the most sophisticated and expensive key machine in the world. This unit, controlled by a computer, can produce virtually any key from code. It has a number of attachments that allow even dimple keys to be cut with ease, and will read a key by laser and correct for errors in the source key being duplicated. Silca also produces a key machine that optically reads virtually any blank, and can reproduce ward milling as well as depth and spacing. This system is available only to law enforcement and certified locksmiths and is in limited production.

The Silca machine, with laser reading attachment, lends itself to the duplication of keys produced from wax, clay, or silicone molding techniques which are discussed below. The principal advantages to laser reading are accuracy and that the original will not be touched or distorted in the duplication process. Silca and HPC, as well as a number of other companies, maintain an extensive database and a complete set of code books for use with their machines.

LSS202: Kaba-Ilco Quattrocode key machine, Courtesy of Steve Fish.

8_3.1.2 HPC BlueSHARKtm

LSS203: HPC BlueSHARK third generation key cutting machine.

HPC has introduced its second generation computerized x-y axis key cutting machine, after several years of research and development, and intense focus groups with tradecraft. The acronym is coined from **S**tand alone **H**and-**A**ctivated **R**obotic **K**ey Machine, and reflects the integration of microprocessors, extensive depth and spacing databases for virtually all significant manufacturers (over 800), and the latest in key cutting and milling technology. The BlueSHARK is the logical progression that began with the 1200CM (Card-operated Code-machine). That product soon evolved into the 1200MAX

(CodeMax, the first computerized code machine), and now the BlueSHARK (which HPC calls the ultimate stand-alone computerized code machine). The 1200CM technology was used to create the 1200PCH (Punch Machine) and the later 1200CM was further developed into the 1200CMB (Blitz). The 1200MAX was further developed into the 1200MAXAA (CodeMax with auto angler).

Figure LSS+829 The HPC BlueSHARK third generation code cutting machine.

The latest entry into the extremely competitive global market demonstrates the sophistication of the locksmith profession, and the demands that modern key cutting machines must achieve. Locksmiths in the United States, as well as throughout the world must maintain significant code data in order to respond to their customers in an efficient and timely manner, in view of the proliferation of lock manufacturers. HPC and other vendors have recognized that key machines must evolve into cutting mills that are controlled by a computer, with comprehensive databases and sophisticated capabilities for a wide range of locks and locking systems. The problem to date has been the complexity of operation of some of these machines and their cost.

Although HPC, Silca (now Kaba-Ilco) and other manufacturers have responded with sophisticated machines, many are outside of the price range of the "traditional" locksmith. Other machines are complicated and require significant training. Both HPC and Kaba-Ilco have expended significant resources to develop

user-friendly computerized systems. This is especially important in the United States, where relatively few locksmiths have computers, or are computer-literate.

The introduction of the HPC system will likely drive other manufacturers to incorporate similar technology, in order to make key cutting virtually error-proof, with little required training for the end user. What HPC has done is to integrate data input and control functions through the use of a touch screen overlay on a liquid crystal display, with proven and rugged cutting technology. This means that the operator needs no computer knowledge or expertise, which translates into the elimination of costly learning curves for employees. From the viewpoint of the author, the system is both interactive and intuitive, and can be customized for each user. An employee can utilize the system almost instantly to produce accurate keys.

The mechanism provides an automated decode function to determine the code of a key, in order to allow for accurate generation to factory standards. This is similar to the system that is available in certain of the Silca machines, but utilizes a mechanical stylus to probe the contour of the key, rather than a laser.

The BlueSHARK system requires no adjustments, and is almost impervious to misalignment issues that are common to traditional cutters. However, the BlueSHARK will not cut certain kinds of keys such as dimple and lasertrack. Optional hardware will allow tubular and Tibbe keys to be produced. The HPC CodeSource database is included, thereby eliminating the requirement for a separate computer, or the purchase of additional software.

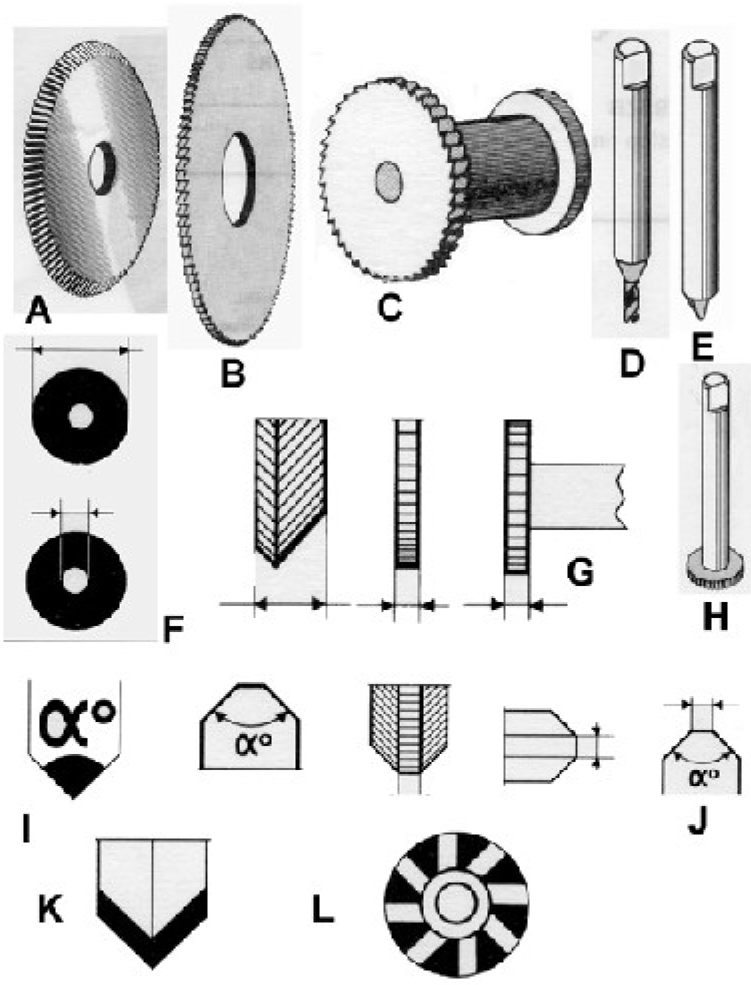
One of the interesting features of the cutting head and computerized key analysis is the ability to control the design of the bitting surface in order to assure smooth operation, minimal wear, and to prevent unintentional removal of the key while inserted into the lock. The system actually evaluates and generates new angles from cut root to cut root. Different patterns can be programmed, including standard cut, contour cut (removal of peaks), smooth cut with barb, angled cut, and radial flats.

The user can easily search for code data from any manufacturer within the database, and can download data from other HPC databases, including MasterKing and KeyTrail. Depth and spacing information is available by DSD number or manufacturer, and also

allows for modification on a temporary or permanent basis in increments of .001".

The system allows for future expansion in terms of data capture and system upgrade, and will surely find wide acceptance as did its earlier generations.

8_3.2 Cutting Techniques



Key machines use cutting wheels with one or two angles. The inexpensive cutters, such as at the local hardware store, generally have cutting wheels that remove metal at a single angle, in a lateral direction, beginning at one end of the key. These machines usually have a motor driven cutting wheel that is mounted in a fixed position. The procedure requires that the tracing stylus be guided across the bitting surface of the source key, from the shoulder to the tip. This process may be automatic or manual, depending upon the sophistication of the machine.

The source and target keys are placed in separate vices, which are connected by a cross-arm. Both keys move in synchronization; one across the cutting wheel, and the other across the tracing mechanism. The source key is "traced" by impressing the bitting against a stylus, connected to the cross-arm. At the same time, the target blank is placed into contact with the cutting wheel. The target key is cut to the exact measurements of the source key, as the source key is "traced", from shoulder to tip.

In manually guided cutters, the operator determines the pressure applied to the source key by the tracing stylus and the speed of the cut. Errors can occur based upon a number of factors, including:

- **Pressure applied to tracing stylus;**
- **Angle of insertion of blank key and source key;**
- **Positions of the source and target key within vice;**
- **Misalignment between key vices;**
- **Poor quality blanks;**
- **Improper blank.**

In contrast, the more expensive commercial cutters and those used during the manufacturing process, generally employ a cutting wheel with two angles. They will generally cut the key straight into the valley or root, rather than from the side. In this way, correct angles are formed on both sides of the root.

8_3.2.1 Characteristics of Cut Keys

Keys cut by the more expensive and sophisticated commercial machines have recognizable characteristics that can often be identified by crime laboratory examination. Specifically, keys which are produced by code will have perfectly formed and equal angles on both sides of the root of each cut. If a high RPM cutter is utilized, the surface of the key will be smooth. Generally, commercial code-cutting machines will operate at about 2200 RPM. Less expensive key-duplicating machines will run at about 800 RPM and are primarily intended for making brass keys.

The more teeth in the cutting wheel, the smoother the cut. If one or more teeth are missing due to breakage, then the cut may not be even. The smoothness of the cut will also be affected by

the speed of travel of the key across the cutting wheel and the RPM of the motor. Misalignment or insertion angle differences between the source and target keys can also affect the appearance and accuracy of the duplicate key.

Commercial key machines will generally maintain tolerances of approximately .0075”-.003", with a variance of .02 mm per copy being acceptable. The tolerance in the production of blank keys is between .001”-.003". Both Silca and HPC can generally maintain acceptable tolerance for ten generations of keys. Thus, the tenth generation from the original key will still be within acceptable limits.

8_3.4 Key Profile Milling Machines

Specialized key cutting equipment is available that will mill and create a desired blank key. **Silca**, **Giuliani**, **DiMark International**, and **Easy entrie** produce or sell such equipment. The **Easy entrie(127)**, manufactured in Germany, is perhaps the most innovative, cost effective, and functional machine that is currently available. There are a number of other profile milling machines that can replicate blanks, but none appear as versatile and portable as the Easy entrie. The Easy entrie has found wide acceptance among locksmiths, crime labs, and special operations units because of its capability to replicate almost any conventional blank.

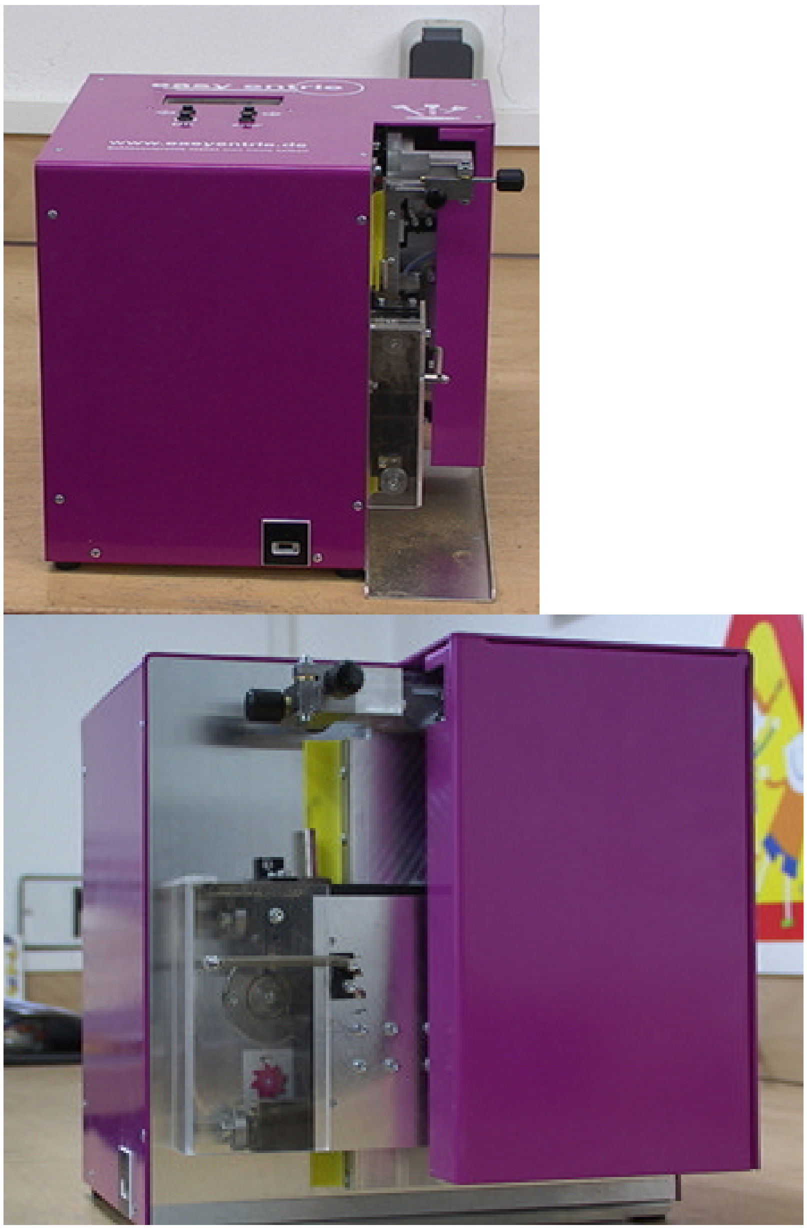
The ability to replicate almost any conventional blank allows great flexibility in an investigation or covert operation. In **chapter 31**, a detailed treatment of the tactical aspects of compromising master key systems is presented. The Easy entrie can be an integral part of such an operation because they offer the capability of replicating a cut key to produce as many blanks as are required.

8_3.4.1 Easy entrie Profile Milling Machine

The Easy entrie can produce blank keys for virtually all conventional pin tumbler locks and for many of the high security restricted keyways throughout the world. The machine is supplied in two configurations that allow for the production of blanks from a source key, or from a digital image of the keyway. A special software package is offered to government agencies that allows a computer to control the mill and to produce keys from a photograph or database. The hardware for both versions is

identical with respect to the measurement and milling processes. Only the interface and operating system will differ. The video will detail the use of the Easy entrie system.

LSS203: Easy entrie key machine demonstration



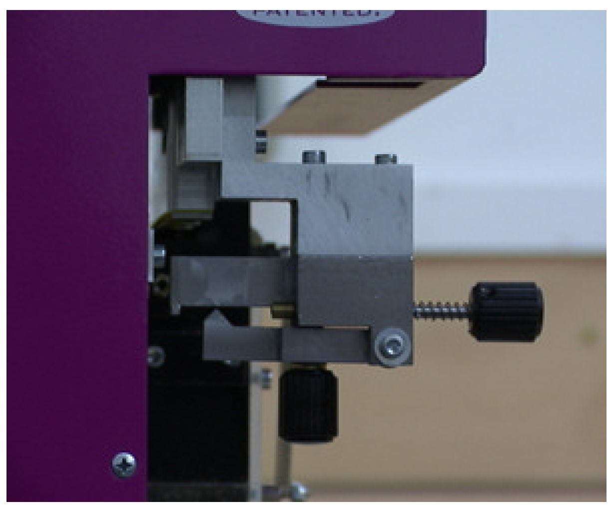


Figure LSS+830 Easy entrie profile milling machine

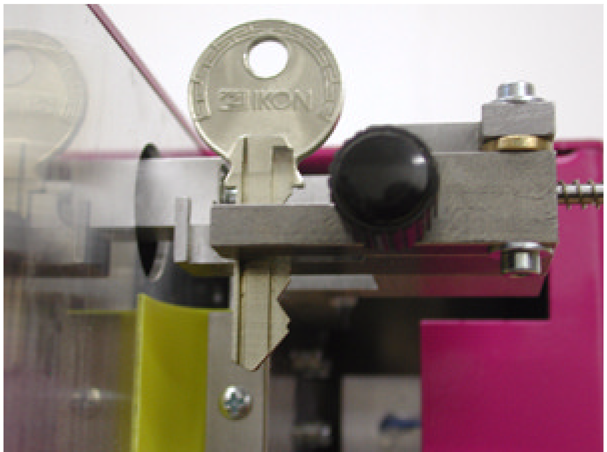
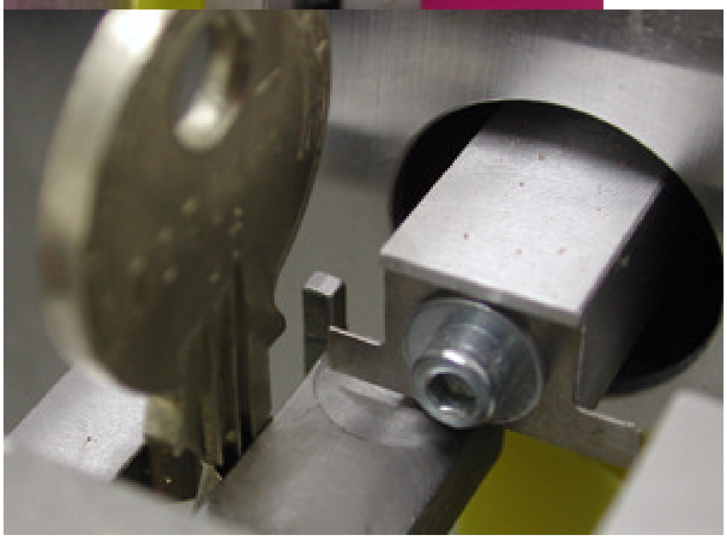
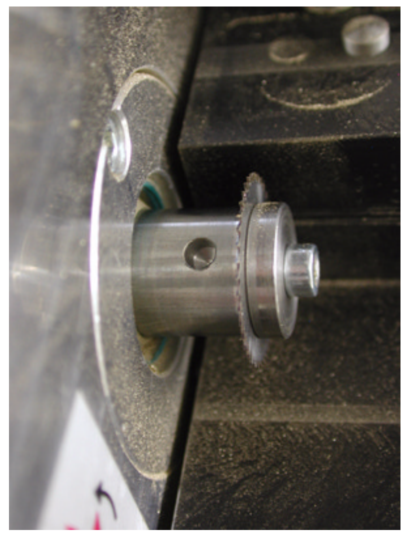


8_3.4.1.1 Overview of the Process



The Easy entrie milling machine is not a key duplicator, but rather a sophisticated system that allows the copying of either a bitted or blank key sample to produce a new blank key with a ward profile that will pass the keyway. The machine will also duplicate some high security blanks that may be unavailable through normal channels. This feature may prove especially useful to covert government operations. As shown in the accompanying video, a two-step process is required in order to generate a blank key.



First, the sample key is measured with a mechanical probe. At the conclusion of the measurement process, the system specifies the correct blank that should be inserted for cutting. All supplied blanks from Easy entrie are the same length, but of different thickness. Each is identified with a unique blank number. The proper blank is selected and inserted. The computer-controlled mill then produces the profile. Once this process is completed, the blank is removed and the end is trimmed to the proper angles for insertion into the keyway. The bitting values are then duplicated on the blank key that has thus been produced using a regular key cutter. The cost to replicate a key blank on the Easy entrie is under two dollars, considering the cost of blanks and life of the cutting wheel (about fifty generations). The machine is portable and operates on 24 VDC.

IKON

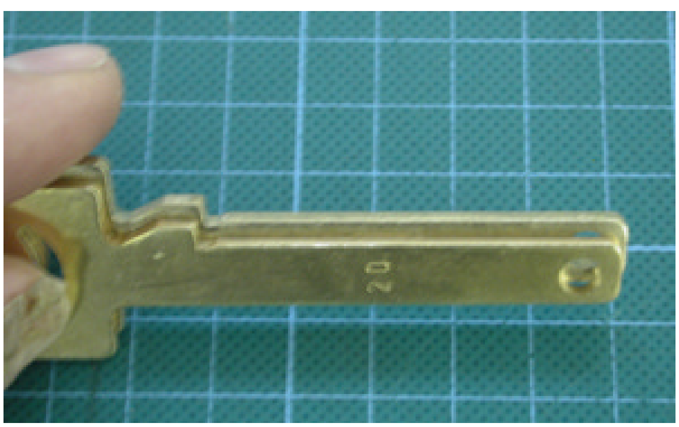


Figure LSS+831 The source key is measured mechanically with a thin probe. The correct Easy entrie blank key is then inserted into the cutting area and milled. There are at least five different blank thicknesses that are available.

As shown in the photographs above, the source key is inserted into a special holding vice that allows it to be read on both sides in one operation. At the conclusion of the measurement process, the on-board computer determines the correct blank and provides that information on a liquid crystal display. A detailed instruction manual is available as an Adobe PDF and is provided here.

8_3.4.1.2 Capabilities of the Easy entrie Milling Machine

The Easy entrie milling machine has a number of capabilities and limitations. These are summarized below.

- **The Easy entrie is not a key duplicating machine; it will not copy bittings or side millings;**
- **A blank can only be created from a source key, unless the enhanced software package has been obtained. Profiles can also be generated from data that has been previously stored within a database (if the machine is linked to a computer), or from a digital image;**
- **Measurements may be made from either the original key or from a copy that has been obtained through the use of a silicone impression and low temperature metal casting;**
- **Certain restricted or unavailable blanks can be replicated;**
- **A blank can be produced from a cut (bitted) key;**

- **All conventional blanks can be precisely replicated if they are less than 3 mm in thickness. In the future, a blank of up to 5 mm can be measured;**
- **Only the first 1/8" of the key will be sampled; the entire surface of the key is not measured. Any variances in the longitudinal surface of the key will not be replicated. NOTE: A sample key may be inserted at different positions for special applications. For example, a deep groove by the shoulder or other irregularities may prevent the source key from being inserted or read in the normal fashion. In such instance, the key can be seated as shown. Be sure that an area is selected that replicates the full bitting area of the blank. The index pin is equal to the sample are of the key. Also, be certain that there are no holes or irregularities in the sampled area;**
- **Side millings and unique bitting designs cannot be copied. Thus, Abloy, Assa, Schlage Primus, Medeco M3, Everest, lasertrack and other specialized blanks cannot be replicated. Note that in certain instances, blanks that are greater than 3 mm in thickness can be replicated by milling the sample area to less than 3 mm, as shown;**
- **Dimple keys cannot be replicated;**
- **Double and triple-bitted blanks cannot generally be produced;**
- **Extra thick blanks, such as Medeco M3 and Best, cannot be duplicated at this time;**
- **The replication of ward patterns is approximate and is calculated to pass through the keyway, but is not exact with respect to the source key. Precise angles are not reproduced;**
- **The duplication of sectional keyways may allow the reproduced blank to enter several different sectional families, based upon the measurement process of the Easy entrie;**
- **Blanks that are produced by the Easy entrie must be trimmed when cut in a key machine;**
- **All blanks that are produced by the Easy entrie must be cut on a standard key cutting machine;**
- **Certain profiles may require different holding techniques in order that the key be seated properly for measurement;**
- **Generally, only the front portch of the key can be sampled accurately. Unfortunately, different sections of the key may not seat properly in the holding vice;**
- **The Easy entrie can be used to measure a soft metal key that was produced by silicone impressioning;**
- **A blank key can be created from a sample that has bittings**

already present. Thus, a cut key can be utilized to generate a blank during the extrapolation of a top level master key, described in chapter 31;

- **The Easy entrie cannot mill portions of a key; it will reproduce the entire longitudinal surface based upon the sampled area of the source key;**
- **All standard lengths and thicknesses of blanks can be replicated. Non standard keys and profiles that are too thick cannot be copied;**
- **The normal Easy entrie machine will not store profiles for later reference without special software;**
- **Once a key is measured, it will allow any number of duplicates to be produced, but the parameters cannot be saved for later generation without special software;**
- **There is no method to modify the way in which the key is milled, unless the special software package is obtained. See the detailed description that follows;**
- **The length of the source key is not relevant; all blanks are supplied in standard dimensions;**
- **Keys with extra wide wards will not seat properly in the holding vice and cannot be accurately copied. Everest is an excellent example;**
- **An external power supply is required to convert mains power to 24 VDC. These are readily available;**
- **The Easy entrie may be operated in a mobile environment with an inverter that is capable of handling a 75 watt load;**
- **There is no bottom-stop or shoulder on the blanks that are supplied by Easy entrie. Thus, care must be exercised if a Pack-a-Punch or similar cutter is employed because there is no way to precisely index the blank;**
- **The design of the cutting mill only allows lateral cuts to be made across the entire surface of the key. No deviations with regard to depth or width can be produced for a specific area of the profile;**
- **An exact replica of the keyway profile is not possible, due to the design of the cutitng mill. The internal program analyzes the keyway and computes the required angles to pass the wards within the keyway; The standard configuration machine is not capable of storing a profile after the required number of blanks have been generated;**
- **Special software is required if the user requires the ability to build a database of profiles;**

- **Additional equipment that is required when using the Easy entrie includes a key cutting machine and a method to trim the end of the blank;**
- **Certain keys may be difficult to firmly lock into position for measurement, due to the design of the keyway.**

8_3.4.1.3 Legal Issues

There can be legal issues that may result from the use of the Easy entrie machine. Specifically, United States and foreign patent laws may protect certain blanks from being duplicated. Issues that may arise include infringement and contributory infringement of a patent. Such action may constitute a federal offense and could subject the offender to civil and criminal penalties. However, this machine does not precisely replicate the contours of a key because of the design of the cutting wheel and the computation of angles when it measures the ward pattern on the source key. If the primary purpose or use of the Easy entrie is to copy or replicate blanks that are protected by patent or to use the machine as a first step to duplicate such blanks, then you may be subjected to liability for doing so.

A number of interesting legal questions are raised with the capabilities of the Easy entrie. These include:

- **Can a specific keyway be protected, notwithstanding the Best v. Ilco decision;**
- **If a keyway is protected, must it be exactly duplicated in order to come within the protection of the patent;**
- **Can a key profile be copyrighted;**
- **Can patent protection be extended to encompass any device, including a replicated blank, that will operate the mechanism;**
- **If a copy of a patented key is made for a customer, does the customer actually own the key, or does he have a license to utilize it in a protected keyway;**
- **Would a simulation of a patented key that can enter a protected keyway be considered a substantial copy and could it come under the protection of the patent;**
- **Can the bitting patter be protected by copyright. If so, can the copying of such key constitute a copyright violation;**
- **Can the bitting values of a master key system be copyrighted;**
- **If the Easy entrie is utilized to replicate a portion of a**

patented key, and another machine such as the Keyway King is utilized to copy the side millings, can both of these machines be seized for infringement of a patent;

- **If the profile is replicated on an Easy entrie, but the blank so produced will not work in the lock without additional milling, can the operator of the Easy entrie be held liable.**

8_3.4.1.4 Producing Blanks From a Source Key

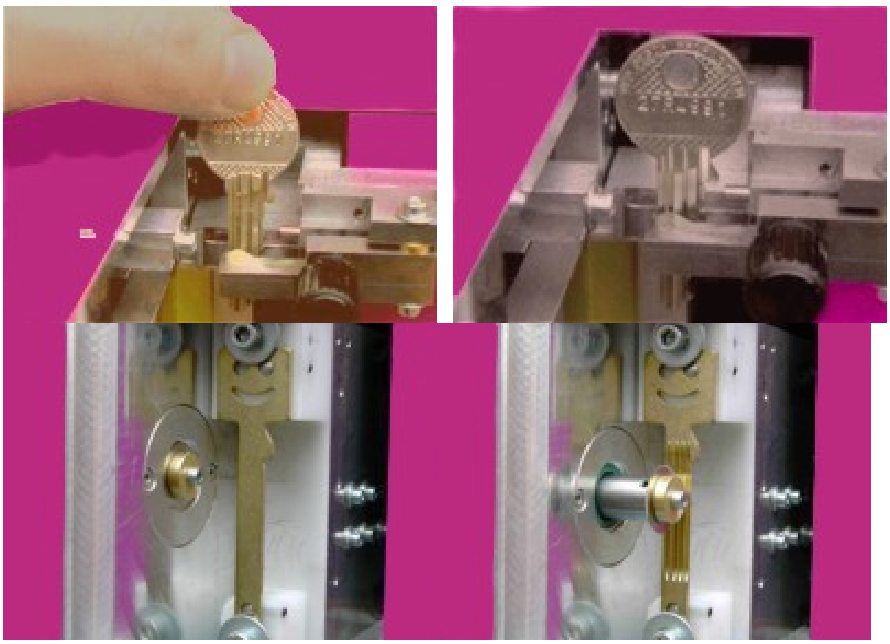

Figure LSS+832 Production of a blank key is straightforward and occurs in two stages. The source key is measured, then removed from the clamp. The correct Rholex is inserted into the milling head and is automatically cut on both surfaces. The finished product is then trimmed and inserted into a key cutting machine, or utilized for impressioning.

The Easy entrie profile milling machine consists of two primary components: measuring and milling. A measuring unit employs a thin shim to mechanically probe the countours of the source key in order to approximate its ward pattern. A milling unit cuts the computed profile into the "Rohlex" blank to fit into the keyway. The Easy entrie is constructed in an extremely compact case with a footprint of about one cubic foot (12" x 12"). Both the measuring and cutting system are self-calibrating. In addition, as the cutting mill loses material from wear, its ability to cut is computed as the profile is created to maintain proper tolerances.

A two-step process is required to replicate a key profile. After the machine is calibrated automatically upon power-up, the source key is inserted into the measuring unit. The system will then probe the key on both front and rear surfaces to measure the changes in the profile. The mechanical probe makes contact with the key and takes enough samples (fine or coarse mode) to insure adequate resolution to compute all required angles. The sample area is quite limited and consists of a very narrow vertical band just after the shoulder. Normal placement of the key assumes that there is a "front porch" that is devoid of bitting, and thus equal to a no-cut condition. The blank can be positioned and clamped at different vertical points if the sample area will not yield the full blade of the key.

Scanning of the source key is accomplished automatically. When completed, the operator is instructed to remove the key. The thickness of the blade is shown on the display, together with the required rholex that is needed for milling. The measurement is stored within short- term memory in order to allow for the generation of blank keys by the mill. The "Rholex" (special blank) of the correct thickness is locked into the mill. The three holes in the key are indexed to protruding pins that precisely link the blank to the cutting head.

The operator is prompted to begin the process. The measured profile will be cut into the Rohlex with a micro milling tool. Both sides of the Rohlex will be milled in sequence, during one operation, thus producing a high precision key blank that will fit its keyway.

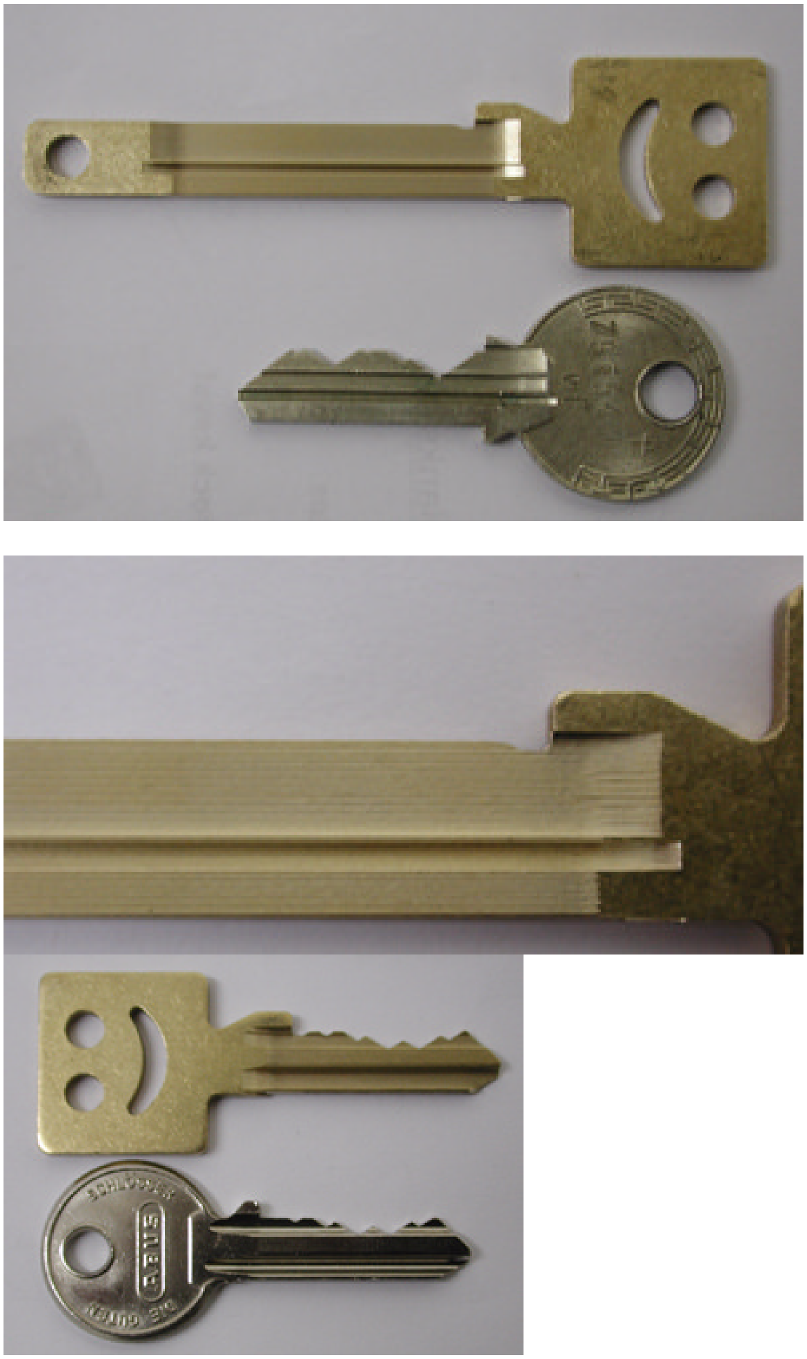

**Figure LSS+833 The milled blank is not an exact replica of the source key, but will
pass the wards within the keyway.**

The operation of the machine can be set for either coarse or fine resolution of the profile. Depending upon the exactness required, the machine will take fewer or a greater number of measurements

in order to analyze the keyway.

8_3.4.1.4.1 Detailed Operating Instructions and Cautions

Detailed operating instructions, as provided by the manufacturer and edited by the author have been included here in Adobe Acrobat format.

Easy entrie Operating Instructions

8_3.4.1.5 Producing Blank Keys from Digital Images

The Easy entrie is a necessity for special operations units that require the capability to produce a wide variety of blank keys for target locks in the field. Often, there is no advanced information that will identify the lock or the keyway profile that must be bypassed. The software has been developed to allow mapping of the keyway in order to guide the cutting wheel. Information regarding the profile can be generated from a photograph, an impression of the keyway, from measurements made from a source key by the normal process using the Easy entrie and stored within a database for later use, or by other means that would include the use of a fine wire pack to reconstruct the open spaces of the keyway to allow the production of its reverse image. This could then be photographed and input into the Easy entrie software. The Easy entrie PC software is available through **LSS+** so that the reader may utilize or evaluate it.

The Easy entrie software provides for certain enhanced capabilities that are not available with the standard machine configuration. These include:

- **One or more blanks can be produced from a photograph of the keyway;**
- **Blanks can be produced from information stored in a database or from a photograph directly, or after modification of the image;**
- **A source key can be measured and the information transferred to the database in the computer for storage and later generation;**
- **No information is required regarding the target lock in order**

to produce a profile that will pass the wards. Note: although the blank may enter the keyway, unless information is obtained regarding the mechanism, the produced blank may not be able to operate properly. This would be true, for example, in the case of the Schlage Everest and the Medeco M3;

- **The software will only allow conventional profiles to be replicated on two surfaces of the key;**
- **All of the restrictions regarding the measurement of a source key by the Easy entrie probe will apply to the use of a photograph. The digital mapping software replaces the measurement process but does not affect the operation of the milling hardware;**
- **The profile for the target lock can be modified prior to milling. A profile can be altered to:**
  - **fit a different section;**
  - **thin the blade to make impressioning easier;**
  - **longitudinal sections of the profile can be widened to allow more vertical movement to make impressioning marks more pronounced;**
- **The entire profile can be made thicker or thinner;**
- **Stored samples can be modified and saved for any number of configurations;**
- **Multiple copies of a key can be stored and generated;**
- **Profiles can be stored within a database for reference and can be e-mailed to other locations;**

There are certain software requirements and limitations. These include:

- **The Easy entrie PC software will only run on Windows operating systems;**
- **The Easy entrie PC software requires an RS232 serial connection on the computer. Most of the new notebook computers only provide a USB interface. In the event that the computer only has a USB connection, then a port adapter from serial to USB must be utilized;**

The software can be run without the Easy entrie machine connected to the computer. Thus, a remote facility can process the image and then transmit a profile back to the field for the production of the blank;

- **A security code is provided for each machine. It will not function for any other Easy entrie unit;**

8_3.4.1.5.1 Digital Imaging Requirements

A digital image must be provided that defines the outline of the keyway in sufficient detail to be mapped in the Easy entrie software. The author utilizes a Nikon Coolpix 990 camera, although many other models will suffice. Any camera with a macro capability is acceptable. The Nikon seems to out perform other models tested by the author and produces an extremely sharp macro image with excellent illumination characteristics. There is no special requirement as to resolution, and the pixel count of the camera is largely irrelevant. The diameter of the plug must be provided in order to reference its size for the software to properly compute its dimensions. The software can only process an image in jpeg format. The author utilizes Adobe Photoshop for image sizing and manipulation, but other image editing software will suffice.

There are certain guidelines for taking and editing images for the Easy entrie:

- **Shoot the photograph of the cylinder without the use of a flash, unless a ring strobe and macro lens is available;**
- **Be sure that the angle of the lens is perpendicular to the keyway to avoid distortion, parallax error and depth of field errors;**
- **Transfer the image to a program that allows editing, such as Adobe Photoshop, Photo-Paint, or Paint-Shop. A simple image editor is contained in all Windows programs. Go to ACCESSORIES + PAINT;**
- **Crop the photograph. Be certain that the outer diameter is visible, as shown in the photograph;**
- **Save the image as a Jpg file;**
- **The image can be saed into any subdirectory, although the default is "C:\Program Files\EasyEntriePc\ZylinderFotos" .**

8_3.4.1.5.2 Producing a Blank Key from a Digital Image: An Overview

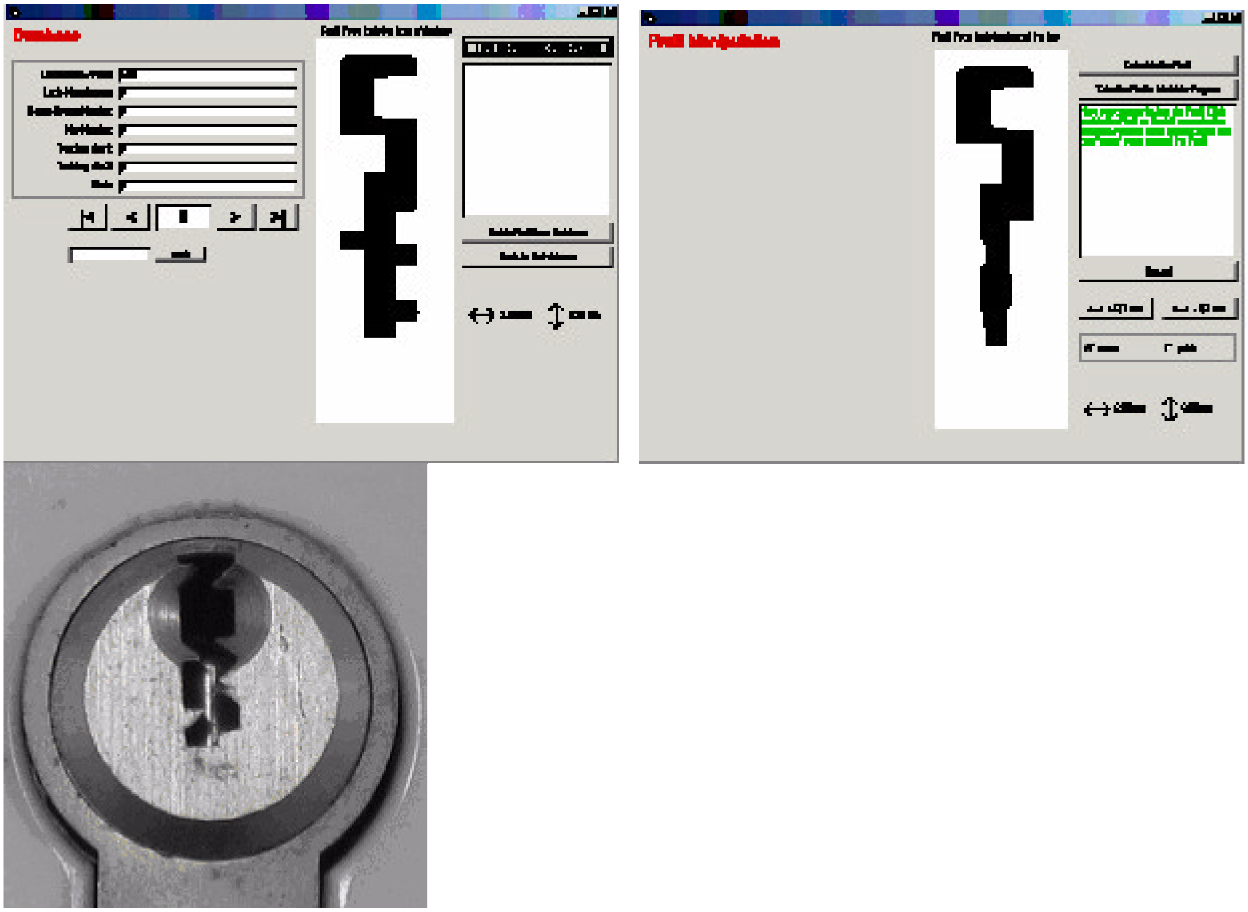
The detailed instructions from Easy entrie have been included in this documentation, together with a video demonstration by the author. The software provides for the following capabilities:

- **Storage of data from source keys that have been measured by the Easy entrie in normal operation. This feature allows profile information to be retained for later generation;**
- **Manipulation of profiles to modify bullet patterns on the key or its thickness. This feature can allow the modification of a sectional profile, for example, in order that a different sectional family be accessed;**
- **Generation of a blank key from the original or modified photograph of the keyway;**

The following description provides an overview of the process.

The information for a previously measured key can be retrieved from the database and a blank can be generated, or a photograph of a keyway can be input into the system, calibrated, mapped, modified if necessary, and a key can be produced. The process is very simple and does not require any special expertise. Essentially, Easy entrie has provided for the storage of measurement data from a source key to allow for blanks to be generated as required. The software also provides a link between the mapped outline of an image and the cutting mill.

The system does not actually evaluate a photograph and determine its profile. Rather, it relies upon the operator to supply an accurate outline of the keyway. This is easily accomplished, using a cursor that is positioned to draw linear segments of the keyway, as shown. The drawing can be edited as required for a particular keyway. The finsihed map is stored within a database, and allows for the generation of blanks. The mapped image can also be modified as needed, and can be transmitted between computers for replication of blanks at remote locations. The data base file is contained in **C:\Program files|easyentriePC\profildaten\Profile.eep**. This file can be sent by email, if required.



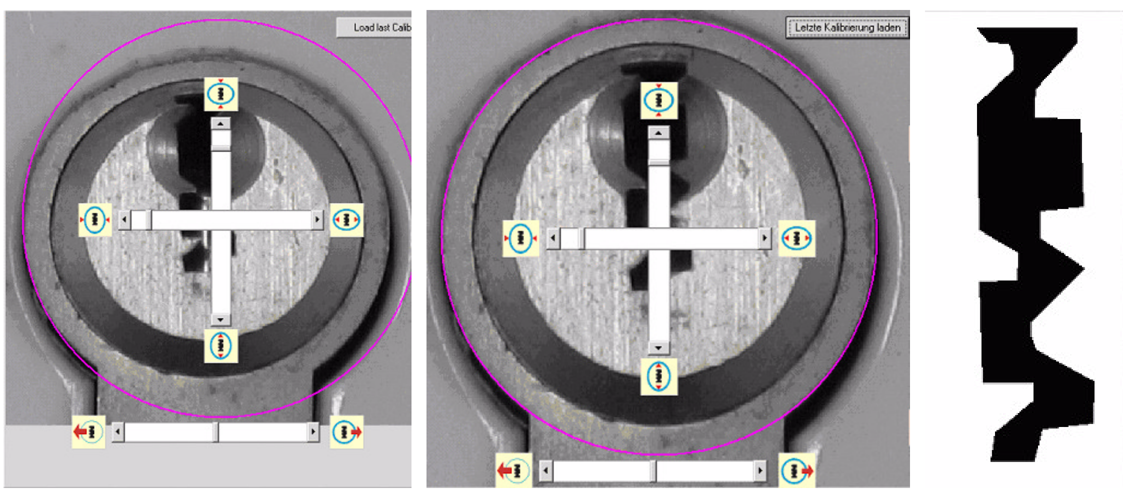


Figure LSS+834 A blank can be generated from stored information in a database, or produced from a photograph.
The software allows for retrieval of a profile and its modification.

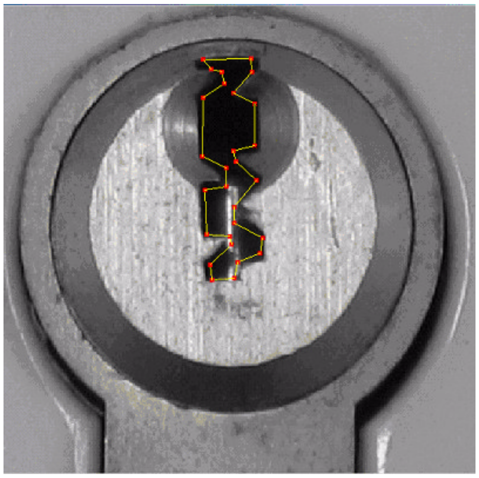

**Figure LSS+835 The edited image is centered within the circle (pink) which has been referenced
to the diameter of the plug in the target cylinder. The keyway is then mapped.**

8_3.4.1.5.3 Detailed Procedure to Generate a Profile

A precise replica of almost any conventional blank can be produced from a digital image. The Schlage Everest is a very difficult blank to reproduce, due to its patented undercut. It will be utilized here as an example of the capabilities of the Easy entrie. The reader is cautioned that replication of this blank may constitute patent infringement. The author does not recommend or encourage the practice except for government operations. Note that the image must be imported into the Easy entrie program as inverted, with the base of the keyway on top. This conforms to the European profile mounting configuration.

Easy entrie PC Software operating instructions

8_3.5 Keyway King Profile Milling Machine

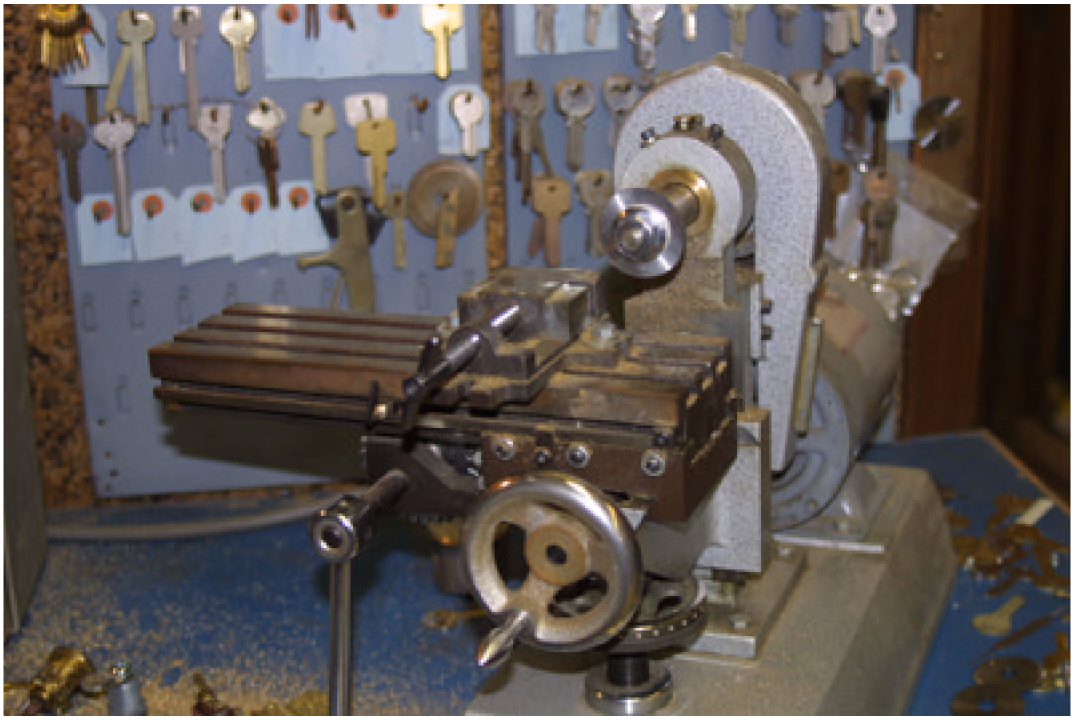

Figure LSS+836 The Keyway King is a milling machine that operates in three planes.

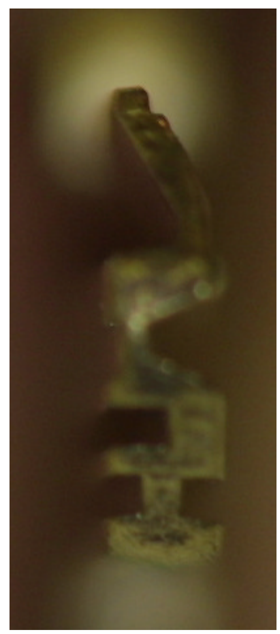
The Keyway King is a machine that allows milling to be accomplished on the X, Y, and Z axis. It is extremely useful for replicating restricted or unavailable blanks, and can be used to create millings on keys that are produced by the Easy entrie. The Keyway King is distributed by DiMark International in the United States. Its use requires a great deal more time, skill, and precision than does the Easy entrie, but it can produce complex key profiles by the use of different **cutting wheels**, shown below. A diagram, showing sixteen factory supplied cutting wheels, is shown in the link.



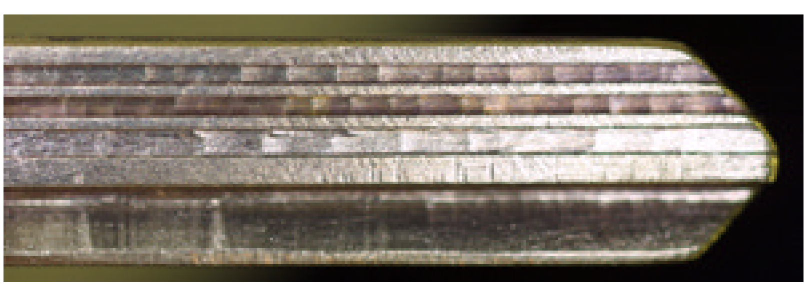


Figure LSS+837 Different cutting wheels are available for the Keyway King.

The process to produce a key is quite a bit more complicated than with the Easy entrie. It requires a visual analysis of a keyway. Lateral milling of a block of metal is accomplished to approximate the wards in the plug. It is a process of experimentation and attempting to closely match the millings with the bullets in the keyway. One feature of the Keyway King is the ability to produce several "blanks" with the same milling, as the key is "built." The vice allows rapid removal of a key and insertion of another. The photographs show two locks for which keys have been produced, at various stages in the milling process.

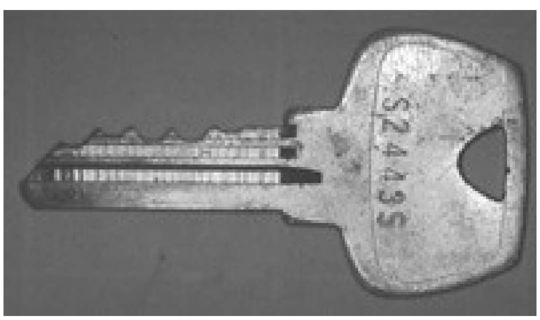
8_4.0 Key Coding

8_4.1 Introduction

All lever, wafer, disc, and pin tumbler keys are coded in some scheme by the lock manufacturer. Coding accomplishes several functions:

- **Facilitate and organize production;**
- **Properly meet customer needs;**

- **Provide complex master key systems;**
- **Inventory control;**
- **Security.**



The establishment of a coding scheme relates to each specific lock and keyway in a product line. Each manufacturer has established standard lever, pin, or wafer lengths, as well as pin diameters for each chamber (in the case of pin tumbler locks). The spacing between detainers is also precisely defined.

8_4.2 Code Numbers on Keys

A manufacturer will generally stamp code numbers on hey heads that will either be **direct** or **indirect** reading. Many years ago, for example, General Motors stamped indirect codes on their keys. These four-digit numbers could be easily read by anyone handling the key, such as parking lot attendants. It was a simple matter to then have a duplicate key cut from this code.

A federal law was then enacted that required the code to be stamped on a knockout in order to stop the improper acquisition of codes and resulting automobile theft. The knockouts had to be removed before the keys could be carried on a ring. Some manufacturers will also stamp code numbers on the lock bodies. This practice is especially prevalent in automobile locks and padlocks.

In the photograph below, a **direct code** is stamped on the head of the key. With this number, a duplicate can be generated. Note the correlation between the depth of each cut and the corresponding digit. The code is read from the bow to the tip.

LSS+804 An example of a factory original key with a direct reading code.

8_4.3 Keys from Codes

Keys can be produced from codes, courtesy of Harry Sher.

LSS205: Gale Johnson on key codes

Once a coding scheme is established, both the manufacturer and locksmiths can produce keys by code for any given lock. Silca, HPC, and others have collected all of this coding information and established sophisticated and complete databases. This information allows keys to be generated on their machines as if factory originals. The HPC CodeMax and the SILCA QUATTROCODE has these databases built into the cutter, so all the user has to do is input the type of key and direct code. The machines will do a lookup retrieve all the needed spacing and depth information and generates a key.

All depth coding on keys produced by the manufacturer will initially be in direct readable form. Each different depth will have a number assigned to it that will correspond to the actual measured depth of the cut. For example, Schlage may establish for a specific keyway the following depth correlation for bottom and top tumblers:

DEPTH CODING OF KEYS		
TUMBLER	**BOTTOM**	**TOP**
0	165	
1	180	
2	195	30
3	210	45
4	225	60
5	240	75
6	255	90
7	270	105
8	285	120
9	300	135

If the bitting is measured from either the top or bottom of the key, depending upon manufacturer, each different depth will equal precisely the vertical distance assigned to a specific depth number. In this manner, keys may be manually decoded.

The factory either will utilize the actual depth numbers for coding keys or will correlate them to unrelated indirect codes. In the Schlage example, it will be noted that each depth has a difference of .150", and those depth cuts (2-9) allow for compensation in length of the top tumbler (called balancing). This is to permit both top and bottom pins to move vertically within each chamber.

8_4.4 Direct Coding

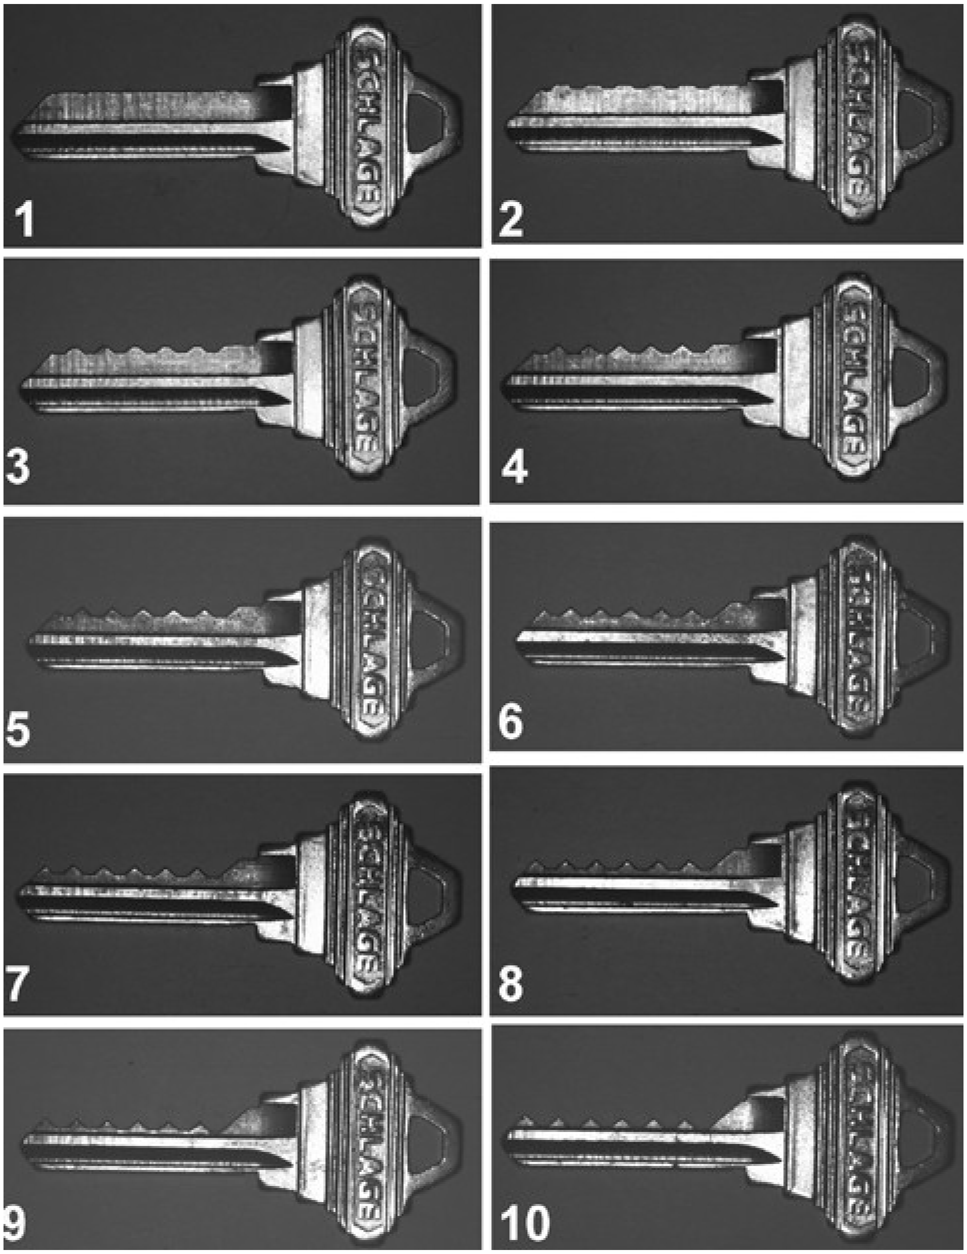
Direct coding means that the code will correspond exactly with the number of tumbler positions and their respective depths. A wafer lock, for example, may be coded by the manufacturer in the following way. The lock maker first decides there will be five different tumbler depths, each having an increment of 0.02”. Numbers are then assigned to each different depth level. A "1" cut would be 0.02” from the top of the key bitting area, a "2" cut would be 0.04”, and so on, to the number "5" cut, which would have a depth of 0.10”.

A code number will then be assigned for each key, which will in fact be the composite of all of the tumbler depths. With the direct code, it is possible to generate the key by use of the composite code number, using code machine or depth keys. Keys may also carry a code designation that is indirectly coded. This means that there is no easily recognizable relationship between the direct code number, to which the key was actually cut by the manufacturer, and the indirect code number that is assigned to the key. When indirect codes are encountered, the correct reference must be consulted to determine the actual direct code for cutting the key.

8_4.5 Depth Keys

Depth keys are available for every lock and can be used in two different ways for producing duplicates.

8_4.5.1 Depth and Spacing



Source keys can be directly decoded, using a set of depth keys as a reference. This procedure requires that each tumbler position on the source key be compared with a set of depth keys having all depth and space variations for a particular lock. The keys are analyzed until the correct depth for each particular tumbler cut of the source key is determined. The resulting derived code can

be used to cut another key by hand or using a machine.

8_4.5.2 Depth Keys as a Reference

Duplicates can also be made by using depth keys, rather than code machines, as a primary reference. Depth keys are specially cut to provide a reference for each of the different tumbler depths and spacing. Thus, a set of keys for a Schlage lock having a total of eight possible depths and six tumbler positions, would be comprised of a set of eight keys. Each key would have six tumbler positions, all cut to one depth. Thus, the first key would be cut to a direct code of 111111; the second key, 222222, and so on.

To use depth keys, determine the direct code for the target key, then substitute the proper depth key for each tumbler position to be cut. If keys are to be made by hand, each position is filed until it corresponds to the proper depth as determined from the depth key.

8_4.5.2.1 Code-Cutting Machine

The information provided by depth keys is programmed into the code-cutting machine. Bitting material is then removed to the required depth for each tumbler position.

8_5.0 Producing Keys from Code

Information

8_5.1 Introduction

In order to cut a key for a specific lock, certain information must be obtained usually directly from the source key:

- **Manufacturer of the lock;**
- **Type of lock;**
- **Blank number or type;**
- **Number of cuts.**

There are, however, instances where the source key may not be available. The information can still be obtained through other means. Circumstances that may dictate obtaining information to allow the generation of a key from alternative sources might include:

- **Keys have been lost;**
- **Keys have been improperly obtained and copied utilizing various decoding techniques;**
- **Locks have been taken apart and decoded;**
- **Law enforcement or intelligence operations requiring repeated surreptitious entry.**

Keys can be made from a source key with a cutter, or information can be obtained from or about the key while in the possession of the holder. A key can then be generated later under more secure or controlled circumstances. Keys can also be produced as a result of information obtained from the lock.

8_5.2 Depth and Space Information

Ultimately, depth and spacing information is needed to make a key. This data, for any specific key and lock, is available from a variety of sources. Once that data has been obtained, it is a relatively simple matter to produce the key, either manually by hand cutting or through the use of mechanical, electric, or computer-controlled key cutters described above.

Methods of obtaining coding information are of primary interest to criminal investigators, crime lab, intelligence, and security personnel. The information can be utilized both for operational

use and as a starting point in analyzing burglaries or surreptitious entry, or the potential vulnerability of such attack by unauthorized individuals.

8_5.2.1 Sources and Methods for Obtaining Key Coding Information

Procedures relating to decoding keys will be detailed in this section, but related information regarding the use of keys as lock picks and other relevant topics regarding keys and surreptitious entry will be found in **Chapter 29.** All applicable techniques can be accomplished rapidly, quietly, and surreptitiously.

There are many sources and methods for obtaining depth and spacing information. These include:

- **Keys visually decoded, then reproduced;**
- **Keys measured utilizing a special micrometer, the measurements translated to depth codes, then cut by code-cutting machine;**
- **Code lists kept on premises by the maintenance department;**
- **Code lists maintained by the local locksmith;**
- **Code lists accompanying invoices from lock manufacturers;**
- **Codes obtained from the factory;**
- **Professional code books produced by HPC, Reed, Silca, and other manufacturers;**
- **Codes stamped on source keys or locks;**
- **Codes obtained from the manufacturer in response to an inquiry regarding a specific lock. In this instance, fraudulent information may be provided to the vendor in order to secure the needed data or to order duplicate keys;**
- **Information retained by a manufacturer or dealer.**

The author, for example, routinely obtains the codes for motor vehicles that are to be seized as the result of drug use or other criminal activity by their owner. The procedure is quite simple. First, the vehicle identification number (VIN) is obtained through a listing by license number or registered owner. Then, a motor vehicle title search is performed to provide the chain of

title and, ultimately, the car dealer who originally sold the automobile. The dealer is then contacted for code information. If the dealer does not maintain such data, then the automobile manufacturer database is queried for the numbers. Once the codes are thus obtained, it is a simple matter to cut a key.

8_5.2.1.1 Keys Duplicated from a Source Key

Depending upon whether restricted blanks are utilized and the level of restriction, all but high-security keys may generally be duplicated without difficulty at locksmiths, hardware stores, gas stations, and many other retail establishments. Direct duplication requires that the source key be available to take to a cutting machine to make at least one copy. If there is a machine on premises, then the task becomes easier. Source keys can be borrowed, removed temporarily without permission, or stolen.

8_5.2.1.2 Keys Ordered from Manufacturer by Unauthorized Person

Keys may be ordered from the original manufacturer or from a local locksmith by submitting false authorization forms or letters to obtain duplicates. The locksmith will generally produce keys by code without verifying the authority of the requesting individual. Likewise, a manufacturer will often supply keys based upon letterhead requests. In any investigation involving access by keys, especially where high-security locks are installed, one source of information would be the lock supplier or installer regarding recent orders for duplicates.

8_5.2.1.3 Keys made by Visually Decoding the Lock or by Using a Depth Gauge

Locks may be visually decoded by looking into the plug and examining the position of each tumbler or by a depth gauge. Visual decoding is generally employed with wafer locks. Unlike the practice of actually disassembling the lock to obtain the required depth and spacing information, this procedure only requires proficiency in viewing and judging the tumbler positions through the keyway. A thorough explanation of the procedure is provided in **Chapter 31.**

8_5.2.1.4 Code Numbers, Books, and Lists

There are many sources for key coding information provided directly by the manufacturer, or taken from new keys and locks by locksmiths and then transmitted to code list vendors for compilation and publication. A number of companies produce comprehensive lists of key and combination codes for the locksmithing industry, both in printed and computer form. **HPC**, Reed, **Silca**, and a number of other vendors sell code books that encompass U.S. and foreign locks.

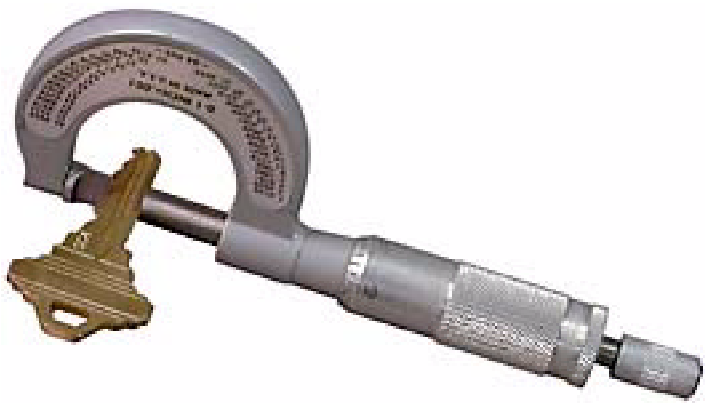
Figure LSS+823 HPC makes their codes available on handheld, laptop, or desktop computers. Shown is the HP720 handheld. Hewlett Packard produces one of the most sophisticated devices for this purpose. The HP720 is a 206 MHz. processor and allows the storage of more than 1 Gigabyte of data on removable PCMCIA cards.

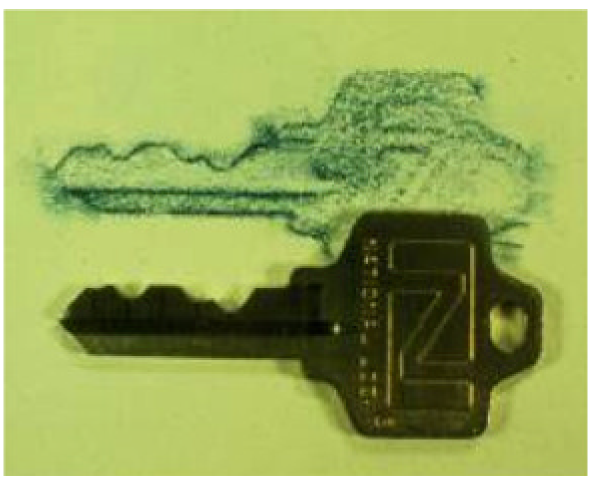
8_5.2.1.5 Keys Made by Visual Inspection of a Source Key

Keys can be visually decoded and later reproduced. With knowledge of depth and spacing parameters for any given lock, it is generally a simple matter to visually inspect a key and derive the direct code for each tumbler. Depth keys or a code machine is then utilized to cut the key. Visual decoding requires that the source key had been cut by code originally, so that the bitting depths are precise.

8_5.2.1.6 Keys Made by Precise Micrometer Measurement

A micrometer, such as the **HPC SKM-2D**, or the HPC **KM-60** may be utilized to precisely measure each depth and spacing position of a source key. A duplicate can then be directly generated from this information, or the data may be correlated to direct codes and input to a code-cutting machine.





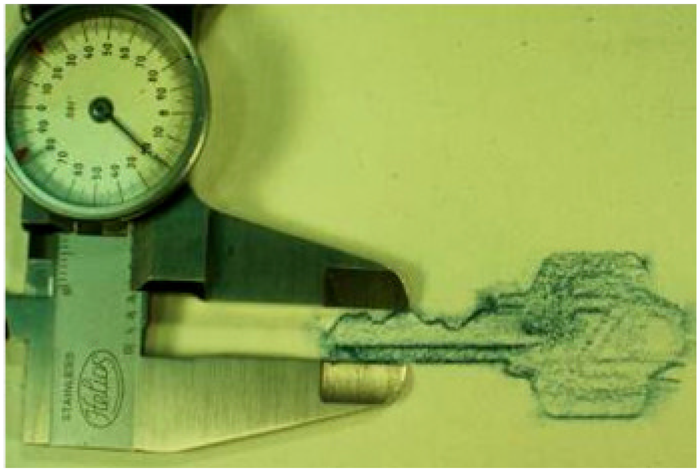


Figure LSS+824 The HPC KM-60 direct reading micrometer.

8_5.2.1.7 Keys Made by Photograph

Source keys can be photographed for an exact 1:1 reproduction. This will generally be accomplished using a macro lens and a finely graduated ruler placed alongside the source key for use as a reference. Likewise, keys may be traced, then measured or decoded. Keys may also be overlaid onto photographic paper and exposed for a precise outline, or placed in a 1:1 copy machine. In the photographs below, a key has been copied by the use of carbon paper, then decoded by measuring the 1:1 reproduction.

8_5.2.2 Keys that are Made by Taking Apart the Lock

Direct codes can be derived by disassembling the lock and examining each tumbler location. A correlation of each tumbler depth to a direct reading code is performed, then a key is cut to that code. The individual tumblers can be measured using a micrometer. Keys can also be made directly from the lock, once taken apart, by cutting the blank until all tumblers, wafers, discs, or levers are visually aligned at shear line.

8_5.2.2.1 Procedure to Produce the Key

A lock may be taken apart in order to produce a key directly from the tumblers. The procedure requires that each tumbler position first be marked on the surface of a blank key inserted into the plug. This will precisely indicate the correct spacing for each chamber. Cuts are then made into the bitting with the proper file for each tumbler. Material is removed until that tumbler is aligned exactly at shear line. Fitting keys to locks is more thoroughly explained later in this chapter.

A special note is required regarding the reproduction of keys for General Motors locks. When the glove compartment cylinder is taken apart in an effort to produce an ignition or door key, some experimentation is required. The glove box lock uses four wafer tumblers, in contrast to the six-wafer tumbler sidebar locks used everywhere else in the car. Thus, the last two tumblers must be determined by a progressive method until the correct combination is found. Since 1974, the ignition cylinder is keyed by itself. The door, trunk, and glove compartment locks are all keyed alike.

8_5.2.3 Keys Made by Impressioning a Lock

Keys can be generated by impressioning the lock. The procedure does not require disassembly and can often be accomplished quickly and without detection. Techniques for impressioning are covered in **Chapter 30**.

8_5.2.4 Keys Produced from Impression Material

Copies of keys can be made by the use of various impressioning materials, including Styrofoam, wax, clay, silicone rubber compounds, epoxy, and low-temperature ductile metals. The copying of keys by these materials should not be confused with the impressioning of locks that involve the production of a key from markings made by tumblers. Specific casting and impressioning techniques utilizing these materials are presented at the end of this chapter.

Impressioning can be accomplished quickly and in virtually any environment. The procedure will allow the copying of any key including restricted blanks. The resulting copy may be used to operate a lock directly, or a brass or nickel silver duplicate can be made. The Silca Quattrocode key machine will generate duplicate keys from impressioned keys using a laser scanner, thus insuring that no damage occurs to a "soft" duplicate.

8_5.2.5 Keys Made by Picking and then Decoding the Lock

Some locks may be picked to an unlocked position, then visually decoded for generating an original key. A borescope may also be used to look down the keyway of a picked plug to determine tumbler depths. In one investigation of surreptitious entry, the author was able to determine that a specific type of lock could be picked, then visually decoded. This would allow a thief to derive the master key combination from only one cylinder without the necessity of ever taking the lock apart.

8_5.2.5.1 Keys Made with a Pick/Decode Tool

Specialized pick tools will decode and display each tumbler using feelers as the tumbler is aligned and brought to shear line. Tubular lock picks in particular will usually allow the generation of a key.

8_5.2.6 Other Methods of Obtaining Code Data

Keys can be produced for warded and some lever locks by placing carbon or wax deposits on a blank key. It is then inserted to obtain markings of the tumblers. This technique is detailed in **Chapter 30.**

8_5.2.7 Keys Made by Feeling and Decoding the Tumbler Positions

In certain cases, keys can be generated through the use of special feeler picks or tools. These devices are inserted into a lock to feel the position, rotation, or depth of each tumbler. This technique has special application to Medeco sidebar and Abloy disc locks. It is discussed more fully in **Chapter 31.**

8_5.2.8 Keys Produced Using Foil Overlay for Dimple Locks

Certain dimple locks can be picked and impressioned utilizing aluminum or similar metal foil. Once the procedure is accomplished, the foil can be decoded and a key produced from the impressions left by the tumblers. The procedure for opening locks utilizing this technique is covered in detail in **Chapter 31.**

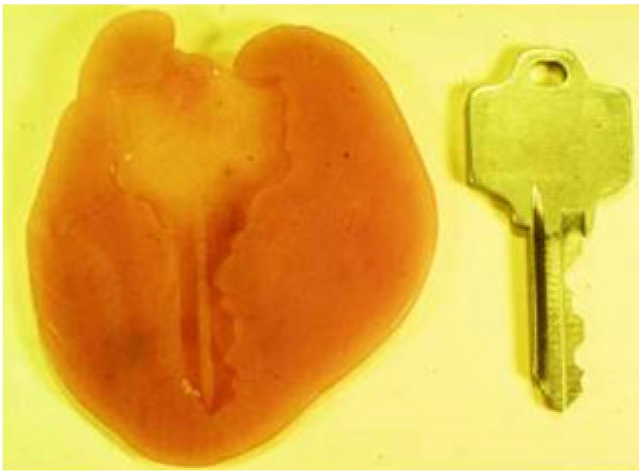
8_5.2.9 Master Key Generation

Master keys can be generated by a variety of methods, generally involving the taking apart of one or more locks. This process requires extreme caution and attention to detail during the disassembly procedure, because the orientation, sequence, and placement of each tumbler segment is critical. It is often necessary to take apart several locks to determine the correct master key code in a complex system. The principles of master key systems are detailed in **Chapter 11.** Once a cylinder is disassembled, one or more levels of master keying can be determined by an examination of the tumblers. In certain instances, however, it is not even necessary to open a lock in order to derive the code of the master key or change key. Cylinders may be shimmed and the splits of all pin stacks determined through the use of depth keys. Master key systems can be analyzed and the top level master key determined through a process described in chapter 31.

The author has conducted investigations in cases involving special types of cylinders where disassembly was not required to determine master key coding. In the case of certain magnetic based locking systems, the master key can be derived with little difficulty through the examination of several locks. The composite coding will provide the necessary information. In contrast, standard pin tumbler locks will not ordinarily yield master key coding data from an examination of individual change keys.

8_6.0 Making Copies of Source Keys by Impression

This section provides detailed information about how keys can be reproduced from molded impressions. **Chapter 30** explains the process of impressioning a lock to produce a key from **tumbler markings.** The two types of impressioning methods are quite different, yet they are employed to accomplish the same result: to produce a working key for a given lock.



8_6.1 Introduction

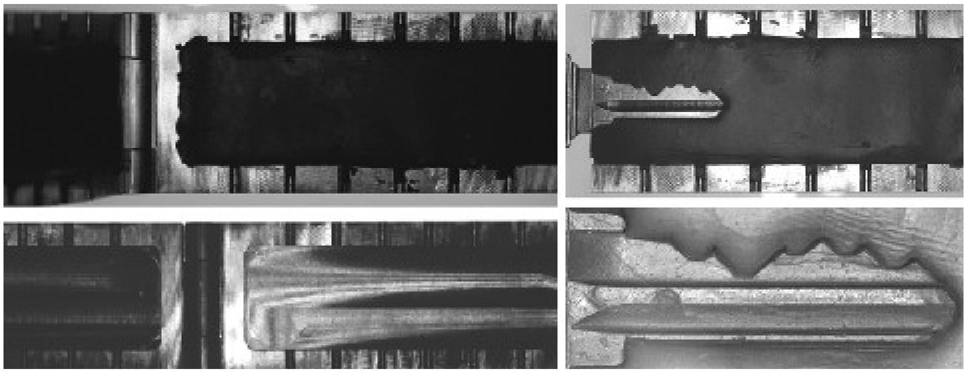
Impressioning techniques were developed at least two hundred years ago by thieves for making secret copies of keys. The first documented major crimes occurred in Europe during the nineteenth century, using keys obtained by wax and clay copies. One of the most famous cases involved the theft, in the early 1800s, of a gold bullion shipment en route from England to France worth £12,000. The shipment was stolen in transit by the use of a key produced by impression to open a safe on a railroad car.

In a similar theft, a like amount was taken from the Bank of England, in a scheme that took months of careful planning to execute. In this case, a bank officer was befriended. After gaining his confidence, one of the perpetrators was able to obtain the bank and vault keys from the employee's jacket pocket for a few minutes. Copies were made and the bank was successfully burglarized.

There have been many instances of keys being copied through impressioning techniques. Today, these procedures can be of value in certain security and intelligence operations. Crime laboratory examiners also employ impressioning and casting

techniques for lifting tool marks, fingerprints, footprints, and other unique evidence. There are several methods of impressioning and casting keys, using materials such as wax, clay, silicone, epoxy, and low temperature metals. The photograph below shows a key that has been copied by making an impression in wax.

The requirement to impression keys generally occurs during intelligence and security operations and in certain evidence-gathering procedures by crime laboratories. Within the context of intelligence and security, the employment of impressioning techniques is dependent upon a number of factors that are outlined in **8_6.3** below.



8_6.2 Overview of the Process

LSS201: Procedure for making keys with a clay mold. Courtesy of MSC.

The procedure for producing a copy of a source key occurs in two stages. Initially, an impression is created as an exact negative image or replica of the key. The precise outline is imprinted into a soft material that will retain the exact dimensions of the source key without distortion. This can be accomplished using silicone or clay. The material is formed within a mold, into which the source key is briefly impressed.

Next, a casting is made to create a positive image, or exact physical replica of the source key. A positive image is formed by pouring molten metal, epoxy, or silicone into the mold containing the impression of the source key. This positive can then be used to directly operate the lock. Otherwise, a copy will be made of the product of the casting in a hard metal such as brass or

nickel silver. See detailed explanation and photographs below.

8_6.2.1 Definitions

The following terms relating to casting and impressioning will be used in our discussion.

Casting is the process of creating a positive image or copy of the source key, through the infusion of material into a mold.

Impressioning refers to the procedure for obtaining and replicating the exact negative image of the source key.

Mold retains the impression of the source key as a negative image contained within wax, clay, or silicone.

Negative Image is the term that defines the original impression of the source key. The negative image is created when the source key is exposed, under pressure, to the impressioning material.

Positive Image is the term defining the product of the casting process after infusion or pouring of material into the mold. The positive image is the actual duplicate source key.

Setup Time refers to the time required for the impressioning or casting material to change from a liquid to a solid, permanent state.

Shrinkage defines the amount of contraction of the casting material that occurs as it changes from a liquid to a solid state. Typically, the shrinkage factor is relevant when low-temperature metals are poured into the mold. During cooling, the metal will slightly contract, causing a minute change in dimensions of the target key.

Source Key is the original key being copied.

Target Key is the key produced as a result of infusion of casting material into the mold. It is the positive image of the source key.

8_6.3 Preliminary Considerations for Impressioning

A number of factors will determine whether impressioning is an appropriate procedure. The following considerations are relevant:

- **Time to make the original impression;**
- **Time to keep the original key in order to verify a good impression has been secured;**
- **Design of the source key and its ability to be withdrawn from the mold without distortion or damage;**
- **Necessity of casting rather than utilizing other technique;**
- **Can the source key be duplicated in a cutter rather than cast;**
- **Location where the source key must be impressioned and where the duplicate key is to be made;**
- **Availability of casting materials.**

8_6.4 Difficulties with Impressioning Techniques

Three major difficulties can be encountered in impressioning or casting procedures.

- **Setup time can be critical in sensitive or urgent operations when using certain materials. Thus, if an operation does not allow much time for processing, then selection of the casting material is extremely important.**
- **Shrinkage after setup can cause tolerance errors in the target key that may result in malfunction. Poured molten metal has a tendency to shrink slightly. This will result in distorted dimensions of the target key.**
- **Soft metal targets may be damaged unless laser**

copied or decoded . If soft metal is poured into the mold to make the original cast, then a harder metal such as brass will be required to make a duplicate of the target key. Otherwise, the original duplicate may be distorted or damaged when inserted into a lock.

8_6.5 Materials Suitable for Casting and Impressioning

Many materials may be used for casting and impressioning.

8_6.5.1 Impressioning Materials

Recognized standard impressioning materials include clay, wax, and silicone. The author utilizes Fimo clay and Kerr Extrude silicone.

8_6.5.2 Casting Materials

Several materials are suitable for casting. These include silicone, Cerrobend or Cerrosafe (low temperature metals), epoxy, and wax. Each material requires a slightly different casting technique.

8_6.6 Impressioning

The initial operation to produce a duplicate source key requires that an impression be obtained. The following discussion relates to impressioning as the precursor to casting.

8_6.6.1 Implements for Impressioning with Clay

The following tools are necessary when using clay as an impressioning medium:

Mold: The impressioning compound is held by the mold. They generally take the form of clamshells or small square boxes, into which agents are poured or impressed. Molds can be made of many materials, but are generally constructed of aluminum, hardwood, plastic, clay, silicone, or layers of sheet aluminum. A mold should measure no less than 4" x 5" x 1" if using metal as a casting compound, and 3" x 1.25" x .25" when casting in clay, epoxy, or other material. Obviously, the exact measurements will

in part be controlled by the length, height, and thickness of the source key. In the case of silicone impressioning, the author uses a small shot glass to hold both the source key and silicone. When the mold is in the form of a box, seating pins are generally anchored on one side of the mold. When the two halves of the mold are pressed together, the pins provide for exact registration of the halves.

Clay: Modeling clay is generally utilized for impressioning. It should be warmed prior to use so that it is easy to manipulate, form, and cut.

Scraper: A scraper is required to trim excess clay from the edges of the mold.

Artist Brush: It is used for spreading talc over the mold.

Slicer: It is used to trim excess clay.

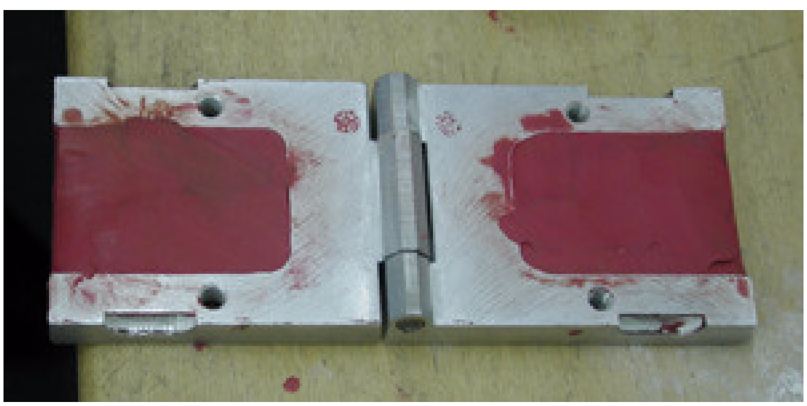
Mold Release: A lubricant is required to keep the impressioning compound from sticking to the source key. Talc, WD-40, silicon spray, Pam, or mold release is recommended.

8_7.0 Impressioning Procedure

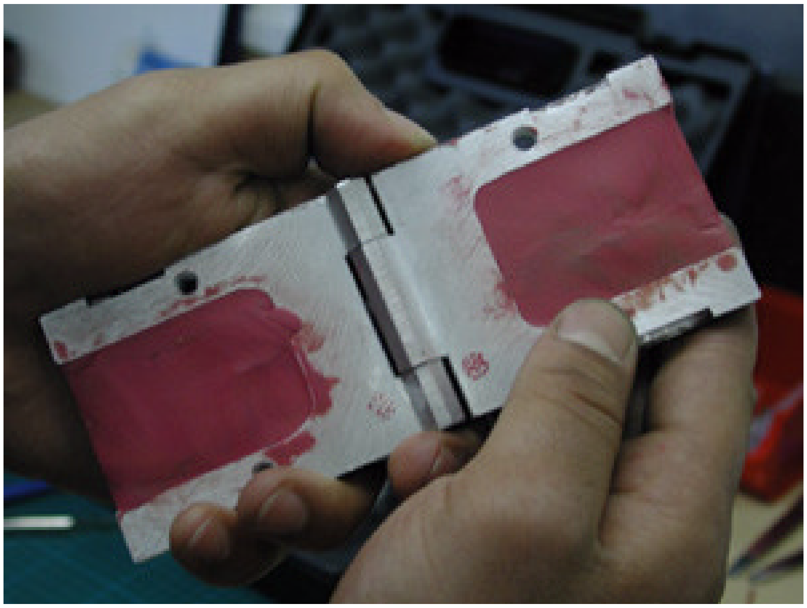
Procedures for impressioning with clay and silicone are detailed below. Although the process is straightforward, there are a number of difficulties that can be encountered which can affect the accuracy and quality of the target key. These were summarized in **6.4** above.

8_7.1 Procedures for Impressioning Using Clay

Impressioning requires insertion of the source key into a mold containing clay, to create an exact impression of the bitting. A casting material in fluid form is then poured into the mold and allowed to harden until a firm, positive image is obtained. Materials that are required to properly complete the process include prepared mold halves, masking tape, and the source key.

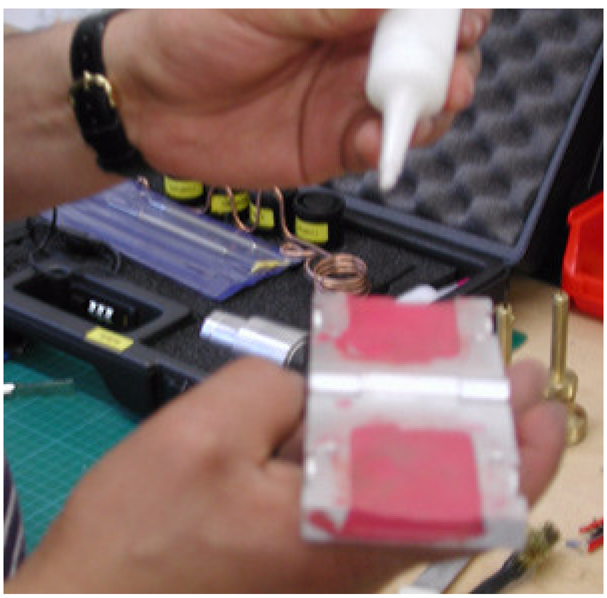


Keys can be copied through the use of clay molds. Courtesy of Hans Mejlshede.



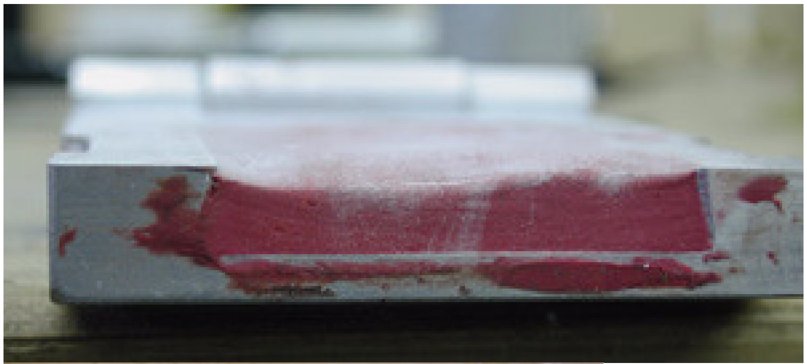
8_7.1.1 Detailed Procedure

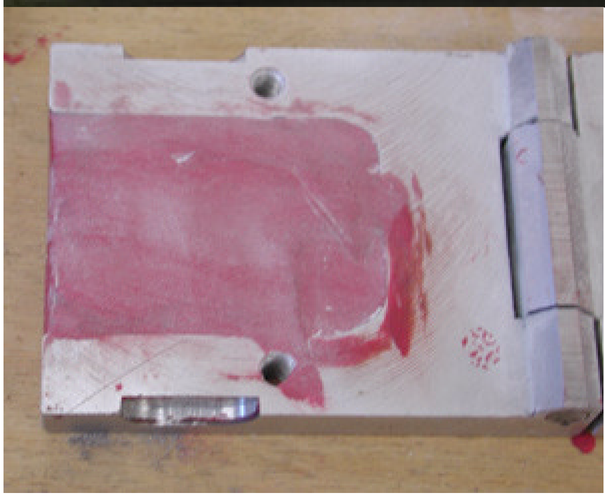
Clay must be pressed into each half of the mold in separate actions and then worked so that it is evenly distributed. There should be no overlapping of clay between the halves, although the clay should initially protrude slightly above the mold. The material should be devoid of cracks to prevent chunking or flaking apart. If there are holes, gaps, or flakes in the surface, more material should be added to the open end of the mold and worked into the mass. Clay should not be added directly to the surface.



Once material is evenly impressed into each half of the mold, a cheese slicer should be used to trim the substance so that it is even with the top edge. Caution should be exercised not to cut any clay below the level of the mold. A scraper can be utilized to remove excess clay from the ends. A fine line should be run through the surface to allow air to escape, and to prevent air bubbles.

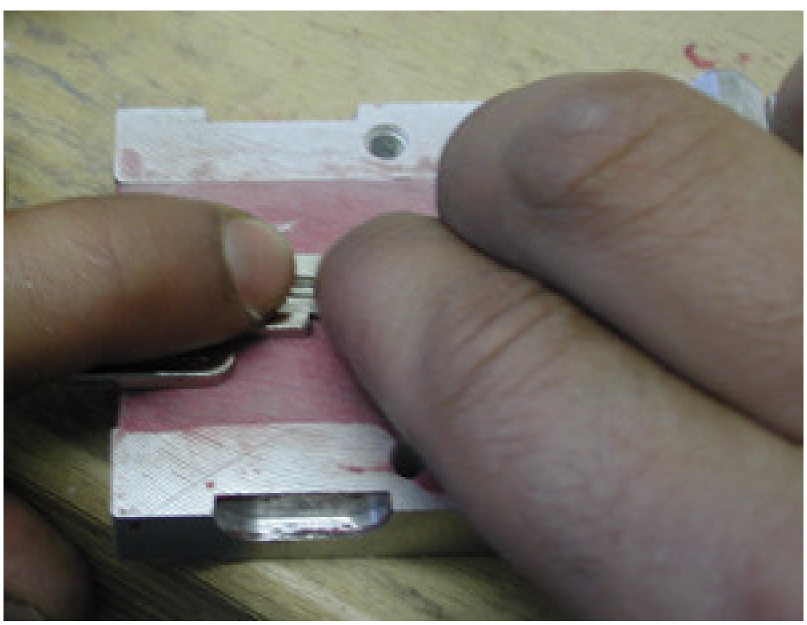
Both sides of the mold should then be dusted with talc using an art brush to prevent the clay from sticking to the source key. WD-40, silicon spray, or mold release is suitable for this purpose. Then, the mold is closed, making certain that there is no extra clay protruding on the surface. The mold should fit together tightly, with any excess clay being removed.





LSS+805 The aluminum mold is prepared by filling with clay, then smoothing the surface to insure uniformity in the impression.

LSS+806 Talc or other lubricant is applied to the clay to facilitate removal of the source key after an impression is taken.



LSS+807 The excess clay is trimmed from the edge of the mold.

LSS+808 The source key is gently placed in position within the mold.

LSS+809 The source key is impressed into the clay to about half of its physical depth. This insures that both halves of the key will be equally impressed in the material.

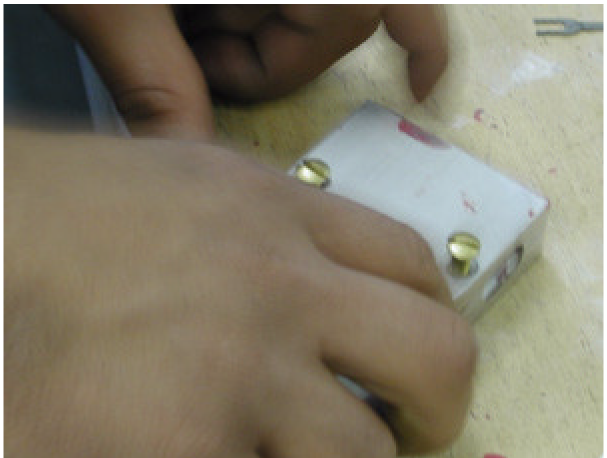
8_7.1.2 Potential Problems During Impressioning

There are a number of potential problems inherent to impressioning in clay. The technician must understand and be able to correct deficiencies in the process to obtain the desired result in the subsequent casting. Simply, these problems relate to an uneven, skewed, or warped impression that will result in unusable negative images. Raised edges within the mold indicate a warping of the original impression, which may cause errors in the target key. This can result in an imprecise copy of the original. Tolerances between the source and target must be held to .002”. Any impressioning errors will likely cause the target key not to work. Warping problems and resulting distortions can be caused by a number of procedural errors. These include:

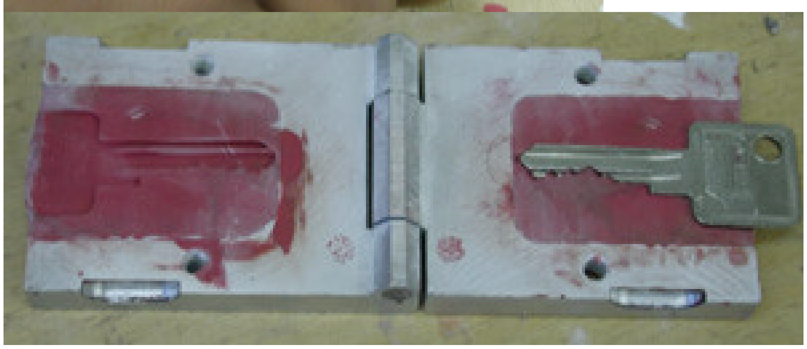
- **Excessive twisting of the key when removing it from the mold;**
- **Pushing or pulling the key while loosening it;**
- **Failure to lift straight up;**
- **Carelessness in removing the key from the mold;**
- **Creation of air bubbles.**

8_7.1.3 Making the Key Impression Using Clay

Although clay is an excellent impressioning medium, it must be prepa properly to prevent casting errors. The following protocol should be followed to produce an impression of the source key.



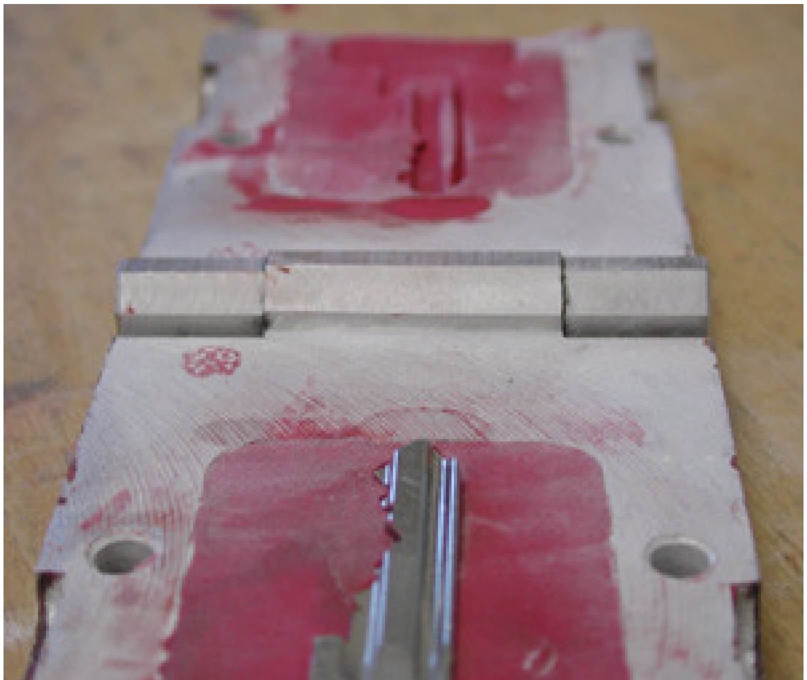
- **Press the key slightly into one side of mold, just**



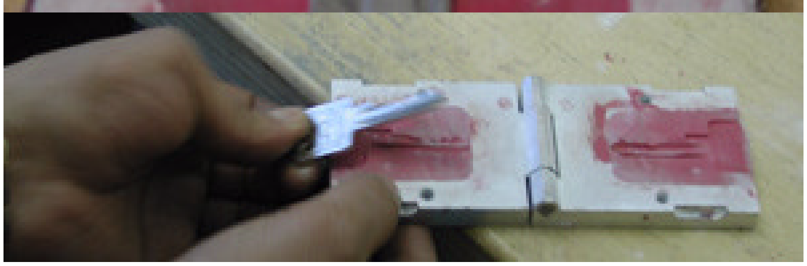
far enough to be held in position by the clay;

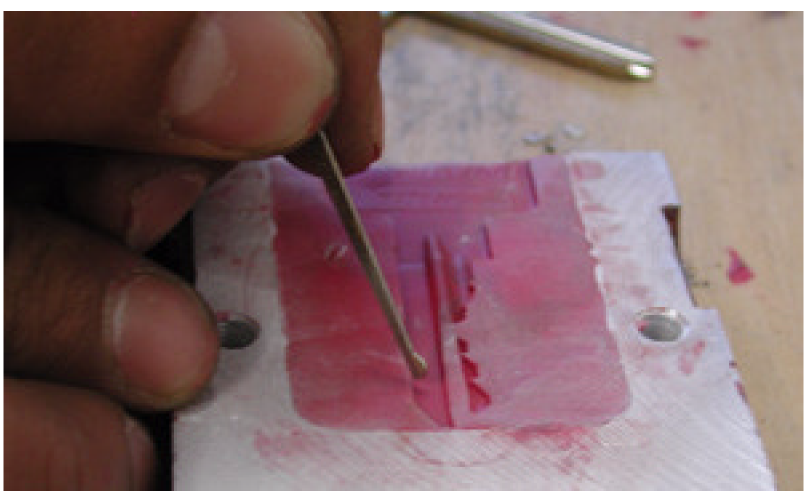
- **Allow half the bow of the key to rest in the clay. This is very important, because a handle is needed to remove the key from the clay once the impression is taken. In addition, keyhead identification data will be impressed into the clay;**
- **Place both halves of the mold together to form a tight fit, being certain that the halves align with the open end out. Be careful that the two halves are exactly parallel when pressing together, so that the resulting impression is not skewed;**
- **Hold the mold together for a few seconds to be certain that an impression is taken. High pressure may be applied to the mold to insure a solid imprint. This may be accomplished by clamping it in a vice or standing on the mold;**
- **The two mold halves should be split apart very carefully while in a vertical plane on a flat surface. If the mold does not come apart easily, the halves must be slowly worked apart with the key facing up;**
- **Lift the key straight up and out of the mold, gently twisting to remove;**
- **Place the mold halves on a flat surface with each of the clay sides facing up, being extremely careful not to damage the impression just taken;**
- **The resulting negative image must be inspected to insure the uniformity of impression and the lack of raised edges;**
- **Create a funnel within the clay, to be used when pouring molten metal into the mold. This is accomplished by cutting away a little clay from each half of the mold, so a narrowed entrance is created at the open end, about 1/4" in diameter. This technique will allow metal to flow quickly into the mold. A letter opener, flat end of a screwdriver, or pen knife may also be used to create the funnel effect;**
- **Dust the impression with one of the lubricants noted above in order to allow release of the target key after casting;**
- **Put the mold together, being certain that the ends**

are aligned properly;



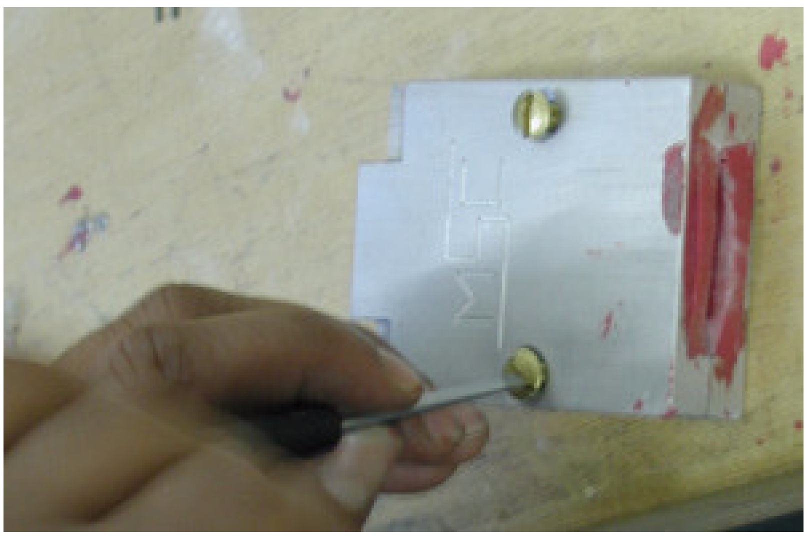
- **Tape the mold together or use rubber bands.**

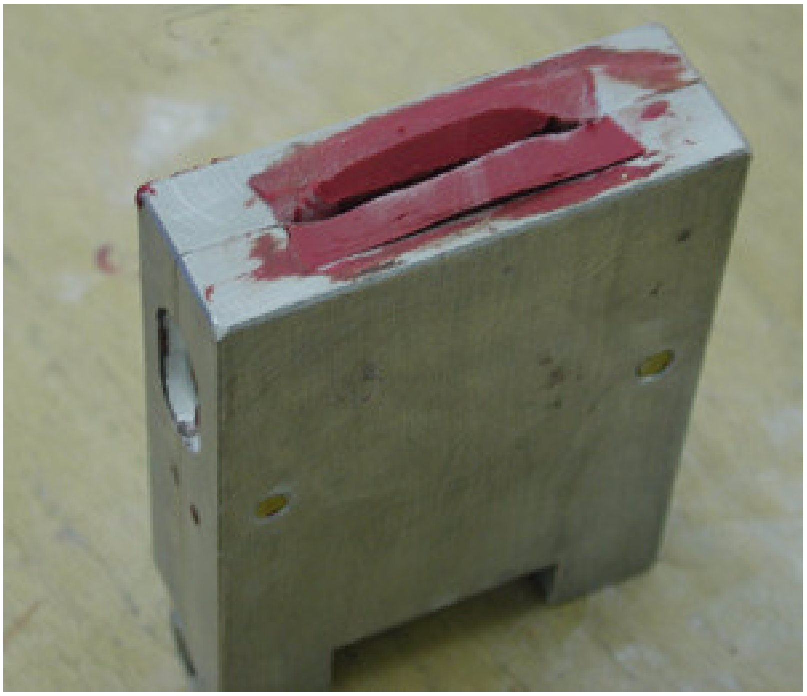




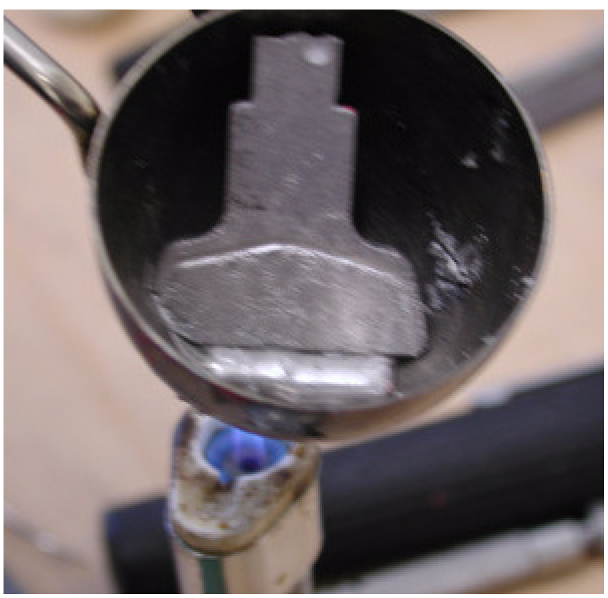
LSS+810 The mold is closed with the source key inserted. Pressure is applied to the closed mold to create an impression.

LSS+811 The mold is then carefully opened.

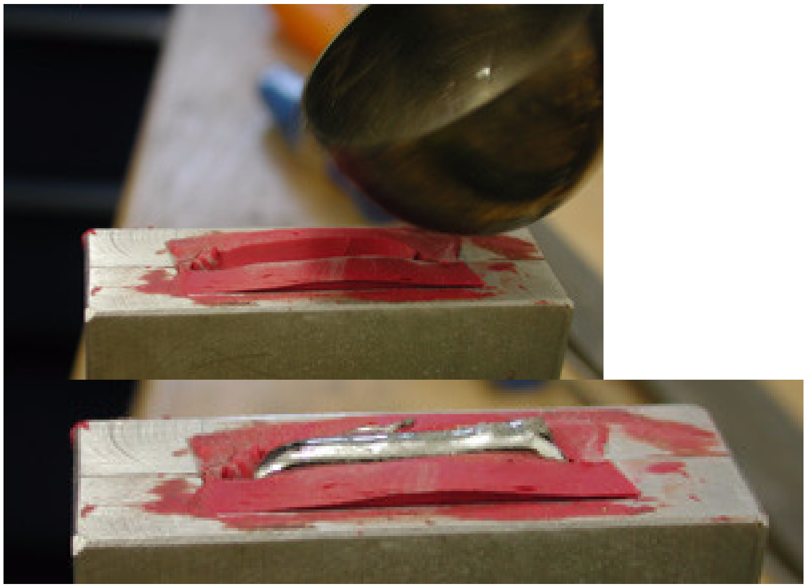




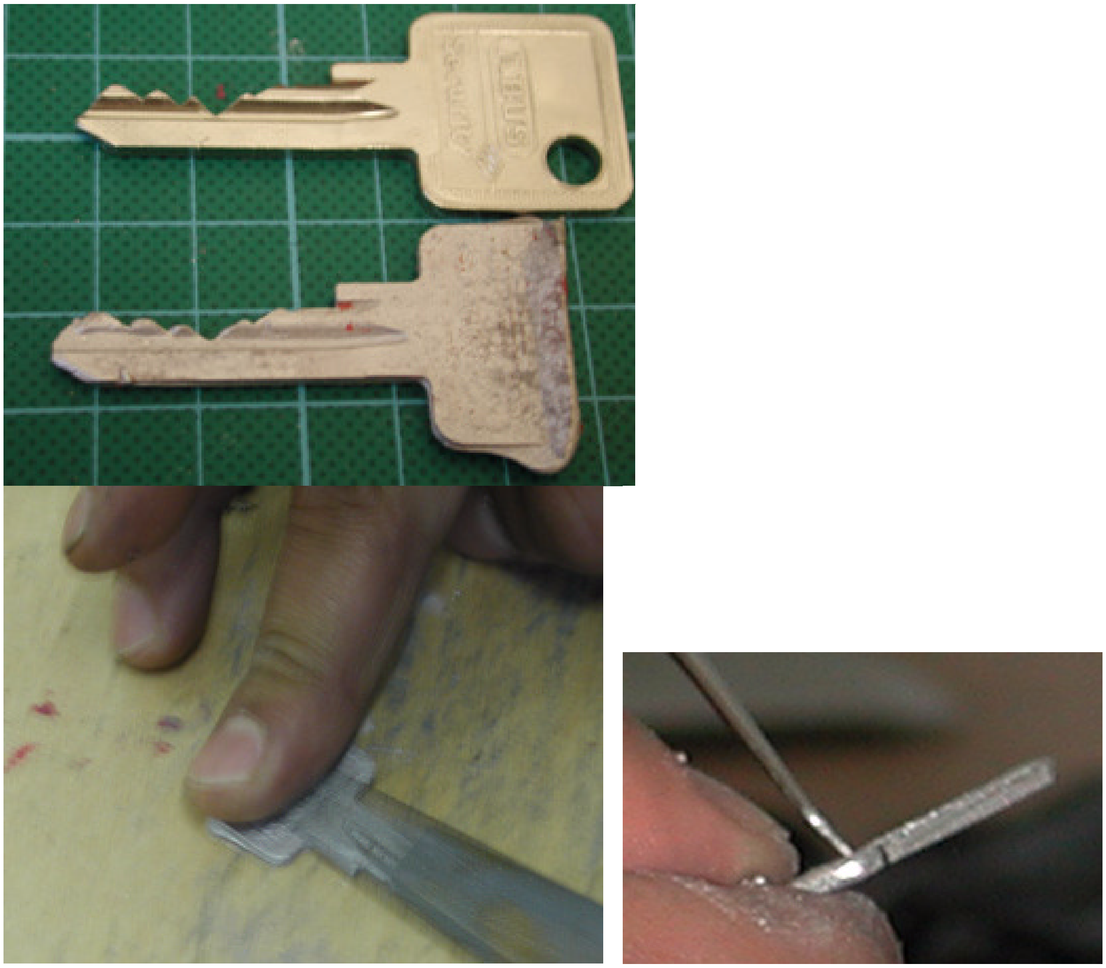
LSS+812 The key is carefully removed from the mold, taking care not to distort the impression.



LSS+813 A matchstick or other tool is used to produce a track for the release of hot gasses generated
during the pouring and cooling of the molten metal.



LSS+814 The mold is secured.



**LSS+815 A small amount of low melting temperature metal is inserted into a crucible
and reduced to its liquid state. It is then poured into the slot of the mold.**

**LSS+816 The mold is allowed to cool. It is then opened, to reveal
a positive copy of the source key.**

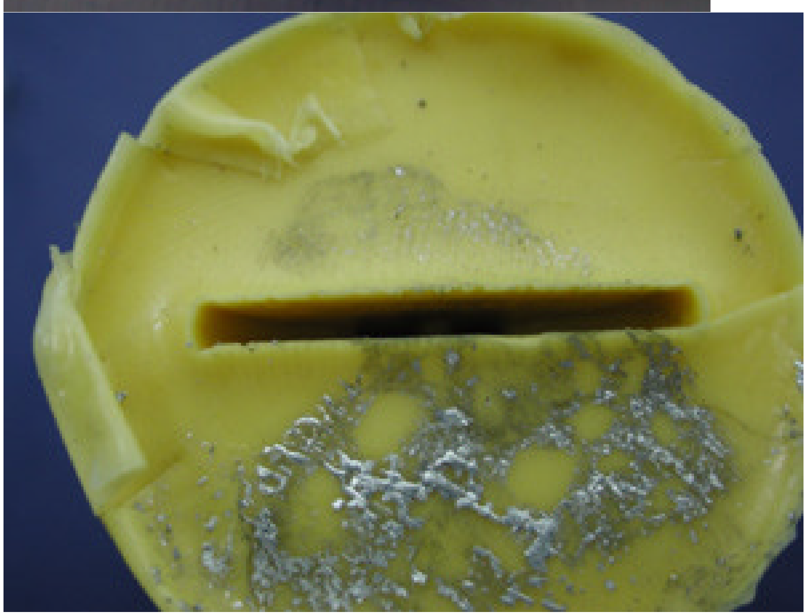
LSS+817 The key is removed, compared, and any burnishes are removed from it surface. Milling of the key may be required if the impression was not precisely symmetrical in the mold.

8_7.1.4 Silicone Impressioning

LSS201: Making keys by silicone impression, Courtesy of MSC

Silicone is an excellent impressioning medium; its only drawback is the time required to set. Kerr Extrude is utilized by dentists for taking impressions of teeth and is quite suitable for work with keys. Kerr Extrude and similar materials will harden within seven minutes, although there is a quick-setting formula that will be ready for casting in less than three minutes.

Silicone generally is supplied as a two-chemical process, much

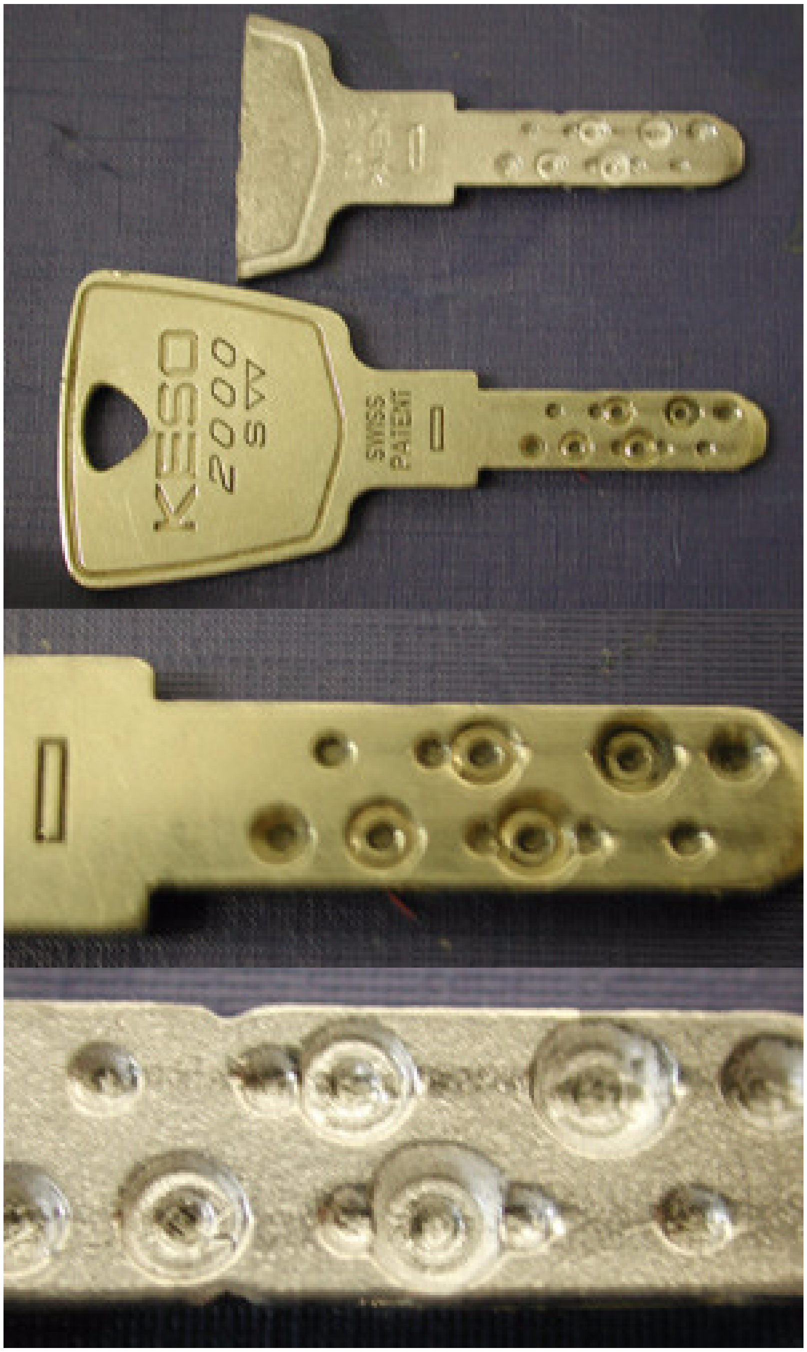


like epoxy. The chemicals are automatically mixed through a syringe gun and are ejected from the tip as a low viscosity liquid, which flows easily around the key.

MSC in Germany produces a kit for the impression copying of keys using a silicone-based product. Their system includes an electric vibrator to insure proper mixing and release of all air bubbles in the silicone material, prior to setup.

The author prefers silicone to clay because of its consistent results and high definition. To impression in silicone, simply:

- **Spray the source key with silicon, light oil, WD-40, or other lubricant, to allow removal from the mold after setup. Although this is not absolutely necessary, it can help when dealing with a complex key design;**
- **Place the source key into a shot glass or other small container. It may be necessary to run a pin, wire, paper clip, or similar item through the head, to suspend the key and prevent it from touching the sides of the glass;**
- **Infuse the silicone into the container until the key is almost fully immersed, leaving a small portion of the head to allow removal when completed;**
- **Lightly rap the bottom of the container on a tabletop several times to release air bubbles, in order to insure proper flow of the material;**
- **Wait for the silicone to harden;**
- **After setup, slightly move the key within the mold to release, and withdraw.**



**LSS+818 Silicone is used to create a negative impression of the source key. The key is surrounded
by the material and allowed to set. The key is then removed and molten metal is poured into the
impression. The result if an exact replica of the source key. A 35mm plastic film container or**

shot glass may be used to hold the silicone during the process.

LSS+819 The silicone block has been removed from its container and cut in half to show the details of the impression. Silicone, unlike clay, allows multiple castings to be accomplished.

LSS+820 The source and target key in two different castings are shown. Exact detail is replicated.

8_7.1.4.1 Impressioning Stamped Numbers on Metal

Silicone may be utilized to make impressions of stamped numbers on metal surfaces. This can be a valuable technique in vehicle theft investigations and other cases where minute marks must be preserved and reproduced. High resolution reproductions can be obtained, if the correct materials are utilized. In one homicide investigation involving a two year old child, the author was able to produce a detailed reproduction of bite marks produced by the victim in his arm.

The following instructions are for making an impression of stamped numbers in metal.

- **All casts should be taken before any number restoration is attempted**
- **Casts should be made with a silicone with sufficient resolution (viscosity)**
- **Thoroughly clean the area of any foreign matter All contaminants including paint and dirt should be removed from the stamped area with a suitable solvent (acetone, alcohol, gasoline, commercial paint remover or "Goo Gone"). A toothbrush can be used for this purpose. A wire brush should never be utilized, as it can produce artifacts that can make identification impossible, and also cause evidentiary problems. Naval Jelly or Goo Gone can be employed to remove rust;**
- **After the surface is cleaned, a dam of pliable clay or similar material should be built around the target area to retain the silicone during setup;**
- **Prior to forming the dam, nylon filament tape or masking tape should be applied at each end of the stamped characters and partly within the dam area to facilitate the cast removal.**
- **All voids around the dam should be sealed to prevent leaking and to insure consistent contact with the target area;**
- **Once the silicone has been poured and set, lift up on the ends of the tape to remove the cast. If the silicone contains significant amounts of paint and rust, additional casts should be made for optimum resolution.**

8_8.0 Casting

The following discussion relates to casting, using low-melting temperature metals, in terms of necessary tools and materials, and specific procedures to reproduce a target key.

8_8.1 Potential Problems in Casting

Two primary problems can occur during the casting process that will require a new impression or casting to be made.

8_8.1.1 Absence of Bitting

An absence of bitting in the cast can result from a lack of penetration into the impressioning material by the source key, trapped air causing bubbles, or too rapid cooling of the metal. If metal cools too rapidly, simply heat the metal longer before the next casting attempt. This problem can often be corrected by recasting. Generally, the mold is not damaged.

8_8.1.2 Blurring of Bitting

Blurring of the bitting generally occurs from air bubbles or damage to the impression material during the impressioning portion of the process. Carefully examine the actual impression against the original key, and take another impression if required. If a new impression is made, rework the old clay and add the clay that was scraped from the mold in the setup process.

8_8.1.3 Bitting Includes thin Sheets of Protruding Metal

This problem is caused by the two halves of the mold not being closed tightly enough, which leaves air spaces into which metal will flow. The problem can be corrected by filing the metal from the target key.

8_8.1.4 Under or Overheating of Metal

If the metal used in the casting process is not heated to the correct temperature, problems will occur. These will affect how the metal flows, which can also cause damage to the impression. If the metal is not raised to the proper temperature prior to casting, then it will cool too rapidly when poured into the mold. This will result in uneven flow. In contrast, if the metal is brought to a temperature higher than required, the mold material may be softened, causing distortion in the impression. A candle or other heat source such as a small torch may be used, if attention is paid to duration of heat application.

8_8.2 Tools and Materials

Specific tools and materials are required to produce accurate and useable castings.

8_8.2.1 Tools

- **Cheese slicer;**
- **Candles, boiling water or other heat source;**
- **Thimble with a twisted wire handle, or other container to hold molten metal.**

8_8.2.2 Materials

The following materials are required for casting using low melting temperature metals:

- **Alloy slug;**
- **Mold containing impression;**
- **Ladle;**
- **Heat source, such as matches and candle or boiling water.**

8_8.3 Casting with Low Melting Temperature Metals

Low temperature metals can be melted and poured at a temperature of about 158°F. The proper procedure for producing casts with low melting temperature metals is straightforward:

THE CASTING PROCESS	
STEP 1	**Place a drop of wax on the bottom of the candle to hold in position.**
STEP 2	**Place a drop of wax on the bottom of the candle, to hold in position.**
STEP 3	**Place an alloy slug in the ladle.**
STEP 4	**Melt the alloy slug for about thirty seconds, until molten. ladle should be positioned about 1/4" above the tip of the This will produce the highest and most reliable temperature**

	This will produce the highest and most reliable temperature
STEP 5	A few seconds prior to pouring the molten metal, hold the m the ladle to warm the mold material. This will delay the p cooling of molten metal in the mold;
STEP 6	Pour the metal into the mold. In order to release air bubbl may build-up, tap the mold on a surface several times, allo molten metal to flow evenly.
STEP 7	Do not proceed until the metal has turned to a solid. This generally occur within two minutes.
STEP 8	Release the two mold halves.
STEP 9	Remove the casting from the mold, utilizing the same tech caution as was employed when the source key was removed aft impressioning. This operation is more critical, however, be there is no longer a bow of the key to hold onto. A corner scraper can be used to lift the casting from one edge. The should be inspected for defects. Recast if the positive im appears damaged, distorted, or unusable.
STEP 10	Make a copy of the cast key in brass or nickel silver. Unl is no alternative, the casting should never be used to oper It should only be employed for the production of a duplicat key, because the casting is too soft for actual use.
STEP 11	If the actual cast key is inserted into the lock, a turning should be used to avoid excessive stress on the soft metal Also, be certain to clean any flash or metal ooze that may developed during the casting process.

8_8.4 Casting with Silicone

After an impression has been produced, silicone can be utilized as an excellent casting medium. After the source key has been withdrawn, a low-viscosity epoxy or metal is poured into the mold until full. The casting material is then allowed to harden, and the new key is removed from the mold. A Silca Quattrocode key machine with laser scanner can be used to make a hard metal copy of the soft key.

CHAPTER NINE: GENERIC TYPES OF KEYS

Producing Keys for Specific Locks

Master Exhibit Summary

Forensic implications of using a shim to open a lock prior to analysis. Courtesy of Hans Mejlshede.

9_1.0 Introduction

This chapter provides basic information regarding the design of keys for warded, lever, wafer, and pin tumbler locks. Proper design is required to allow the generation or duplication of a key for each of the basic locking mechanisms. The chapter is not intended as a comprehensive treatise on the subject, but merely to provide the basic skills needed to meet law enforcement and locksmithing requirements. There are many ways to generate keys for locks. In large part, the technique depends upon the design of the locking mechanism, tools available, skill, time, and location.

As has been previously noted, keys can be produced from other keys, from the lock itself, or from information about the key in the form of codes. In **Chapter 8**, the sources for such information were described. They are mainly determined by the type of mechanism. In this chapter, the three most popular methods of producing keys are examined for each type of mechanism. Information is provided about **disassembling the lock, impressioning, and visual decoding.**

9_1.1 Disassembly

Most locks can be disassembled, although this is least likely within warded mechanisms because they are generally fastened by rivets. If the lock is held together by screws, retaining clips, arc rings, or similar devices, then obtaining access to the mechanism is generally straightforward.

Locks may also be taken apart using the techniques of **shimming, picking, and rapping.** Each of these procedures will result in aligning the detainers at shear line, causing the lock to open. Once in the unlocked position, a key can be matched to the specific tumbler configuration. These techniques are more fully discussed in **Chapter 29.**

9_1.2 Impressioning

Locks can be impressioned, producing a working key through the marking of the surface area of a blank. Different impressioning techniques are employed, depending upon the type of lock. These are discussed in **Chapter 30.**

9_1.3 Visual Decoding

Certain locks may be visually decoded in order to determine tumbler combination or location. Decoding is accomplished externally, or from each tumbler or wafer in a disassembled condition. Techniques for decoding are presented in **Chapter 31.** The materials that follow will focus on basic procedures for producing keys to each type of locking mechanism based upon the mechanical configuration.

9_2.0 Warded Locks

Chapter 13 presents a detailed discussion of warded locks and their mechanical functionality.

9_2.1 Introduction

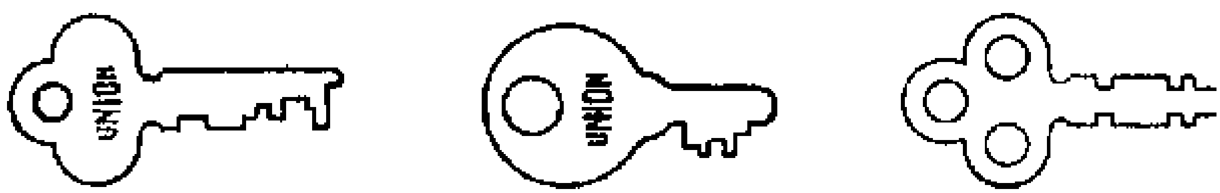
The warded lock has been in existence for several hundred years and was the first "modern" locking mechanism since the Egyptian pin tumbler. Security is a function of the placement of wards, which block the entrance and rotation of all but the correct key. Depending upon the mechanism, keys for warded locks take several forms. Although they may differ in appearance, keys and locks generally have two common traits: warded keys have square cuts,

and, unlike any other mechanism, generic skeleton or master keys can bypass them. Warded padlocks produced by Master and others are popular and very prevalent in low-security applications. These are also the easiest to bypass. A set of five skeleton keys is available for warded padlocks and will open most of them without difficulty. HPC produces such a set (**HPC PKS**).

Keys for warded locks are made of soft iron, cast iron, steel, brass, bronze, zinc alloy, or aluminum alloy. Blanks are usually readily available. Warded keys, however, may in fact be more difficult to cut than other types due to complex patterns. The tolerance and spacing required in a warded mechanism is minimal due mainly to the locks construction and principle of operation. Thus, key generation is fairly simple.

9_2.2 Warded Keys

There are three primary types of warded keys: **mortise**, **padlock**, and **specialty**, such as cabinet and luggage.



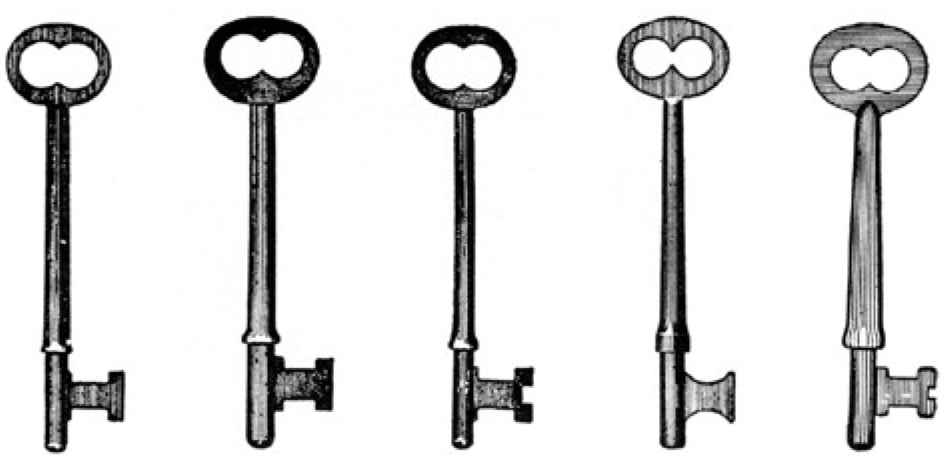


Figure LSS+903 Examples of three warded flat keys. From left, locker key, luggage, and padlock.

9_2.2.1 Keys for Mortise Locks

Keys for warded mortise locks take many forms, often having very complex and artistic designs. The active portion of the key, called the **bitting**, is comprised of cuts and grooves to pass the wards. The names associated with the various parts of the key will slightly differ, depending upon country.

The **bit key** is the oldest form, dating back to Roman times two thousand years ago. It is probably the most popular in the world, except in the United States and Canada. Keys are cast and, thus, low tolerances are maintained. No two keys are identical. The bit key has two basic variations, depending upon whether the stem is solid or hollow, and consists of three primary parts: the **stem**, **bow**, and **bit**.

9_2.2.1.1 Identification and Function of Parts

Bit Key: This actually describes a key with a bit projecting from its shank. There are different variations, generally described as the **pin**, **pipe**, or **barrel** key. Differing slightly in design from the pin key, the **barrel** or **pipe** key has a hole drilled in the post that fits over a corresponding pin or post within the lock. There are generally no shoulders on the barrel key.

Bit: At the working end of the key is the bit. It is the most important and complex part of the warded key. All bits are essentially rectangular and cut in square steps on the bottom and sides.

Bow: The bow, usually oval or round, can be any shape and performs the functional purpose of providing a handle with which to grasp the key for use. Its design is irrelevant to operation.

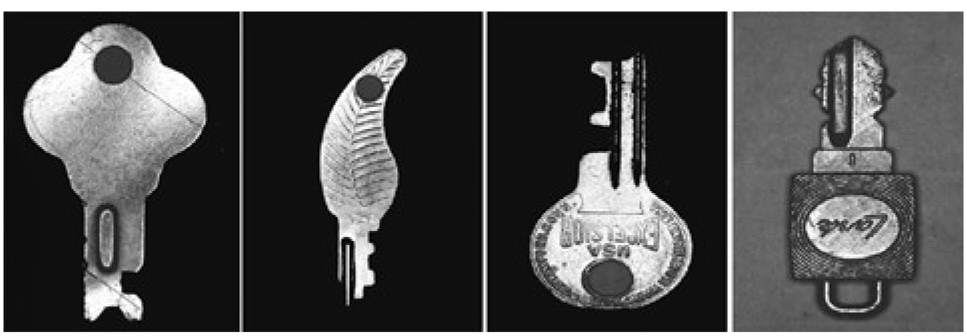
Bullets: Bullets are grooves cut longitudinally across the bit, to form different keyway designs.

Pin or Post: The pin or post, either hollow or solid, provides an anchor and rotating center point when the key is inserted into the lock. The post, if a hollow pipe, is designed to fit over a pin within the lock and rotate around that pin. If the stem is solid, its tip is intended to pass through a "0" in the keyhole to anchor the key for rotation.

Shoulder or Collar: The shoulder forms a stop point, projecting

ring, or flange, to block further entrance of the key. The diameter of the shoulder or collar is slightly larger than the shank. The keyway will not pass this larger diameter.

Stem, Shank: The stem or shank forms the long part of the key, connecting the bow with the bit.



Throat or Neck: The throat is the spacing between the shoulder and the bitting.

9_2.2.2 Keys for Warded Padlocks

Keys for warded padlocks are very distinctive in design. They can be identified by their square symmetrical cuts. These are required to pass the wards in order to release shackle-locking bands. Master Lock is the predominant supplier of these mechanisms worldwide.

9_2.2.3 Keys for Specialty Warded Locks

Luggage, trunk, cabinet, and specialty locks utilize the warded principle and are the simplest form of lock produced today. Many kinds of luggage keys can be ordered precut for specific locks. Flat keys are used in padlocks, letter boxes, lockers, cash boxes, cabinet locks, and safe-deposit lever locks, and are described in Section **9_3.2** below.

9_2.3 Generating Keys for Warded Locks

Keys for warded locks are produced by hand filing from an original or through the impressioning process.

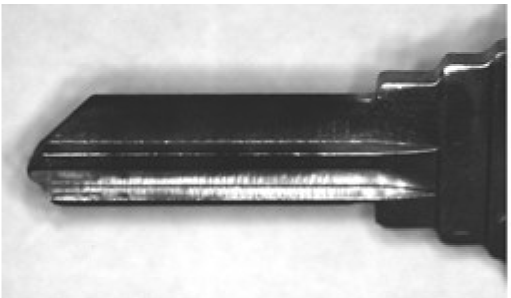
9_2.3.1 Cutting Keys by Hand

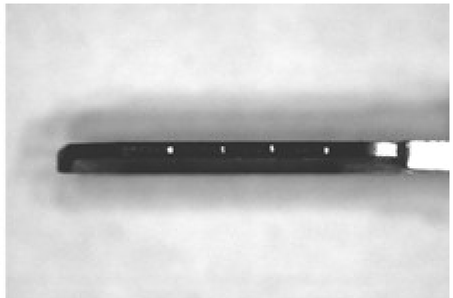
Generally, the easiest way to duplicate a warded key is to **smoke**

the source, using a candle, lighter, or match until all of the bitting is covered with black carbon. Then, take a blank key and cut the same pattern as found on the source. Place the target against the original and file until the carbon is barely marked on the source key. Another technique is to press sticky-backed aluminum foil onto the source key, then remove, cut, and overlay onto a blank. Regardless of method selected for key duplication, there are certain guidelines which must be followed:

	GUIDELINES FOR KEY DUPLICATIO
BOW NOT IMPORTANT	**The shape of the bow is not important. correct dimensions will work.**
SHANK AND POST SAME LENGTH	**The shank and post must be the same len target key.**
BIT DIMENSIONS	**The bit on the target blank must be hig or equal to the source key. The thickne same on both keys.**
POST DIMENSIONS	**The diameter and length of the post mus**

Some bit keys can be very complex in design, including a bullet or side groove in the bitting that forms part of the keyway. A depth gauge or micrometer can verify the cuts during duplication.





9_2.3.2 Impressioning Keys Using Carbon or Wax

Warded locks can be easily impressioned, thereby eliminating the requirement of disassembly to produce a key. The procedure is based upon distinct markings that are created on the face of the blank. Because the wards prevent a key from turning without the proper corresponding cuts, marking will occur in the absence of such cuts. Torque is required to cause the imprints.

In order to impression the lock, be certain that the correct blank is selected. It must be both long enough and sufficiently wide to operate the bolt mechanism, especially in padlocks. If the key is too narrow, it will not be able to spread the release spring to unlock the shackle.

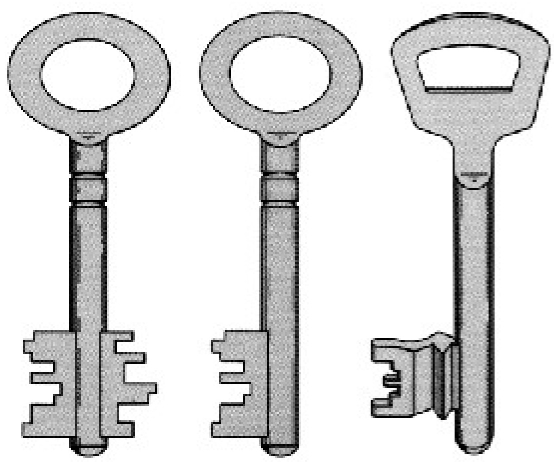
Smoke the blank key, insert it completely, and turn sharply without actually twisting the metal. This allows the key to partially turn within the lock, making contact with the wards. Upon removal, spots will indicate the position of the throat and

ward cuts. Make the throat cut first so as to allow proper contact with the other wards. Marks will appear because a blank key is blocked from rotating past the wards. Only when metal is removed from the key, corresponding to the precise location of the wards, can the key be turned freely.

Use a triangle file to begin each cut. Place the cutting edge down, and apply pressure in a forward motion. Finer cuts can be produced with the smooth edge down. Draw the file forward to widen the cut angle. Once initial indentations are made, a flat, square warding file should be used to cut the remainder of the key. For padlocks, symmetrical cuts are required. All cuts will be to the same depth and will be in line with the edge of the tip of the key. If a cut is not wide enough, the key will not operate. Simply widen slightly until impression marks disappear and the key operates without binding. If too much of the bitting surface is removed, a skeleton key will be created that will open more than one lock.

9_2.3.3 Skeleton, Pass, and Master Keys

Skeleton keys are created by removing all bitting material, except that which is required to actuate the bolt or shackle-release spring. Because it is so simple to make such keys, warded locks offer little security.



HPC and other companies sell a set of five skeleton keys. These are made of thin metal shim stock and will open virtually every warded padlock. Two keys can be overlaid and inserted into the lock as one composite if **three** shackle-release springs are present. These will bypass all of the wards and only act upon the release mechanism.

9_3.0 Lever Locks

9_3.1 Introduction

In the United States, lever locks are primarily used in safes and vaults, safe-deposit boxes, cash boxes, mailboxes, telephones, and certain low-cost, low-security applications. In Europe and most other parts of the world, lever locks are very popular for use in high-security safes, as well as in mortise configurations for hotel, residence, and business door locks. They are preferred over combination locks on many high-security safes.

Lever mechanisms can offer extremely high-security, and thus, tolerances for key duplication must be precise. Keys for lever locks are generally made of steel or nickel silver and are either flat or double cut. Most safe-deposit locks utilize flat keys.

Double-bitted lever keys can be found in higher security applications on safes and vaults and in prisons. Blanks are readily available, and many of these keys are produced from codes. Keys may be cut either by machine or by hand.

9_3.2 Keys for Lever Locks

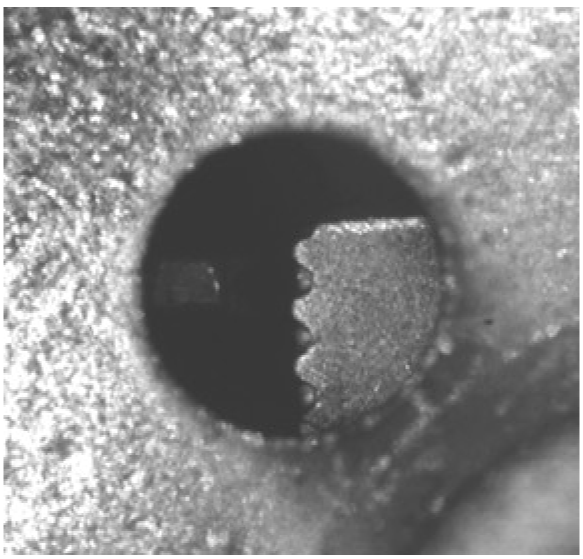
Flat keys are generally easy to duplicate. The manufacturer-designated key blank is often not required, because similar blanks can be cut to match the source key. Even a flat piece of metal or plastic can be employed, if necessary. The length of the blank must be correct, and the width cannot be smaller than the source key. Thickness and height should also be comparable in both the source and target.

Warded and lever keys often appear identical, and in fact, a warded lock may be confused with a lever mechanism in many applications. The design of the key requires that for every lever, a corresponding rectangular cut be made. All sides must be perpendicular, and the bottom of each cut is flat and horizontal.

9_3.2.1 Hand Cutting Lever Keys

Lever keys are usually cut by hand with a file. Prior to beginning our discussion of how to make a key for these locks, the method of cutting must be analyzed to insure that the key will work properly. A 6" flat warding file that has a thickness **less than or equal to** the width of one lever tumbler is required for cutting keys by hand. This concept should be clearly understood prior to attempting to make a key.

One must consider the operation of the key in the lock in order to understand the relationship between the tumbler and the geometry of the cut on the bitting. Each individual cut corresponds to one lever tumbler; each cut raises one lever to the correct position. Therefore, if the cut on the key is too wide, more than one tumbler will be picked up. It also follows that if the cuts are too narrow, a tumbler will be raised but not necessarily to the correct level.



9_3.2.2 Producing Keys for Lever Locks

The following discussion assumes that the interior of the lever lock is available for inspection during the cutting process. If such is not the case, the reader is directed to **Chapter 30** for a discussion of impressioning. The correct blank for the lock is first selected, making sure that it is both long and wide enough to reach all tumblers so that it may lift them to the correct level. The blank is then inserted until stopped by the tip. Several sharp rotations are made, as if to open the lock.

After removal of the blank, there should be fine marks or scratches on the key that will indicate the exact point where the lever tumblers came into contact with the metal surface of the blank. The marks are necessary for the determination of where to file each tumbler cut. If the tumblers do not leave clear marks, the surface of the key may be polished to a mirror finish or be smoked. Smoking is accomplished by holding a lighted match under the key and allowing a thin film of carbon deposit to build-up on the surface. The key is reinserted into the lock and sharp

turning motions are applied. The key is then carefully withdrawn, and marks should be clearly visible.

After the tumbler positions have been precisely determined, one simply files the key to the point where all gates are in alignment with the fence. Because many lever assemblies will have windows or holes cut in the face of the assembly, the alignment of the lever gates with the fence can be observed through these openings or by taking the lock apart. A key can be produced using the viewing window. Insert the blank and determine how much filing will be necessary to line up the first visible tumbler; it will be closest to the bow of the key. Remove the key and file until this tumbler is aligned with the fence. When this is accomplished, the second tumbler can be lined up in like manner, continuing this procedure until all of the levers are aligned with the fence and the lock opens.

This procedure does not require the lock to be taken apart, nor is the tumbler combination disturbed because levers have not been removed. The blank must be inserted in a perfect vertical angle to insure that the key aligns the tumblers correctly. It may be preferred or required to remove the top plate of the lock in order to produce a key or to change the tumbler combination. This is the case when there is no window to view the tumblers. In such instances, the top plate can be lifted by removing a few screws.

With the plate gone, the tumbler arrangement is visible. One then inserts the blank in the keyway, being careful to keep the keyway guide exactly vertical and centered. Each tumbler position on the

key is then filed to the correct level. The proper depth of each cut is determined by rotating the key as if to open the lock and bringing the fence and gate into precise alignment. The tumblers also may be completely removed from the lock and reinserted one by one as the key is produced.

The situation may also arise in which a key must be made for a lever lock that is in the locked position and cannot be removed. In such a case, it may be necessary to drill a small hole in the precise spot that allows a view of the tumbler alignment. A key can then be cut by the procedure outlined above. If the lock is first picked open, it may be removed for keying. A key can be produced by the impression method or the tumblers may be visually decoded with a borescope.

9_3.3 Impressioning Lever Locks

Lever locks can be impressioned, even in cases where serrated levers are employed. In addition, visual inspection of the wear patterns on the bottom of the levers can provide information as to tumbler depth. During the nineteenth century, lock pickers used wax as an impressioning medium for determining the correct lever depths. The subject is more fully discussed in **Chapter 30**.

9_4.0 Keys for Disc or Wafer Tumbler Locks

9_4.1 Introduction

There are several different wafer lock designs, employing discs, wafers, plates, or other similar forms of tumblers. For a thorough discussion of these mechanisms, see **Chapter 15**. This section will provide information relating to the most common wafer locks, although the techniques are generally applicable to most of the mechanisms in use today.

Keys for wafer or disc tumbler locks are usually made of brass, nickel silver, or aluminum. Wafer locks are prevalent in the vending industry and are an inexpensive substitute for pin tumbler cylinders. Most wafer locks are offered in a **cam** configuration and are frequently cast from alloys. The mechanism consists of a plug containing all of the springs and tumblers, which rotates within a shell. Wafer keys can be single, **double**, or **triple**-bitted. The locks usually have from four to six tumblers, and the keys often appear identical to those for a pin tumbler lock, except that the blanks are generally smaller.

9_4.2 Generating Keys for Wafer and Disc Tumbler Locks

Duplicates can be made from a source key, from code information, from visual decoding of the tumblers, from disassembly of the lock, and by impression.

9_4.2.1 Duplicating from Source Keys

Keys can be generated by hand cutting or machine. The same rules apply with respect to hand cutting of wafer and pin tumbler keys. See Section **9_5.0** for information on producing keys for pin tumbler locks.

9_4.2.2 Duplicating Keys by Code

Most wafer keys can be cut by code, either by hand filing, by mechanical punch machines, or with electric code cutting machines. Keys can also be reproduced through a visual decoding process, explained in detail in **Chapter 31**. This procedure involves inspection of each tumbler within the lock, correlation of the viewed tumbler depth with the proper depth code, and cutting a key to match the derived information. A decoder (**HPC HKD-75**) micrometer (**HPC SKM-2D**, KM-60, SKM-1) or various gauges can also be used to measure the depth and spacing of wafer keys. These instruments can verify measurements or provide the data to hand cut keys by code.

9_4.2.3 Keys Produced After Disassembly of the Lock

It is a relatively simple procedure to produce a key directly from the internal wafers. The lock is first disassembled by removing a retaining screw or arc ring located at the rear of the plug. This will allow the complete internal mechanism to be withdrawn.

A blank key is inserted into the keyway, and pressure is applied to the top of each of the wafers. This will mark the surface of the key to determine exact spacing. Then, each tumbler position within the bitting is created, filed, and shaped until the wafer rests at shear line. Once all tumblers are properly aligned, the plug can be turned within the shell.

Double-bitted keys can be produced in similar fashion by first disassembling the mechanism to expose the plug and wafers. The significant difference between single and double-bitted locks is that there are two shear lines, at the top and bottom of plug. The wafers alternate between the two shear lines rather than being aligned only at the top of the plug. The correct blank is selected and both surfaces filed flat until the key will enter the keyway completely. Pressure is applied to each individual wafer in order to establish correct spacing. The key is then filed until all tumblers are at shear line.

Although a key appears to be double-bitted, it may in fact only have one active surface. To allow for customer convenience, certain keyways are designed for the blank to be inserted to allow either vertical orientation of the bitting surface. The bitting will only mate with one set of wafers or tumblers, regardless of the position of the key. Many automobile locks appear to have two sets of tumblers but in fact only have one, although the keys are double cut.

9_4.2.3.1 Decoding of Wafers

The wafers can be inspected and decoded once the lock is taken apart. There may even be numbers stamped on each of the discs to indicate the depth of the cut. A key can be cut by code based upon that information. Although the HPC handheld decoder (**HPC HKD-75**) will not work with double-bitted keys, it is an excellent tool for single-bitted wafer locks.

9_5.0 Keys for Pin Tumbler Locks

9_5.1 Introduction

The modern pin tumbler lock was invented by Linus Yale in 1844 and is used throughout the world in every imaginable security application. Keys for pin tumbler as well as wafer locks are made of brass, nickel silver, or an aluminum alloy. Many high-security lock manufacturers produce their original keys in nickel silver, because it is physically stronger than other metals.

Blanks are inexpensive and easily obtained for most keyways. **Silca** and **Ilco** are probably the world's largest blank manufacturers and maintain complete data on virtually every lock that is produced and sold. In 2000, Silca was purchased by

Ilco-Unican. As can be imagined, there are thousands of different keyway combinations, many of which are very similar. Therefore, care must be taken that the proper blank is identified before cutting a particular key.

Keyways may be restricted to provide a greater measure of security against unauthorized duplication. They can also be made highly pick resistant through a complex design of wards.

Keys for pin tumbler locks can be produced from a source key, from code information, and from disassembly of the lock. Unlike wafer locks, keys cannot be reliably produced from visual decoding of the tumblers **externally** except in rare instances.

9_5.2 Source Key Duplicates

Direct duplicates of source keys can be made either by hand or by machine. Source keys can also be decoded. The information thus derived can then be input into a code-cutting key machine in order to produce the equivalent of a factory original.

Careful attention to spacing and cut angle is required whenever a key is cut by hand. If the V cut angle is greater than the range of 90°-120°, the key will have a tendency to hang up in the lock. This condition is known as **back cutting**; it can result in a great deal of difficulty when attempting to remove the key. Tolerance of the depth cuts is quite close, usually between .015” and .020”, leaving little room for error. Key duplicating machines must be adjusted for a maximum error of no more than .005”. The HPC key micrometer may be used to measure and verify each cut.

9_5.3 Producing Keys from a Disassembled Lock

Keys may be produced by actually taking the lock apart, then filing a blank key, one tumbler at a time, until all tumblers rest at shear line. Through disassembly, we gain direct access to the plug and shell together with all tumblers and springs. Once the lock has been taken apart using one of the described techniques, a key is cut from the information derived from each tumbler.

A pin tumbler lock must be taken apart for one of four reasons:

- **Change combinations;**
- **Make a key for the lock due to loss or other**

reasons;

- **Master key the lock;**
- **Cleaning and maintenance.**

Before one can work on the lock, it must be disassembled. Regardless of the design, the process for taking the lock apart is the same. Through disassembly, direct access is obtained to the plug and shell. We must be able to get at both sets of tumblers and the springs to effectively service the lock.

In the description that follows, procedures will be detailed pertaining to the cylinder lock, for this is the easiest to describe. Most of the other mechanisms can be taken apart in the same manner. Three basic tools are required for working on any pin tumbler lock: a **setup tray**, **follower**, and **pin loading tweezers**.

9_5.3.1 Disassembly Procedures

Locks can be disassembled in several ways, although there are two basic means for directly taking the cylinder lock apart. The first method involves removing the spring retaining strip, then dumping all of the springs and tumblers out of the shell through the chamber holes at the top of the cylinder. The second method requires removal of the plug from the lock directly without disturbing the retaining strip. The first technique is a simple procedure, the second can be made difficult in certain instances.

9_5.3.1.1 Removing Spring-Retaining Strip

In most cylinder locks, there is a flat piece of soft metal, generally brass, which will be crimped or pressed into a slot directly above the springs. This strip seals the pin chambers, thereby providing a stop for each spring so that tension is created for each top tumbler. Tapped setscrews may also be used in certain locks such as Medeco, in place of the spring-retaining strip.

With a pointed instrument such as a small screwdriver, the end of a drawing compass, or an ice pick, the strip can be pried back and withdrawn. Care must be exercised to remove the strip slowly, preferably with the index finger covering the chamber holes as the piece is withdrawn. If removed from the lock improperly, the springs will fly out of the chambers because they are under constant tension. Once the retaining strip is released, the

springs, drivers, and lower pins are carefully removed, the cam is taken off the back of the lock, and the plug is withdrawn.

A word of caution when removing the tumblers: If a key is to be made or if the lock is master keyed, extreme care must be exercised to insure that the tumbler order and stacking is not disturbed. The use of a setup tray is recommended. The tumblers can be individually released from the chambers and put into the tray. They can be replaced in the same order.

9_5.3.1.2 Removal of Plug Using the Correct Key

The plug, containing the lower set of pins, may be directly removed from the lock. The correct key is inserted into the keyway, the plug turned 90°, and then withdrawn from the shell after the cam is released. In order to remove the plug and lower pins without disturbing the driver and master pins, a **follower** or **following tool** is utilized. The follower is a wood or metal rod having the same diameter as the plug.

Followers may be made from wooden dowels or purchased from lock supply houses. HPC makes a following tool kit (HPC SUT-14) that has four different sizes, diameters, and ends. In addition, a spring-loaded, adjustable follower (HPC SUT-22) is available and recommended. Various plugs have ends with different shapes, thus requiring matching followers. However, a flat-ended tool may be used in a majority of locks, if care is exercised during insertion. A kit containing followers with the diameters of .395" (small size Yale and Corbin) .495”, .5" (common plug diameter) and .55" (large diameter plugs) is a necessity.

After the cam has been **removed**, the follower is placed against the back of the plug, and slight pressure is applied so that, in essence, the follower and plug form one continuous rod. As pressure is applied from the rear, the follower forces the plug out the front of the lock. The cylinder is held in the right hand, the follower being pressed into the lock with the left, while the right thumb is used to control the movement of the plug as it is withdrawn.

Applying pressure during the removal process is required to retain the proper order of pins, especially where there are master pins and where pin-stack length may be critical. It will be recalled that the term **“pin-stack”** refers to the total length of driver and lower pins. There must never be a gap between the

follower and end of the plug. The function of the following tool is to prevent the drivers and springs from entering the space occupied by the plug when removed. Remember, the top tumblers are under constant bias: if the plug is simply pulled from the lock without a follower in place, there is nothing to prevent them from ejecting into the void.

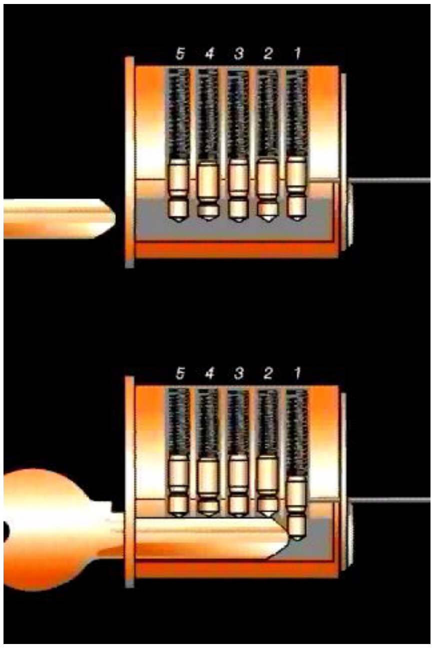
This procedure presumes that the correct key is available. Often, however, keys have been lost or a key must be fitted to the lock for other reasons. When this occurs, the initial problem becomes how to remove the plug from the lock. In many instances, the **spring-retaining strip** can be removed, but often this is impossible due to the locks construction, especially in mortise cylinders. Realizing that the drivers must be above shear line in order for the plug to be turned and removed, there are several means to accomplish this. **Shimming**, **bumping**, **rapping**, or **picking** are all options.

Whichever method is utilized to ultimately remove the plug, a note of caution is in order. **Always rotate the plug 90° prior to removal.** Often, a lock with six chambers may only be keyed for five pins. There is thus an extra hole in the plug in the sixth pin position. If the plug is not rotated prior to being withdrawn, the fifth driver and spring will drop into the empty sixth hole. When this occurs, the plug must be withdrawn with the spring jammed between the plug and shell. It will feel as if there is gravel in the lock, and of course, the springs will be destroyed.

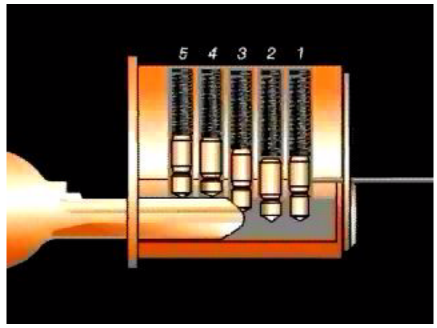
9_5.3.1.3 Cam-Retaining Mechanisms

A number of different means are employed to secure the plug within the shell, including spring steel arc rings, pins, screws, and screw-on caps. The arc rings can be removed with the aid of a special set of pliers. Care is required to insure that the rings are inserted with their flat side towards the plug for proper seating.

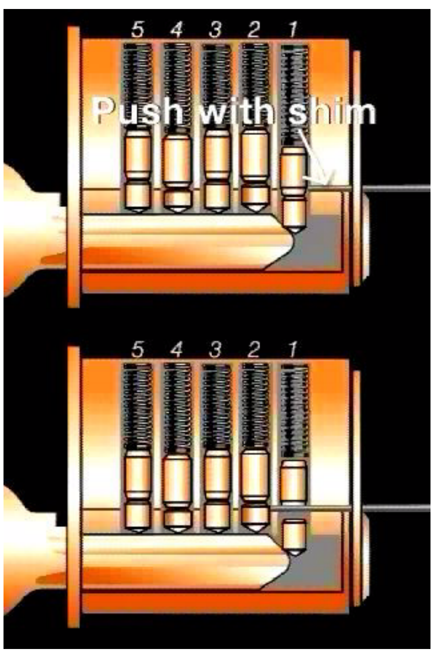
Spring-loaded pins are quite easily removed and reinserted. They provide a wedge so that the plug cannot be withdrawn from the lock when in position. A number of manufacturers, including Schlage, use a screw-on cap arrangement together with a **spring-loaded pin** to retain the plug. When the cap is screwed tightly to the back of the plug, the pin will lock itself into the cap and thereby hold it in a secure position. Screw-on caps have the advantage that the plug rarely works itself loose.



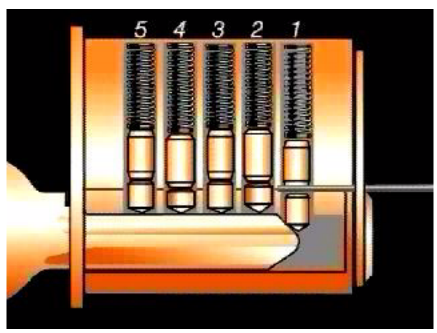
The use of screws is perhaps the most common means of securing the plug. Generally, two screws are present, through a tailpiece. Cam screws must be tight to insure proper operation of the lock. If they are loose, keys cannot be properly withdrawn and it may become necessary to place frontal pressure on the plug to allow removal of the key.



9_5.3.1.4 Disassembly of the Locked Cylinder without a Key



As has been described, locks may be taken apart for a variety of reasons. In cases where the cylinder is locked and no key is available, the plug can be removed using the techniques detailed below. **Chapter 16** provides additional information regarding pin tumbler cylinder disassembly.



9_5.3.1.4.1 Shimming Open the Lock

Shimming is a technique whereby pressure is applied against the edge of each tumbler, in succession, by a very thin strip of metal called a shim. It is inserted from the back of the lock in the clearance area between the plug and shell. As each tumbler is forced upward, the shim will slip between the tumblers as they cross shear line.

5 4 3 2 1

5 4 3 2 1
Push with shim
5 4 3 2 1

5 4 3 2 1

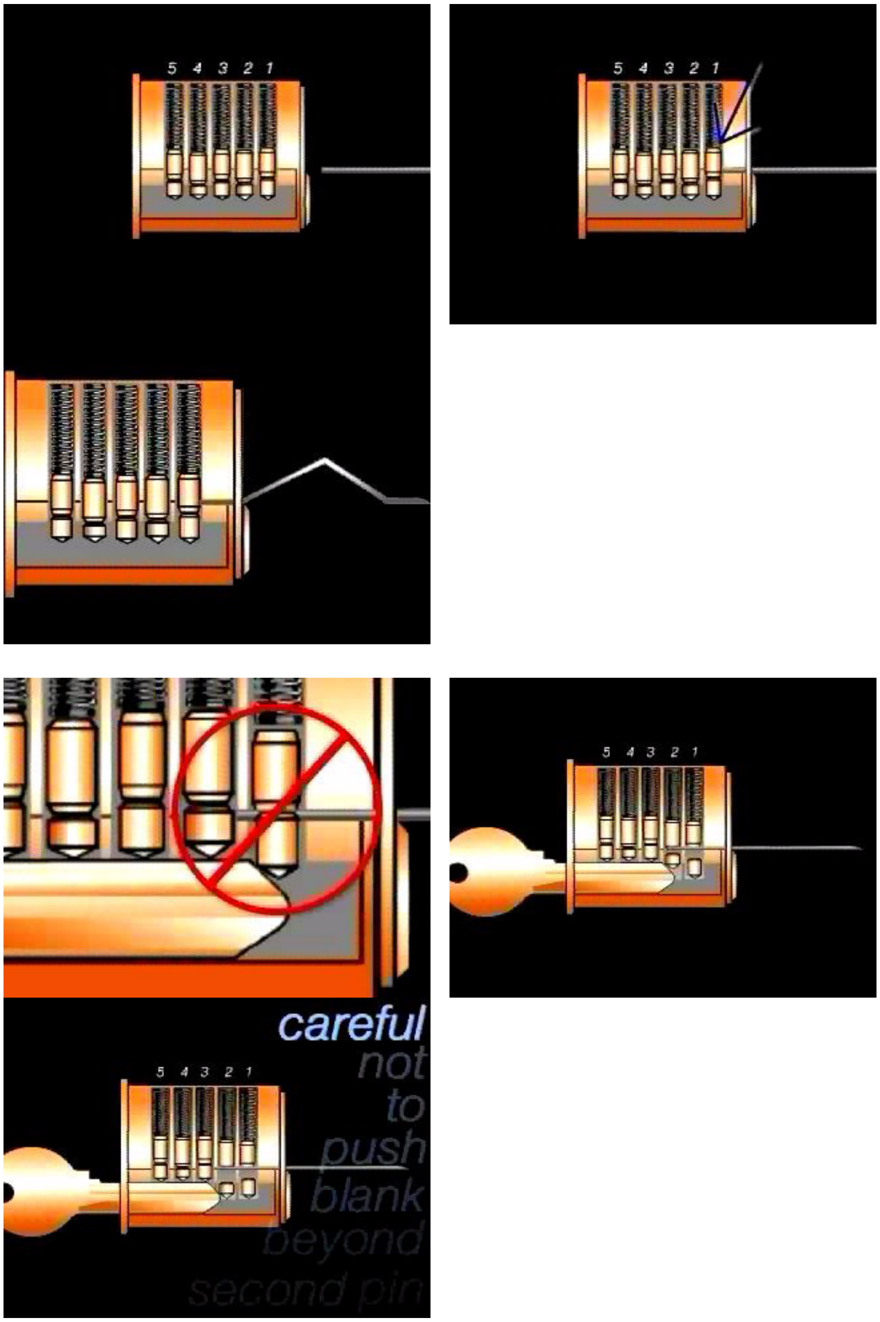

Figure LSS+901 This series of drawings illustrates the proper use of a shim to split the bottom and top pins within a cylinder that is locked. The key is utilized to raise each pin to shear line while pressure is applied with the shim against each pin in sequence. Be certain not to apply too much pressure to the shim, and never attempt to force the key under a pin that has been split by the shim. Courtesy of HPC Interactive Learning Series.

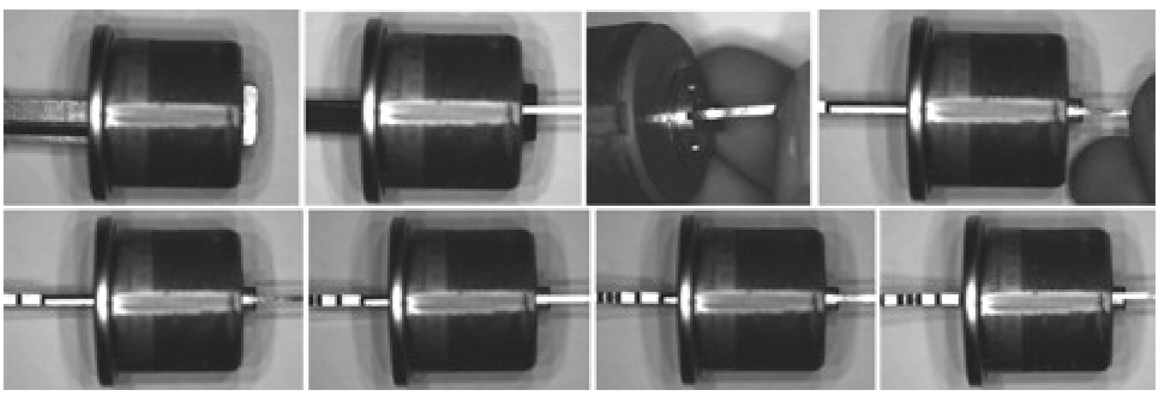
A very thin (<.005”) metal shim may be utilized to **split** the

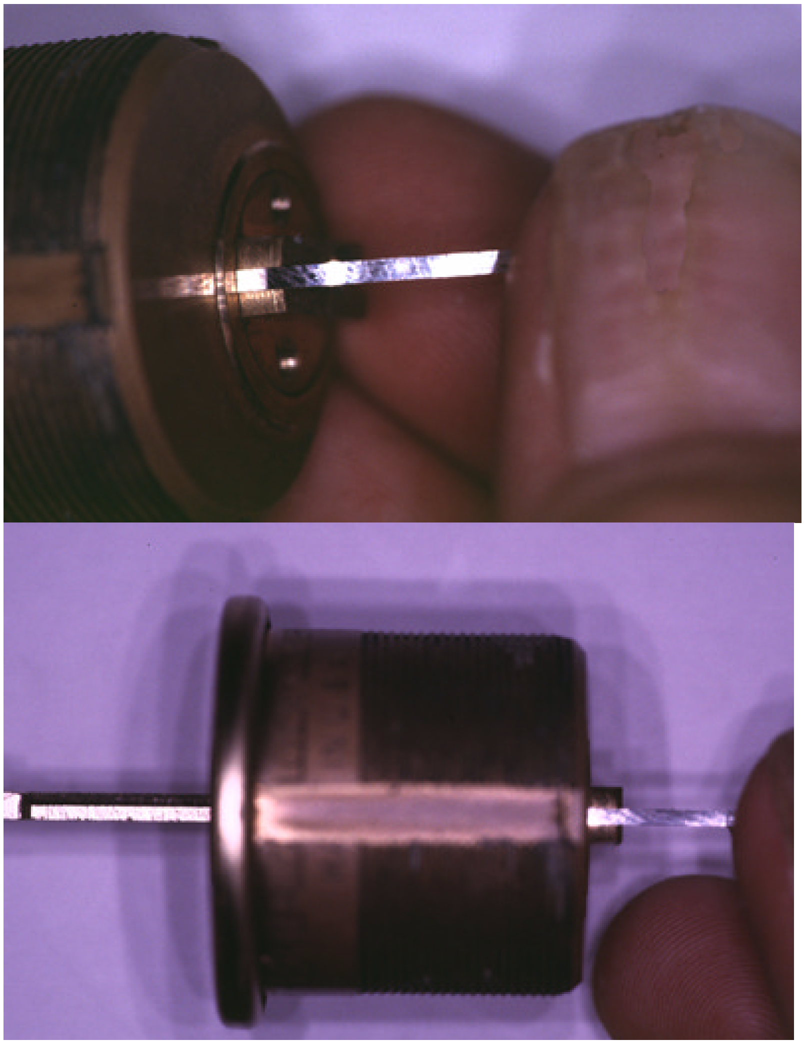
lower and upper pins at shear line, thus allowing the plug to be removed. The shim may be made of flat or curved spring steel stock, usually between .002″ to .0015", 1/8" wide, and several inches in length. An excellent shim consists of the mainspring or suspension wire from a watch or clock. These may be obtained from most jewelers or jewelry supply houses.

Shims can also be produced from film negatives. The celluloid can be cut into narrow strips. Shims are also made from metal stock. A set of shims with the following thickness will suffice for a majority of situations: .0015″, .002″, .0025″, .003″, .004″, .006″, .008″, .010″, .012″, .015″. A complete set of shims is available from HPC.

The proper procedure to open a lock by shimming requires the following steps:



- **Remove the plug retaining screws and cam;**
- **Insert the shim in the clearance area between the plug and shell, from the last tumbler position at the back of the lock;**
- **Exert a forward pressure on the shim until it is stopped by the farthest rear tumbler. The pressure required for shimming is minimal: excessive bias will prevent the bottom pin from falling or will deform the shim. One can feel each tumbler as the shim scrapes its vertical surface;**
- **Insert a blank key from the front of the lock; it is used to raise each of the lower tumblers above shear line;**
- **Retract the blank very slowly. As the first tumbler with which the shim makes contact is lowered to shear line, the thin wire can be pushed between the driver and the lower pin until the wire is blocked by the second set of tumblers. It may be necessary to move the key back and forth slightly in order to engage the shim;**
- **The blank is carefully pulled back, allowing the wire to be slipped between the second driver and lower pin;**
- **Repeat the procedure for each pin-stack. This process is continued until all of the tumblers have been separated. As each tumbler is split, the key will extend that much further from the front of the**



lock;

- Never move the blank over an already split tumbler;
- Once the shim has split every pin-stack, the plug is free to turn, because there are no drivers projecting into the plug. They are held above shear line by the wire. With the wire still in place between pins, the plug is turned approximately 90°, and the shim removed. It is now a simple matter to insert a following tool and withdraw the plug.

Shimming a lock containing security tumblers can present more difficulty. If mushroom, spool, or serrated pins are encountered, pull the shim back slightly in order to clear the indented portion.

9_5.3.1.5 Rapping Open the Lock

A pin tumbler lock may be rapped open, through the application of slight pressure to the rear of the plug, after the retaining screws and cam have been removed. The procedure involves the sharp rapping or striking of the top of the cylinder with a rubber or wooden mallet, plastic screwdriver handle, or similar object, while pressure is applied to the plug. Lightly slamming the assembly against a hard rubber work surface, such as a tabletop may also open a cylinder.

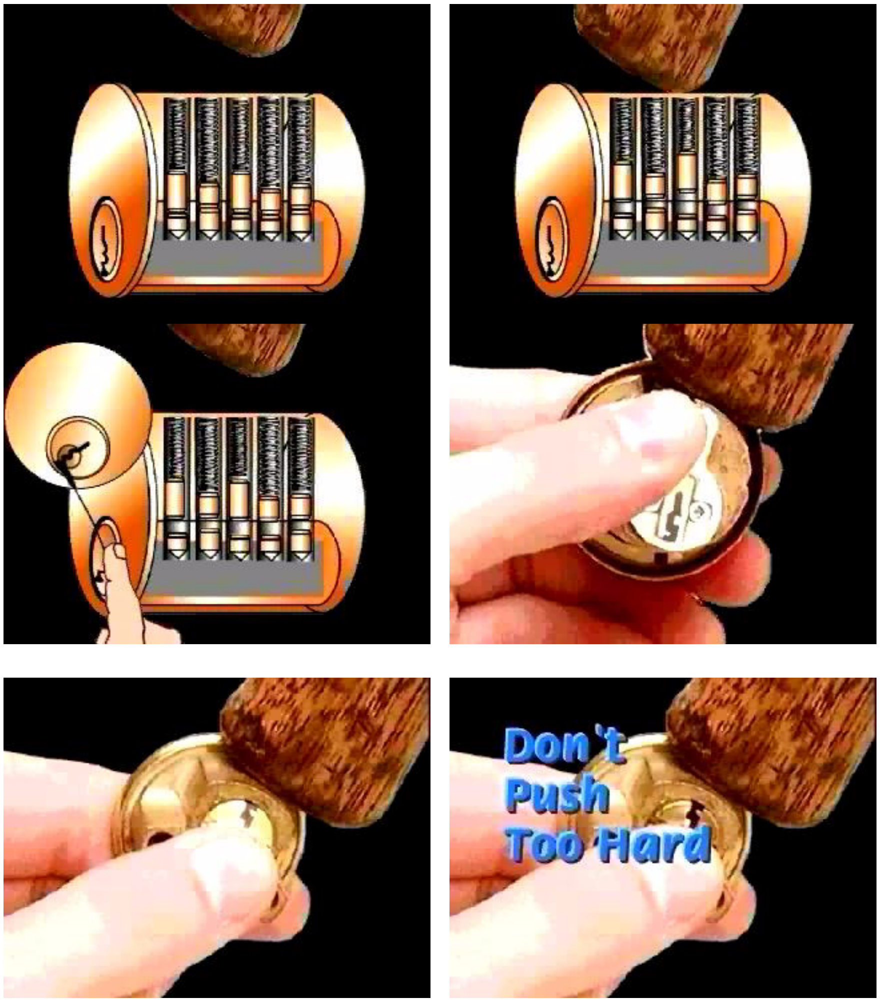

Figure LSS+902 The process of rapping a cylinder requires that sufficient energy be provided to bounce all of the driver pins above shear line. A wooden or rubber mallet may be utilized for this purpose. In practice, the cam is removed from the rear of the cylinder and pressure is exerted to the rear of the plug while shock is applied to the shell to bounce the tumblers. Courtesy of HPC Interactive Learning Series.

In theory, the sudden shock causes all of the upper tumblers to bounce above shear line, leaving a break between all lower and upper pins just long enough for the plug to be free to turn. The driver pins will be moved based upon **Newton's Third Law of Motion:(128)** for every action, there is an equal and opposite reaction. The theory is the same as when using a snap pick gun, discussed in **Chapter 29.**

In practice, the cylinder is held in one hand, with the index finger pressing against the rear of the plug (after removal of

any cam-locking device). The lock is rapped above the springs several times. If done correctly with only two or three hits, the core can be pushed forward to clear the drivers. Care must be exercised that the plug is not pushed too far forward, allowing the drivers to enter the lower pin chambers. If this should occur, removal can be very difficult.

Once the pins are split, the plug should be rotated 90°, the follower tool inserted, and the plug removed. To facilitate successful rapping, the plug should be cleaned, allowing the pins to move easily in their chambers.

9_5.3.1.5.1 "999" Rapping

A modified form of rapping, quite popular in Denmark, is referred to as "999" rapping or bumping. This technique involves the use of a precut key that fits the keyway of the target lock. The blank is prepared by code cutting all tumbler positions to the greatest possible depth (usually a 9 cut). The "999" key is inserted into the lock completely, then withdrawn one tumbler position. A very slight turning pressure is exerted while the head end of the key is rapped with a mallet. In this manner, a shock is applied to all tumblers simultaneously that causes them to bounce the drivers past shear line. With practice, the lock can be opened with one or two strikes. A full discussion of this technique is presented in **Chapter 29**.

9_5.3.1.6 Picking the Lock

The lock can be picked open and the plug removed. In this procedure, the lock is picked, the following tool inserted, and the plug rotated and removed. When picking, special care must be exercised for master keyed locks. Many times, some of the lower pins and wafers will be picked at the same time. The pins must be removed carefully in order to insure that the combination is not disturbed.

9_5.4 Making the Key After Disassembly

Making a key directly from the internal components of the lock is a straightforward procedure. The lock is first disassembled by one of the methods described earlier in this chapter. The tumblers are placed into the setup tray, one chamber at a time, so that the combination is not disturbed. Special care must be taken when master pins are present in order to insure that the

proper sequence of pins is properly transferred. The correct procedure to produce a key from the bottom set of pins requires the following steps:

- **Select the correct blank for the keyway;**
- **Insert the blank into the plug;**
- **Move a sharp-pointed instrument such as the tip of a file or the point of a compass across the surface of the key, through each chamber hole to mark their position on the blade. In the alternative, slight cuts may be made on a blank, using a code- cutting machine, to indicate tumbler spacing;**
- **Insert the first tumbler into its proper position within the plug;**
- **Remove the key and file until the tumbler is at shear line;**
- **Shape each cut for angle and size;**
- **Continue this procedure until all of the tumblers have been reinserted into the plug and are even with the shear line;**
- **The plug may be replaced and the lock reassembled.**

An alternative procedure is to measure each lower tumbler and then determine the depth correlation from manufacturer data. A key can then be reproduced from the information so derived.

9_5.4.1 Master Keys

Making a key directly from the tumblers removed from a master keyed cylinder often requires several different attempts. This occurs because the precise combination may not be readily discernible from the tumblers due to the mix of lower pins and wafers. Difficulty may be encountered because the master key may be a combination of lower pins in certain positions, and lower pins together with master pins in other positions. The problem can become even more complex if there is more than one master pin utilized in any chamber, which is typical in a multilevel keying system.

9_5.5 Assembling the Lock

After a working key has been produced, the lock must be put back together. This is a simple procedure but must be done carefully.

Whether the metal spring-retaining strip was removed prior to disassembly will determine the procedure for replacing all of the tumblers during the assembly process.

9_5.5.1 Replacing Retaining Strip

If the lock was disassembled by removing the metal-retaining strip covering the springs the correct lower tumblers, followed by the drivers and springs, are dropped into each chamber. After all pin stacks have been replaced, the strip is slid back into its original position. Care must be exercised to insure that the strip crimps none of the tops of the springs and is properly seated.

9_5.5.2 Assembling the Lock Through the Center

When a lock is completely taken apart, having removed all of the top and bottom pins and springs, more skill is required to replace the parts. This is especially true if the spring-retaining strip was not used to gain access to the chambers. Each of the top pins and springs can be replaced going through the void in the shell left by the plug. The lower pins can be inserted into the plug without difficulty. The springs and drivers present the problem. For this operation, a following tool and a good pair of long tweezers (HPC TPT-5 or equivalent) are required.

Conceptually, the following events must occur to properly reassemble a lock:

- **Each chamber must be loaded with its spring and top pin;**
- **As each chamber is loaded, the partial pin-stack must be retained in position, using a follower;**
- **When all chambers have been loaded, the plug containing all lower pins and master pins is inserted into the lock, replacing the following tool.**

The proper procedure to reload a cylinder requires the following steps:

- **Replace all lower tumblers in the plug;**
- **Insert the correct key into the plug, and verify that the shear line is perfectly level;**

- **Insert any master pins;**
- **Place each spring and associated driver into an individual chamber, using the following method:**

  - **The following tool is inserted from the front of the lock and pushed back to the middle chamber;**
  - **A top pin is picked up with the tweezers and pressed into a chamber. It is best to hold the driver at a 90° angle to the tweezers and press straight down into the hole. If the HPC TPT-5 is used, a pin-pushing attachment is included for ease in depressing the driver into the chamber;**
  - **As the tumbler is pressed into position, some resistance will be encountered due to spring action. The problem becomes one of how to hold the driver in the hole long enough to force the follower over it. The easiest method is to press the pin into the chamber about halfway, then apply pressure against the pin with the follower tool. With this pressure applied, it is a simple matter to push the pin all the way into the hole;**
  - **After the first driver is seated, the process is repeated, placing a driver in the next chamber toward the front of the lock;**
  - **The follower tool is moved forward, now covering two chambers. In like fashion, the next chamber toward the front is loaded with a driver;**
  - **When all of the chambers, from the middle of the lock to the front, are loaded, then the follower tool is pulled through the lock to the front, exposing the remaining chambers at the rear. These are loaded, from the chamber in the middle to the last chamber at the rear;**

- **After the driver pins have all been inserted into the shell, the plug is put back in place;**
- **The cam screws are then tightened. This last point is very important, because the plug will be pulled out of the lock if the cam screws are not present.**

9_5.6 Keys by Code

Code machines and books are available for cutting keys to fit most pin tumbler locks. Keys can also be cut with a set of depth keys, or by hand using an accurate set of calipers or micrometer. HPC, Reed, Silca, and several other companies offer compilations of codes, both in book form and on computer, allowing the generation of keys for almost any lock.

CHAPTER TEN: SECURITY RATINGS

High-Security Locks and Keys

10_1.0 Introduction

The requirement for high-security in locks and keys is found within both government and the private sector everywhere. As will be detailed, there are different levels of security based upon construction, design, and programming criteria. This chapter will define and provide evaluation criteria for high-security locks, their keys, and keying systems. Combination locks are not included in this discussion; they are presented in **Chapter 34.** High-security locks are also examined in **Chapters 24-27** in the context of forensic investigations.

10_1.1 High-Security: What is it and What Does it Mean?

High-security is an extremely broad term, having no precise definition. Its meaning is dependent upon user requirements and environment. High-security for government, for example, may have an entirely different connotation than for a bank or jeweler. The security objective of a GSA Class 6 container, for example, will be vastly different than for a safe containing negotiable instruments. Whereas the contents of the GSA container will generally be documents and information having no actual worth, the bonds or currency within the safe will have a defined value. The loss of negotiable instruments or money can be calculated precisely. The compromise of classified documents or the information contained therein may be inestimable, especially if the penetration is not detected.

Many aspects and factors constitute high-security in a lock or key system. In its simplest form, the concept simply means that a lock meets certain tests and standards that make it more

difficult to penetrate, compromise, or open than an ordinary lock. The term "difficulty," of course, also has to be defined. The difficulty in compromising a lock relates to physical methods, available tools, skill and time. A lock will receive a higher security rating as these factors increase. Standards for locks are discussed in **Chapter 37**.

10_1.2 High-Security Lock Manufacturers

There are many high-security locks produced throughout the world. Different design schemes are employed utilizing mechanical, magnetic, electronic, electromechanical, and hybrid configurations. There is not one "best" design. In part, this is because different configurations meet varying and unique needs that are based upon the user, location, environment, area or objects to be protected, cost, and other factors.

Major manufacturers of locks that offer or represent that they offer high-security include **Abloy**, **Assa**, **Chicago**, **Chubb**, **DOM**, **Evva**, **Ikon**, **Kaba**, **Keso**, **Medeco**, **Miwa**, **Mul-T-Lock**, and **Schlage**. A detailed examination of many of these locks is presented in **Chapters 17-23**.

10_1.3 Standards and Ratings

In America, Underwriters Laboratory standard UL 437 defines high-security for key locks, and UL 768 for safes. Military standards for locks, safes, and enclosures that are used for storing classified documents may also apply. The reader is directed to **Chapter 37** for a detailed analyses of the provisions of UL 437 and related European/EC standards.

The UL 437 standard addresses both forced and surreptitious-entry techniques and the resistance of a lock to such physical and non-physical attack methods. Specifically, the standard provides tests for picking, impressioning, forcing, drilling, sawing, prying, pulling, and driving. All high-security locks should meet UL 437 or the equivalent European or EC standard.

10_2.0 Evaluation of High-Security Locks

Criteria have been developed to evaluate high-security locks. The following issues are relevant to such evaluations.

10_2.1 Criteria for Evaluating High-Security Locks

High-security locks must frustrate forced and surreptitious attempts to open them. Each manufacturer will define its own concept of high-security. A rating requires certain standard design features, options, methods of construction, and production and distribution controls that must be incorporated into such products. The most recognized of these criteria, relating specifically to keys and keying systems, are discussed in this section. Evaluation of locks, in the context of forced and surreptitious entry, is described in more detail in **Chapters 24-27.**

10_2.1.1 Key Control

Physical design and construction of high-security locks is equal in importance to the ability to rigidly control the production, generation, and duplication of keys. **Key control**, in the context of high-security, has a number of interrelated requirements, functions and purposes. The concept of key control encompasses requirements relating to keyways, blanks, master keying and standard keying options, protection from pirating, key machines, key design, and key codes. Key control also relates in part to the willingness and legal ability of the lock manufacturer to restrict the sale and distribution of keys, key codes, blanks, and key duplicating machines.

Properly implemented key control policies and procedures should address the following issues:

- **Limit unauthorized acquisition of keys;**
- **Control distribution of authorized keys;**
- **Provide organization of keys and key records;**
- **Insure that the premises, rather than people provide the basis for system design. That is, the keying system should be based upon building use or function, rather than individual users;**
- **Will promote the splitting of large systems into smaller, more manageable ones;**
- **Avoid cross-keying and and unintended master keying issues;**
- **Avoid maison keying, if possible;**
- **Define hardware limitations;**
- **Reduce keying levels;**

- **Provide for a method to account for all keys.**

10_2.1.2 Legal Protection for Keyways and Blanks

A manufacturer can take certain legal measures to increase the security of their products against unauthorized copying. Prior to purchase of high-security locks, a buyer should verify whether the keys, keyways, and other proprietary designs have been patented or copyrighted. Keyway sections should always be patented in order to restrict the ability to obtain key blanks or duplicate keys from other than the original manufacturer. In the absence of a patent or copyright, lock and key manufacturers have no legally protected proprietary right to prevent others from making facsimile or knockoff keyways or blanks. If keyways have been patented and/or copyrighted, then reproduction, import, sale, possession, or distribution can be prohibited.

Enforcement of such protection is through injunctive relief and seizure of contraband product pursuant to federal law. Generally, a patent can be valid for 20 years; a copyright for 50 years. Buyers of high-security locks should determine from the manufacturer when patent protection will expire in order to insure against the commercial availability of restricted keys to prevent compromise and duplication.

The first American patent for a keyway design appears to have been issued to Walter Schlage. After that, all high-security lock manufacturers have depended upon the protection afforded by the granting of design and utility patents. That legal protection may, however, be in jeopardy. See later Schlage patents for the Triad-C and Triad-D keyway series (5715717 and 5809816).

In 1992 and 1993, Best was granted utility patents on locks, and design patents on their keyways. In 1994, Ilco, an international key manufacturer, released key blanks with the Best keyways, in violation of the patent. Best sued Ilco for infringement of patent 5,136,869 and lost the lawsuit. In effect, Best patents were ruled invalid, because, said the Court, they contained nothing new or unique. What they described were prior art, already invented, and enumerated in Best patent 1,866,342.

Best Lock Corp v Ilco Unican Corp(129), 95-1528 (Fed Cir, 29 Aug 1996). Best Lock owned design patent 327,636 for the ornamental design for the operative portion of a key blade blank, for use

with Best Locks patented (5,136,869) key blade and cylinder lock assembly using a wider key profile to deter lock-picking. Southern District of Indiana held the '636 design patent invalid as functional, not ornamental. The Federal Circuit affirmed the decision: 'Any aesthetic appeal of the key blade design shown in the '636 patent is the inevitable result of having a shape that is dictated solely by functional concerns.' Judge Newman dissented, saying that 'the fact that the key blade is the mate of a keyway does not convert the arbitrary key profile into a primarily functional design. It is not the design of the key profile that is functional, but the key itself.' This litigation may define the limits of protection for design and utility patents as they affect keyways and key blanks. If Ilco ultimately prevails, then all restricted keyways may be subject to duplication and knockoff.

10_2.1.3 Restricted Keyways

A manufacturer will create what are known as restricted or ***proprietary*** keyways and sections, not commercially available to the public. Restricted blanks for such keyways may be designed for a specific customer or for a class of customers. For example, the White House may have a restricted keyway. The manufacturer in such case would only provide blanks to authorized purchasers, such as the Secret Service. No other customer, anywhere in the world, would have the same keyway or keyway groups for their locks. Each customer may have its own unique restricted keyways.

There can be several levels of restrictions. The lowest level may be a generic restricted keyway that is available to locksmiths who distribute a manufacturer's product for use by any customer of that locksmith. The next level would be a keyway sold to one specific customer in a given area, but repeated in other geographic areas in the country or the world. A higher level of security would provide for a custom-designed keyway for use by one customer only.

Many design variations can be applied to keyway control. For example, Schlage and Assa sidebar pin tumbler locks utilize a system whereby the sidebar portion of the keyway is varied according to dealer or customer. Each locksmith in the world who sells Assa or Schlage is provided with precut blanks with a certain sidebar combination. The local distributor will then cut the vertical-bitting portion of the key to different combinations, but the sidebar combination will remain constant for a given geographic area.

The distribution of key blanks for restricted keyways must be closely controlled by the manufacturer. In many instances, this protection has been rendered ineffective, because unlicensed manufacturers or vendors provide locksmiths with blanks for restricted profiles. Knockoff blanks may also be produced, although patent and copyright infringement occurs. A registration system should be offered by the original manufacturer that will restrict the sale of cut keys only to authorized individuals. Compromise in security may also result if key blanks, similar in design and commercially available, are modified through filing or milling in order to fit restricted keyways.

10_2.1.3.1 Compromise of Multilevel Keyways

Another security issue involves restricted, multisection keyways incorporated within a master key system. The function of such systems, in large complexes, is to provide different sectional keyways, with one master key that will enter each of the individual subkeyways.

Higher security is maintained with respect to cross-keying, because no sectional key can enter any other keyway. The local distributor or locksmith may only stock the master key blanks rather than all of the sectional blanks because of availability and cost. The logic is that it is simply easier to stock one blank rather than ten or fifteen for the different sections. When a customer wants a key copied, it is often duplicated on the ***master*** blank rather than the proper sectional blank. The result of this practice is that the copy may open locks it was not intended for, simply because the key can now be inserted into any keyway in the system.

10_2.1.4 Key Duplication

Key control is enhanced when duplicate keys cannot be made on conventional key machines. Many lock manufacturers design their keyways and blanks to require special key machines to duplicate them. For example, Medeco keys cannot be produced on a conventional machine, because both vertical as well as angled cuts must be made. Likewise, to reproduce an Assa key, special side-milling cutters are required. The difficulty in producing keys contributes to a locks high-security rating.

Because authorized key holders usually want to obtain additional keys locally without delay or inconvenience, vendors will

generally make available to their dealers the necessary equipment to produce and duplicate keys. There are also a number of key machine suppliers who can provide a variety of devices capable of duplicating most keys, irrespective of the wishes of the original equipment manufacturer.

10_2.1.5 Key Codes

High-security lock makers will tightly control the access to direct code data for duplicating their keys. Often, such information will not even be available from the manufacturer. A vendor cannot legally prevent, however, the distribution of such data if it was gathered and published independently. Thus, several companies can provide code data on certain high-security locks. The ability to restrict the distribution or availability of such information should be considered in the evaluation of any high-security locking system.

10_2.2 Key Blank Design and Differing

Key blanks for high-security cylinders are typically made of nickel silver and are of one-piece design. The key blank, and particularly the bitting blade, should not easily bend or break under normal use. The thickness of the blade should be a minimum of 0.090”.

A high differing potential must be available, allowing the capability for millions of different keying combinations. Generally, blade depths are divided into 10 steps of 0.015”. When tolerance at shear line exceeds 0.005”, then bitting steps of 0.015” are too small to prevent key interchange. Bitting steps of less than 0.060” invite cross-keying. Master keying requires several million theoretical key differs to yield only a few thousand non-interchangeable keys for some high-security installations.

10_3.0 Keying System Design

Most high-security locks will incorporate two distinct and independent locking mechanisms. In the Medeco design, for example, there will be conventional vertical cuts and rotating tumblers. Thus, many complexities in multilevel keying must be taken into account.

There are several aspects to keying system design, including the

selection of keyway subsections, individual key bitting design, and the configuration of the master key system. In addition, secure keying techniques are required to prevent persons who have limited access to keys from modifying them, through milling or filing, to operate more locks than intended. Thus, a system must be designed so that individual change keys cannot be cut deeper to create a master key. Ideally, a master key should never have the capability of being generated from a change key.

10_3.1 Modification of Master Key

When an unauthorized person attempts to reproduce a master key, he will take a change key and cut it down to the master. This practice is especially prevalent where a restricted keyway is used and blank keys are unavailable. Typically, a change key is reported as lost then used to make a master, if the system has not been designed properly. For example, a change key may be coded 33308, the master, 80008. To convert the change key to a master, the first three tumblers are cut from 333 to 800. As noted, the way to prevent the practice is to design the master key with at least one cut which is higher than any of the change key depths.

All modern master key systems are computer-designed and generated. Such programs take into account and protect against:

- **Cross-keying;**
- **Adjacent depth-cut restrictions (placing a deep cut next to a shallow cut);**
- **Tolerances;**
- **Number of submaster levels;**
- **Keyway subsections;**
- **Improper conversion of change keys to master keys;**
- **Other parameters.**

All high-security master key systems should be capable of master, grand master, and great grand master levels. To increase security, mushroom-shaped driver pins should be randomly applied to each cylinder. False grooves may also be placed on the bottom pins to provide additional resistance to manipulation.

Some vendors have integrated computer control into master key systems for greater flexibility and security. Such systems can monitor:

- **Access by location as to time of day, day of week, holidays;**
- **Duration that a door can remain open;**
- **Entry or exit control;**
- **Number of times a door may be opened;**
- **Activation and deactivation dates;**
- **Limited number of users;**
- **Alarms;**
- **Door unlock time;**
- **Identify, control, and classify keying levels, such as standard, management, system override, or special needs key;**
- **Other factors.**

All cylinders should be factory master keyed pursuant to owner requirements. All keys and blanks should be sent from the factory, via registered mail, and hand delivered directly to the owner's representative.

10_4.0 Product Flexibility

The flexibility of a product, to meet customer-specific requirements, is integral to the security and functionality of a system. Product flexibility encompasses the following issues:

- **Serviceability;**
- **Functionality;**
- **Depth of product line;**
- **Master keying levels;**
- **Standard keying options;**
- **Keyway restrictions;**
- **Convenience in obtaining duplicate keys;**
- **Factory key control;**
- **Ease in rekeying;**
- **Training;**
- **Widespread government acceptance;**
- **Level of keyway protection;**
- **Keyway restriction to one customer, or reuse in other geographic areas;**

- **Requirement for special key machines;**
- **Cost of key machines;**
- **Availability of key machines;**
- **Difficulty of rekeying cylinders on premises;**
- **Supplemental security hardware available from the manufacturer to allow installation of cylinders in such a way as to resist sharp pulling force that is intended to remove cylinders and expose locking mechanisms;**
- **Cylinders should be capable of immediate rekeying to new combinations or a new system at any time;**
- **Serviceability on location;**
- **Installation of cylinders should require no modification to U.S.-manufactured commercial grade locksets;**
- **Manufacturer's keying should be designed to fit mortise locks, rim locks, knob cylinder locks, interchangeable core cylinders, padlocks, dead bolts, cam locks, and switch locks;**
- **Technical support provided by the manufacturer is extremely important. Technical training should be available, detailing all phases of service, keying, installation, troubleshooting, integration of electronic systems, and other related areas.**

10_5.0 Evaluation Criteria for High-Security Locks

Certain mechanical criteria has been established for high-security locks relating to:

- **Type of mechanism;**
- **Level of security of that mechanism, i.e., number of levers or tumblers;**
- **Availability of keyways;**
- **Number of differs;**
- **Materials of manufacture;**
- **Purpose of lock;**
- **Method of affixing;**
- **Pick resistance;**

- **Drill resistance;**
- **Forced-entry techniques;**
- **Tolerance at shear line;**
- **Key interchange;**
- **Tumbler manipulation;**
- **Decoding;**
- **Impressioning;**
- **Key jiggling;**
- **Progressive compromise.**

See the discussion in **Chapters 24-27** regarding analyses of a lock for bypass potential. The following summary provides a synopsis of evaluation criteria for high-security locks.

10_5.1 Mechanical Manipulation Evaluation Criteria

The following detail of mechanical evaluation criteria relate to the manipulation of internal components.

A. MINIMUM TOLERANCE AT SHEARLINE
B. RESIST KEY INTERCHANGE
C. RESISTS TUMBLER MANIPULATION
D. RESISTS DECODING TECHNIQUES
E. RESISTS IMPRESSIONING
F. RESISTS KEY JIGGLING
G. RESISTS PROGRESSIVE COMPROMISE

C,D,G
Any chambers that permit slight lateral movement of the plug before pins are lifted can permit decoding of bottom pin lengths.

A,B,E,F
Wide tolerances at shear line will facilitate jiggling, impressioning, and cross-combinations.

10_5.2 Forced-Entry Evaluation Criteria

The following tests are performed to determine resistance to the use of forced-entry techniques.

A. RESISTS COMMON DRILL BITS
B. RESISTS SAW BLADES
C. RESISTS HOLE SAWS
D. RESISTS HAND FILES
E. RESISTS THREADING OF KEY SLOT
F. RESISTS RESHAPING OF KEY SLOT
G. RESISTS FRAGMENTING WITH PUNCH, CHISEL, SCREWDRIVER, ETC.

A
Insert full key blank. Drill into cylinder body to engage all driver pins. Remove key blank. Rotate plug with screwdriver.

B,C,D,F
Saw or file between pins for systematic compromise.

E
Drill and tap key slot to pull key barrel with slam-hammer.

CHAPTER ELEVEN: COMPLEX SYSTEMS

Keying Systems

Master Exhibit Summary

11_1.0 Introduction

Specialized keying systems are required whenever there are a large number of locks in use at one installation or facility. Such systems can address complex issues of security, access control, convenience, safety, simplified organization, and executive access. The concept of a keying system relates to a hierarchy of keys and locks and individual access to them. The term can also describe a grouping of different locks for which one or more keys can be used to activate one or more single locks within each such group. A system can be designed so that each lock belonging to a level of keying can only be operated by an authorized user for a specific group or level. Ideally, each person should need only one key to access all locks within his individual sphere of responsibility (group).

Security requirements may dictate that certain locks not be master keyed or included in a master key system. In many institutions, there is a clear distinction between locks in administrative areas and those protecting higher security locations or property. It cannot be overstressed that every master key system suffers from a significant lack of security, regardless of whether so called "high security" locks are installed.

In the following discussion, each primary classification of mechanical lock and how they can be utilized in different keying systems is examined. General levels of keying (including key alike, master keying, maison keying, and construction keying) will be described. Later in the chapter, details regarding each system is presented. Keying systems are designed to facilitate access.

The terms “specialized” or “complex” encompass the following levels or forms of keying:

- **Change key;**
- **Keying alike;**
- **Maison keying;**
- **Master keying;**
- **Complex master keying, including hotels;**
- **Construction mastering.**

This chapter explores various systems of keying and their impact upon security. Detailed information is provided regarding the analysis of conventional master key systems in terms of planning, coding schemes, advantages and disadvantages, and the potential vulnerabilities of each system. In subsequent chapters, techniques and procedures are examined with regard to the compromise of the most common master key systems.

11_1.1 Definitions and General Concepts Relating to Keying Systems and Levels of Keying

Keying systems are designed to facilitate access. Locks and locking systems can be configured to allow access by one key or several levels of keying, depending upon administrative, convenience, and security requirements. Specialized keying systems contemplate any group of locks that provide for the use of more than one individual change key for access to a lock or groups of locks. Each system and level of keying is covered in detail in subsequent sections of this chapter, with a brief definition provided here. Our discussion will focus on pin tumbler mechanisms, although keying levels are also presented for warded, lever, and wafer locks.

11_1.1.1 Individual Keyed

The lowest level of keying requires that one key fits one lock (or a group of locks if they are keyed alike). In this type of arrangement, the lock is not part of a master key system or group of locks that is associated with any other keying level. There are only two tumblers within each pin stack (bottom pin and top pin), and thus, only one virtual shear line.

A lock may also have one change key that operates it, yet be part of a master key system. In such case, the lock may or may not be controlled by one or more levels of master keys, depending upon security and access requirements. Individually keyed locks and locks with an individual change key on a master key system constitute the lowest level of keying. It is simply a question of whether the lock is set so that only one bitting combination will open it as a stand alone lock, or whether a change key and one or more master keys will also allow access. Interchangeable core locks may also be individually keyed at the change key level, but may be master keyed at the control shear line.

11_1.1.2 Keying Alike

Locks that are "keyed alike" all have the same pin combinations and thus are interchangeable. Any number of locks can be keyed alike and can be considered as a subset to locks that have one individual change key. It should be noted, however, that several locks can have the same change key, yet also be master keyed. In this instance, for example, several cylinders within a work area could have the same change key, yet all be controlled by one or more master keys. Key alike systems are the simplest and allow one or more locks to be operated by a common key. Any lock can be keyed in this fashion.

11_1.1.3 Maison Keying

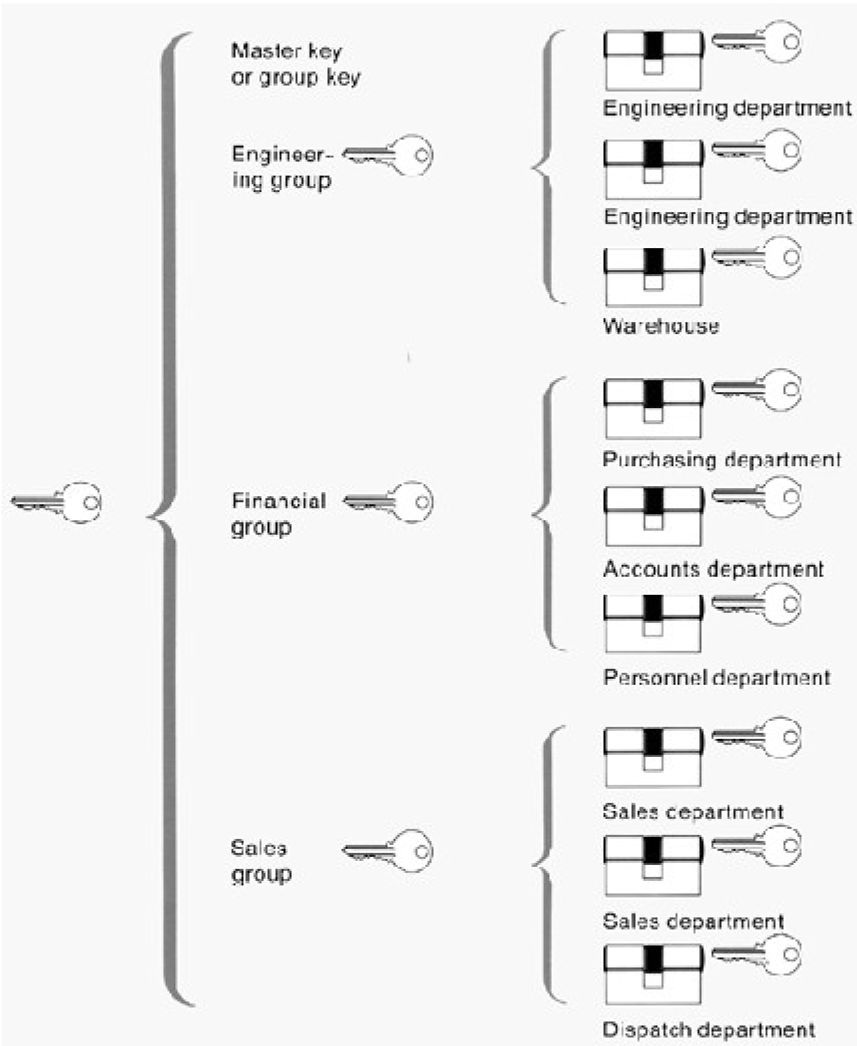
In the progression of keying systems, maison level can be thought of as a mix between keyed alike and individually keyed locks. In a maison system, all locks have their own change key and part of every change key may be common to the maison locks. **Maison** (French, meaning **house**) keying is used in apartment houses, college dormitories, and other communal areas where the individual change key must open both the room lock and also an outside door, garage, cellar, or other common access point. Typically, a resident must be able to unlock outside access doors and an individual apartment. Rather than issuing separate keys for each lock, the management can maison-key all access locks in a way that each change key can open them. Maison keying cannot be classified as a master key system. Rather, it should be thought of as a subset of a keyed alike system. The maison locks are keyed to the identical combination for one or more chambers in one scheme, and multiple virtual shear lines are created in another technique. As shown in the diagram, six tenants can access each of their apartments as well as three common areas in another example of a **maison system**.

It can be thought of as the reverse to a master key system where one key is designed to fit every lock within a certain group or level. In the maison system, all keys will fit one or more locks in common areas, yet allow each individual change key to fit one or more specific locks. A maison system can also be part of a master key system. In such an instance, cylinders are pinned in order to create intentional cross-keys. This concept is explored in later sections. In any installation where maison keying is employed, a significant reduction in security will result. Difficulty can also be encountered if maison-keyed locks must be re-keyed, depending upon which keying technique is employed.

Maison systems can be easily compromised in a variety of ways, including picking, "key picking", and the use of keys that are not intended to open a lock. Key picking, the technique of moving an unintended key in and out of a lock, allows the manipulation of pin segments (much like rake picking) in order to raise each pin stack to a shear line.

11_1.1.4 Master Keying

A master key system in its simplest definition is one that has two or more keying levels. In such a system, the locks can be combinated so that one key will open all of the master keyed locks that are associated within a group, yet allow each individual change key to operate one or more locks that have been pinned to that specific key. In reality, master keying systems are simply a grouping of numbers that correlate to the bitting of keys and locks that are linked or associated by function in one or more groupings. Such groupings can be called master key levels and can provide for access by one key to one or more groups.



The master key system is the most complex of keying arrangements. The goal is to allow the use of two or more different keys for one lock without a compromise in security from picking, use of skeleton keys, cross-keying, decoding, or a decrease in tolerances. Every master key system establishes a hierarchy of access, dependent upon security, convenience, and need.

The ability to master key a lock depends upon the design of its mechanism. In the warded lock, there are **fixed detainers** that significantly restrict master keying complexity and security. In contrast, lever, wafer, and pin tumbler locks utilize **double-detainer action**, allowing secure forms of master keying in often complex environments. Master keying in the double-detainer type of lock will rely upon certain functions associated with the operation of the individual change key. A second contact point, shear line, or mechanism may also be created for the operation of the master key.

A master system allows one or more locks to be operated by a key having a combination different than that of the change key. There are several levels and techniques applied to master keying. The simplest system level is one in which each lock has its own change key and can also be operated by one master key. This would be designated as a **master keying** level (two level system). A **grand master** offers one level above master keying (three level

system) and is used to open locks in several different submastered series or groups. In other words, a building may have two different wings, where each wing may have its own master key. A master key designed to operate in one wing would not open the locks in the other wing. The purpose of the grand master, then, is to work all of the locks in both wings.

The next step above the grand master is the **great grand master** (four level system). The same principles apply. There is a practical limit to the number of keying levels (generally six levels of keying) that can be established in a conventional system. Limitations are dictated by differs, tolerances, and adjacent cut restrictions. More sophisticated locks, such as the Medeco Biaxial, Medeco M3, and Evva magnetic sidebar system can allow more flexibility in complex systems. See **Chapter 19.**

11_1.1.5 Complex Master Keying

Complex master keying systems can provide up to six levels of keying, allowing for complex access to one lock or groups of locks. Such systems are described in later sections, and would include **hotel keying systems** where several levels of master keying may be required to allow for limited access by maintenance, cleaning, and housekeeping staff, while providing full access to security and management.

The factory will promulgate design specifications for each cylinder in order to insure that the system meets all mechanical requirements and limitations for optimum security. Standard progression techniques (TPP or RC) must be used; otherwise, a

significant decrease in security will result. Failure to adhere to standard keying techniques and resultant use of one progression is the minimum depth increment is less than .023" can result in the improper generation of combinations, leading to the use of master pins that are too thin.

If the spacing between master and change key codes is only one depth-cut apart, a thin wafer can flip sideways in the pin chamber. When this occurs, the lock becomes jammed and will not open. This condition can prove very inconvenient and costly. Generally, master key systems require that there be at least a .023" thick master pin to avoid problems.

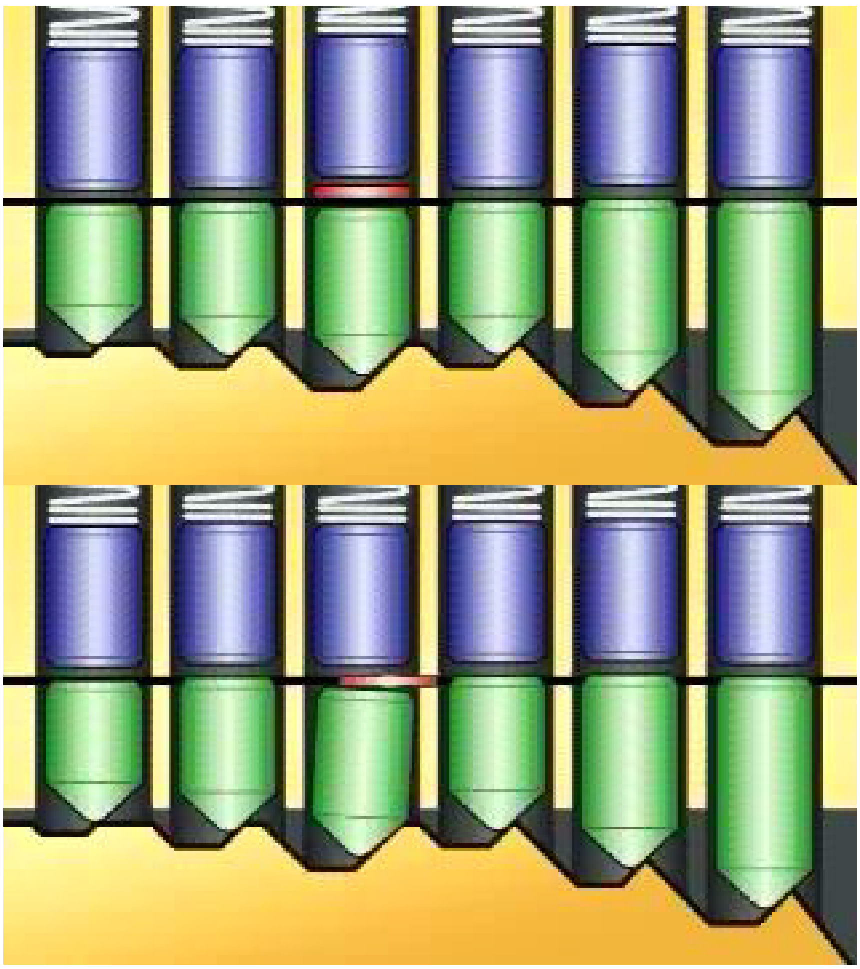


Figure LSS+1102 If master pins are too thin, they can dislodge within the chamber and cause a lock-out. Courtesy of HPC Interactive Learning Series.

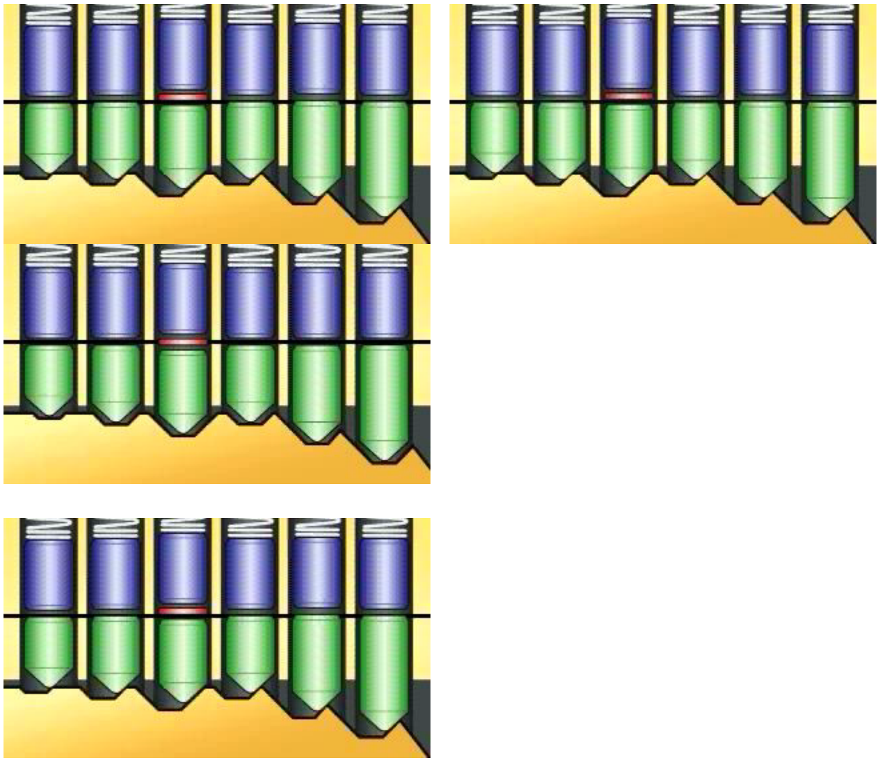

Figure LSS+1103 If master pins are too thin, then a change key can be jiggled back and forth to raise the pin, as shown. Maintenance problems can also be created. Courtesy of HPC Interactive Learning Series.

11_1.1.6 Hotel Keying Systems

Hardware used in the lodging industry must provide both security and enhanced auditing functions. Mechanical cylinders will usually have six or seven pin tumblers and utilize standard keyways. Lockout functions can be activated by guests inside the room, and once activated, only an emergency key can enter the keyway to retract the bolt. Hotel systems have unique keying requirements with multilevel access for different staffing functions. Generally, total position progression systems are employed in these installations. It must be noted, however, that hotel keying systems are extremely vulnerable to decoding and compromise of the TMK because it is easy to obtain a change key in order to derive the codes for the top level master key. This subject is thoroughly examined in subsequent sections.

Many ingenious systems have been designed for the hotel industry. One of the most unique was patented by **Winfield(130)**. The Winfield **cylinder** contains two distinct keyways: one for the

guest and one for the maid or maintenance staff. These locks have also found limited acceptance within colleges and other complexes where instant reprogramming is desirable. See **Chapter 23** for a thorough discussion of hotel locks and those produced by **Winfield.**

11_1.1.7 Construction Master Keying

A **construction master** system allows one or more keys to open all locks within a building site during construction. In order to prevent workers from later using these masters, the system is converted automatically at the conclusion of the project so that the construction keys will no longer function. Certain cylinders have been designed to meet the security needs inherent in buildings under construction. Their function is to prevent the compromise of master keys by project workers while offering the needed job site access to different areas. Workers can be granted access during the project, but denied after completion.

Initially, they provide for the operation of all locks using special keys or inserts, allowing workers to enter all areas without restriction. When a building is completed, the special inserts are removed or the tumbler combinations reset or cores exchanged so that the locks are ready for use by the tenants. The original keying scheme no longer exists, thus rendering all construction keys inoperable. There are several schemes for construction mastering that are based upon different fundamental design configurations. Keyway lockouts, second shear lines, removable cores and unique parking of tumblers are all in use. Examples of construction keying systems are presented later in this chapter.

In large tract construction sites where hundreds of homes are built by one contractor, locks are often master keyed for worker convenience. No special construction keying systems are employed in such instances. At the conclusion of the project, homes are turned over to buyers with individual change keys. Unfortunately, the locks are still master keyed and are subject to compromise through disassembly or by the extrapolation and decoding of the master key through procedures detailed in **chapter 31**. In burglary investigations in townhouse communities, for example, it would be well to examine one or more locks to determine if the complex has been master keyed. Such information may provide a clue as to entry techniques.

11_2.0 Warded Locks

11_2.1 Introduction

The warded lock is the most primary of all mechanisms. Because of its extremely simple construction, it offers a very limited range of keying options. The warded lock may be keyed alike or master keyed for two keying levels, but the number of wards will limit the number of available combinations.

11_2.2 Warded Master Keying

Master keying schemes generally rely upon an alteration of the design of the key rather than the wards. In some systems, different keyways may also be employed. It will be recalled that wards are fixed obstructions and thus cannot be changed. A **skeleton key** may be produced to open all warded locks within a series. Complex master keying, in the practical sense of the word, is not possible. For this reason, warded locks have a very limited use in any environment where security is at issue. Except in hotels and prisons, few warded locks are master keyed. In these instances, special locks can be used that are designed to accommodate higher level keying. They are still vulnerable to skeleton and pick keys, however.

11_3.0 Lever Locks

Lever locks can be individually keyed, keyed alike and, in some cases, master keyed to allow a total of two keying levels. The instance of high-level keying is rare, however. There are four primary uses for lever locks in the United States: lockers, **safe-deposit**, **mailbox**, **pay telephones**. Everywhere else in the world, they are quite popular in all applications.

Safe-deposit boxes generally utilize double cylinders; the customer (renters) lock is keyed individually, the bank lock (guard) is keyed alike. Coin phones are generally keyed alike for the electronics (upper) housing, with individual keying of the coin box vault. All U.S. mailbox collection points are keyed alike in groups, geographic sectors, by city or zip code, or by specific location. Standard keyways for mailboxes, drop boxes, and certified or registered mail pouches have been adopted throughout the United States.

11_3.1 Master Keying Schemes

There are many master keying techniques for lever locks, some dating back 150 years. The most accepted methods are:

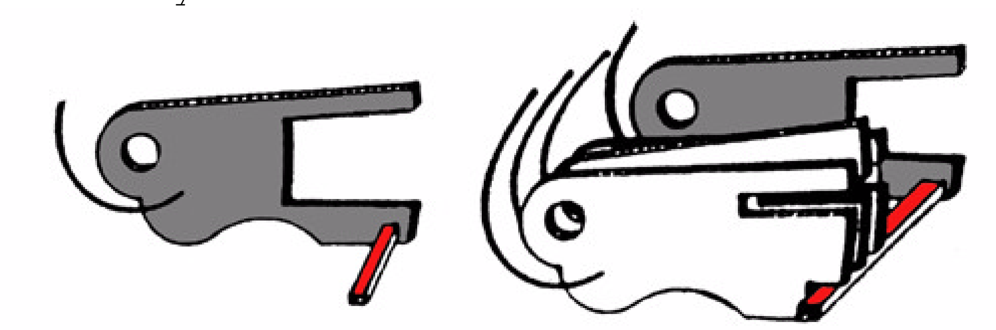
- **Two sets of levers;**
- **Two sets of gates in one lever;**
- **Wide gating;**
- **Two keyholes;**
- **Two points on which the keys bear on a set of levers;**
- **Special slots on the bottom of levers;**
- **Butters' System**
- **Special master lever that picks up some or all of the other levers.**

11_3.1.1 Two Sets of Gates in One Lever

The simplest technique provides that each lever tumbler is cut with two slots or gates. In the **spring-biased** lever, one gate will be used for the change key, the other for the master key. In the **dead bolt lever**, however, this scheme is more difficult to accomplish. It will require removal of most of the bar separating the pockets, thereby severely reducing security. The preferred method is to utilize wide rather than double gating.

11_3.1.2 Wide Gating

The wide gating of ordinary levers is one of the more practical methods to accomplish master keying. In practice, the gating on one or more of the levers is made wider than the thickness of the bolt stump. This will allow the stump to pass through, regardless of whether the change or master key is used. The technique severely limits differing potential and is not recommended.



11_3.1.3 Slots on Bottom of Levers

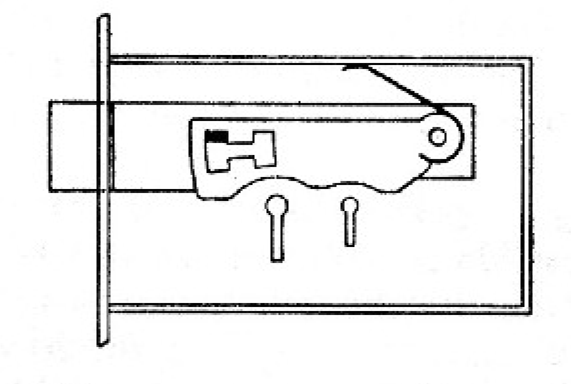
The master lever is one of the most popular approaches for keying lever locks. It consists of placing a slot on the bottom of each tumbler, rather than at the end where the normal gate cuts are made. In this way, the master key is allowed to bypass all but the master lever tumbler. This special tumbler will lift all of

the regular levers to the correct alignment position in order for the fence to slide into the gating. This method of master keying is commonly used in such applications as lockers, cabinets, and desks. No resulting loss of security occurs from cross-keying using this method.

The master key will be cut so as to bypass all of the standard levers, much like a skeleton key does in a warded lock. All bitting positions other than for the master lever tumbler are cut to their deepest position on the key. The master key bitting will only make contact with the master lever tumbler, thereby causing the bar or rod, shown in the illustration below, to raise all of the remaining levers simultaneously so that all gates are aligned with the fence.

The master lever can be positioned anywhere in the lever pack; the pickup bar can extend in one or both directions. This system allows for great versatility, in that two different master levers can be utilized for progression of change keys under different master keys.

11_3.1.4 Two Keyholes



A number of schemes have been developed using two keyholes to accomplish master keying. In the most common form, found in safe-deposit boxes worldwide, there are actually two sets of levers operating more or less in tandem. Each set must be lifted to allow clearance of the stump to permit retraction of a single bolt. In this design, one set of levers is operated by the bank guard key and the other set by the renter's key.

In a design that was first patented in 1898 in Britain, elongated levers were provided with curved bellies in two positions corresponding to the keyholes. Either one of two different keys with unique combinations could thus be used to lift the levers to

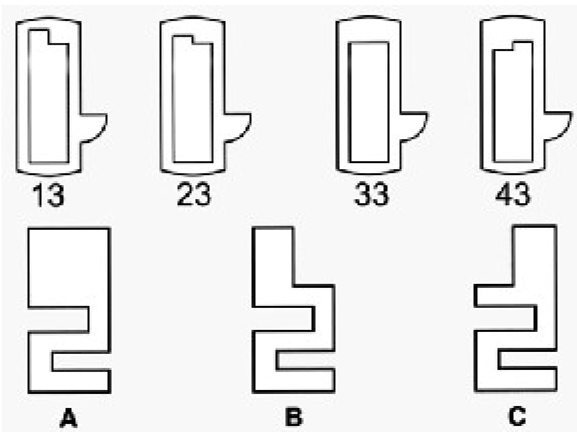
the correct position to clear the stump. No cross-keying results.

11_3.1.5 Two Contact Points at Bottom of Levers

A compound lever, first patented in England in 1922, has two contact points or bellies. The change key and master key actually make contact with and raise the lever at different points created by different radii of the bellies. A similar system is used in wafer locks.

11_3.1.6 Butter's System

In the Butter's system, gating on lever-like detainers consists of a small, shallow slot on the edge of each lever. This creates **double gating** using two slots. Because the slots are shallow and bear no relation to the length of travel of the bolt, two sets of gates at different positions can be placed on the levers to match the lift of two different keys. The lock is particularly suitable for master keying because it provides a relatively large number of differs.



11_4.0 Wafer Locks

Wafer locks, both single and double-bitted, can be master keyed without difficulty, using a specially designed tumbler.

11_4.1 Standard Single-Bitted Wafer Configurations

Master keying of these locks is accomplished through the creation

of a wafer with two steps or contact points. The individual change key lifts the wafer by contact at one point, while the master key raises the wafer at a different contact surface. In order to rotate the plug within the shell, the wafers must all be lined up at shear line. In operation, the change key lifts the left step or contact point on the wafer; the master key lifts the right step. Blanks with left and right orientation are used for change and master key to create the correct pickup angle.

11_4.2 Double Bitted Wafer Locks

The double-bitted wafer lock can be master keyed in the same manner as the single bitted type described above. The bittings on the blank picks up a different portion of the tumbler, depending on whether a change or master key is used.

11_4.2.1 Schlage Wafer Lock

Master keying for the old but very popular Schlage double-bitted wafer lock was described in detail in **Chapter 7** of the first edition of this text, and, therefore, it will be dealt with only briefly here.

The Schlage wafer lock can be very simply and quickly master keyed. The theory is based on the fact that there are only two levels of cuts (binary) in the Schlage system. A "no cut" is used for the master key, a "full cut" for the change key. A master pin can be placed in any one of seven positions within the Schlage plug. The locks were once used extensively in schools, hotels, motels, and other large complexes and can still be found in operation throughout the United States. Interestingly, this lock has now been reproduced in Asia and imported into the United

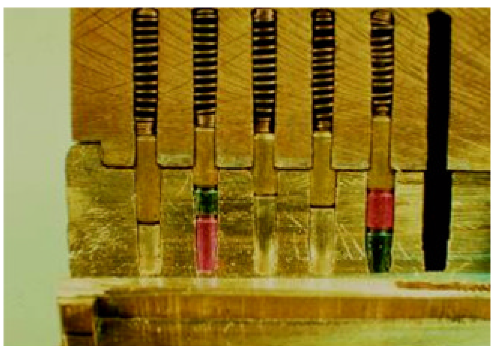
States. They may indeed become popular again in this country.

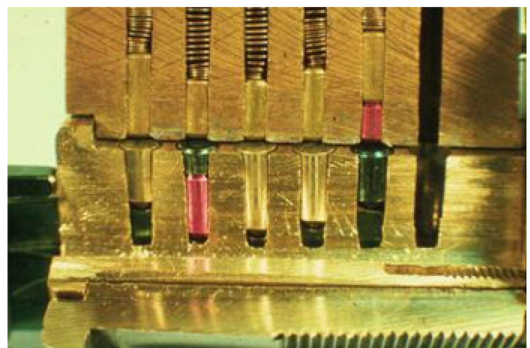
11_5.0 Pin Tumbler Lock

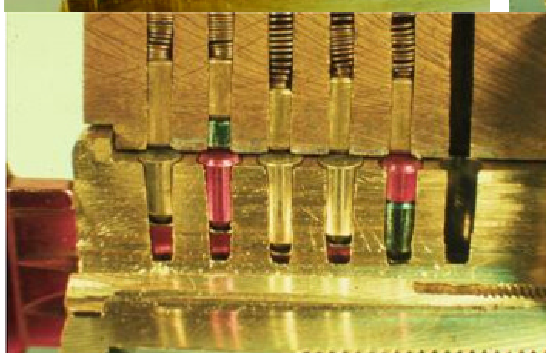
The pin tumbler is perhaps the most versatile mechanism for master keying. Therefore, a detailed description of keying theory will be presented here. Many schemes have been devised since the introduction of the Yale lock. The simplest form required the use of two distinct cylinders: one keyed individually, and one keyed alike with all other cylinders. Other systems described within **LSS+** include pin subsets (master pins) that create different virtual shear lines, master rings, and positional systems.

11_5.1 Introduction

Pin tumbler locks can be individually keyed, keyed alike, maison keyed, and master keyed. Their design allows for complex keying, and, in the case of high-security cylinders, such specialized keying will not affect or reduce security, although the overall integrity of many master key system may be compromised through techniques discussed later in this text. High- security locks do not guarantee that the system cannot be compromised; they simply may make it more difficult. This section will describe different keying applications for which the pin tumbler mechanism is so ideally suited. The following discussion presents information regarding the theory of each keying level.







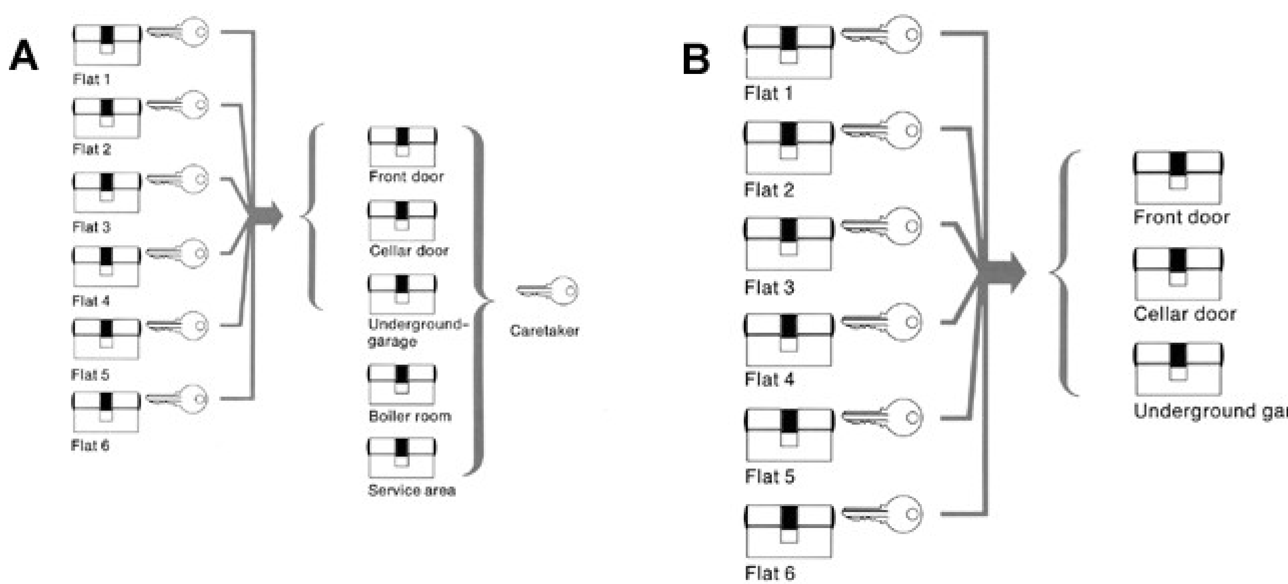
As previously described, there are several levels of keying available for the pin tumbler mechanism. Whatever the requirements, the underlying principles will remain constant in conventional systems. **Positional** master key systems are based upon a different scheme and are discussed later in the chapter.

All conventional keying systems will require a configuration of the pins to create one or more virtual shear lines. This may be accomplished with split pins, called master pins, or with a master sleeve or ring that creates a second physically distinct shear line. A unique rotating piston master keying system was invented by Lipschutz in 1983 (**4409807(131)**). This technique relies upon the rotation of tumblers in conjunction with the bitting of the key.

There are two primary schemes to define the combination for master keys and the security of master key systems in conventional pin tumbler cylinders. These are identified as **Total**

Position Progression System (TPP) and **Rotating Constant (RC).** Each master key scheme protects against certain vulnerabilities inherent when multiple virtual shear lines are created. Modern master key systems will contain a maximum of two pins per chamber below the the top pin (bottom pin and master pin) in order to minimize the number of incidental master keys, cross-key combinations, and to increase the security of the cylinder. Pin segments may be added to meet special keying requirements. This rule, of course, does not apply to IC locks and master ring.

In the photographs below, multiple virtual shear lines are created by the introduction of additional pins.



Certain keying systems and hardware can present security problems, resulting in cross-combinations, compromise of master keys, and reduced resistance to picking. If sectional keying is employed, added security issues can result from alteration of blanks, thereby allowing unauthorized access to one or more sections. In those systems where sectional keyways are employed, there is always a risk that a local locksmith may only stock higher section blanks, thus defeating the purpose of sectional keyways. In such an event, a key that is duplicated on the wrong blank would allow entry into unintended keyways. If the same combination was utilized for a different section, the key would enter the lock and open it. The Medeco M3 system offers a unique

alternate or enhancement to sectional keyways by adding a third level of protection through the use of sliders that control a sidebar for change key or master key. See the discussion in **chapter 17.**

11_5.2 Maison or Central Locking Systems

Maison keying is used in situations where a number of different keys must all operate individual locks and one or more central or common locks. In the apartment house complex, for example, each tenant's key will fit the individual apartment in addition to the entrances to the building, garage, utility room, exercise facilities, and laundry. This form of keying is done primarily for convenience. Two methods can be employed to implement a maison system: they both significantly reduce security.

11_5.2.1 Maison Keying Security

Conventional mechanical locks that have been maison-keyed are subject to picking, raking, key picking (jiggling), and key interchange. Unless a magnetic system, sidebar, or other more sophisticated cylinder is utilized, security is severely compromised. In one scheme, the number of pin combinations within these cylinders is usually reduced so that, in many cases, keys for other systems will work. In addition, individually-keyed tenant locks have fewer differs, thereby increasing the potential

for use of unauthorized keys either within or from outside the system (key interchange). This results when all tenant locks have one or more common bitting depths to the maison-keyed common locks. Resistance to picking is also greatly diminished. This can be readily appreciated when it is considered how a lock with two or three tumblers (or multiple shear lines) can be picked, in contrast to a lock having five of six pins and only one master pin in each chamber. The security of a maison system is still further diminished when master keying is also employed.

In any burglary investigation involving possible surreptitious entry, the use of maison keying should be determined. Questions that may be raised in conjunction with any analysis of maison systems include:

/• **Have keys been lost? One of the major drawbacks to maison keying is the inability to change common access locks if keys have been lost or compromised. Access cannot be prevented for any key, once granted;**

- **What type of maison system has been implemented? Are there active pins in every chamber, rather than having only two or three chambers populated;**
- **Has the system been designed so that it cannot be easily key picked? This means that keys cannot be jiggled or manipulated in the cylinder to effect an opening;**
- **What is the policy with regard to changing common locks in the event that tenants leave. Usually there is no such policy, which means that there is no security in the system;**

Security in such systems is reduced because of the following issues:

Added master pins:

- **Reduce pick resistance;**
- **Increase the likelihood of key interchange;**
- **Create more keys that will open the lock (cross-keys);**
- **Increase the ability to key pick or jiggle a key to manipulate tumblers to shear line;**
- **Increase the probability that a blank key, paper clip, or pocket knife can be used to open the lock by simulating the right bitting combination or manipulating each tumbler to shear line;**

- **Increase the ability to rap the lock using a "999" or bump key;**

Reduced number of pins or active chambers:

- **Reduce pick resistance;**
- **Increase the likelihood of key interchange;**
- **Increase the ability to key pick or jiggle a key to manipulate tumblers to shear line;**
- **Increase the risk that a key may be withdrawn while the plug is in the turned position;**

11_5.2.2 Maison Keying Theory

Maison keying can be considered as master keying in reverse, in that a number of **different keys** must open a common lock. Locks can be maison keyed in three ways: they may contain a fewer number of pins that are common to all locks within the complex, use of segmented pins, or a combination of the two approaches. Maison keying generally requires that additional master pins are required, creating cross-keying to allow multiple keys to operate the lock. Whether double pinning or the pinning of fewer chambers is implemented in such a system, security is drastically reduced.

11_5.2.2.1 Cylinder with Two or Three Pins

The maison cylinders may only have two or three pins that are common to all locks in the system. This means that at least two cuts will be the same on all keys, and then the maison locks are combinated to these two pins only. In an apartment complex having four different tenants with keys that must all open a common cylinder, the individual apartment locks could be set to the following combinations:

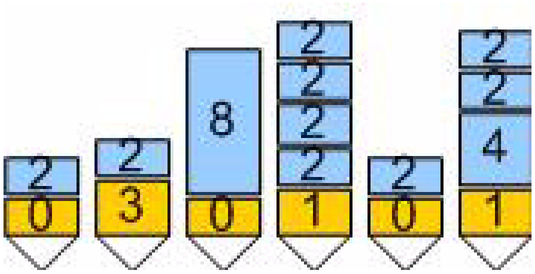
Apartment one	***62804***
Apartment two	***62738***
Apartment three	***62887***
Apartment four	***62534***
Entry Lock	***62---***

Note that each apartment key has the same cuts for the first two tumblers, **62**. The entrance lock then matches the first cuts. No other pins are used in the entry lock. If a master keyed system

also incorporates maison-keying, it is important to verify the actual number of active chambers if the cylinder is to be decoded through the use of a change key to derive the TMK. A detailed analysis of the procedure to extrapolate a TMK is presented in chapter 31. The validity of the decoding process can be affected if the target cylinder has been maison-keyed.

11_5.2.2.2 Segmented Pins

In order for many keys with different combinations to all operate one common lock, the pin sets must create several virtual shear lines. This is accomplished by a number of small tumblers being stacked one above the other to create the different splits. These are called master pins and are more fully discussed below. In our example, let us assume we have a large apartment complex with three levels of keying and maison keying. Thus, there is a change key for each apartment, a master key for a specific complex, and a top level master key that will open several different buildings within the complex. The common area locks must allow the TMK, master key, and the five tenant keys to open the front, back, and garage door locks:



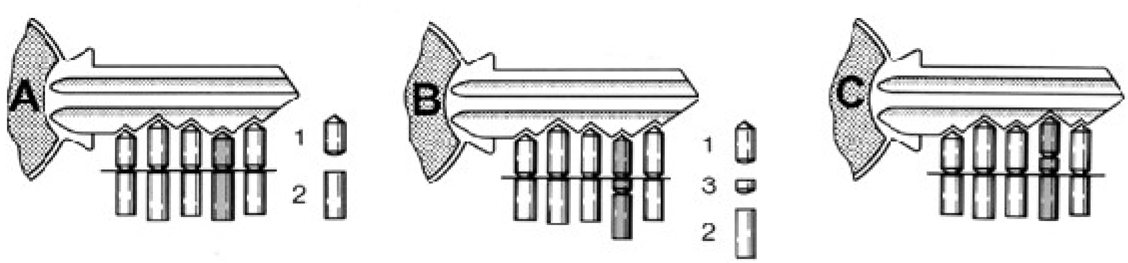
258307 TMK
030307 Master key

030121 change key
030125 change key
030521 change key
030725 change key
030929 change key

In order to allow all of these keys to work in common access areas, chambers four and six must have three extra master pins. This process is referred to as double-pinning and should be avoided whenever possible. In our example, intended cross-keying is implemented. The tables below show the required depths for each position in order to allow all of the keys to open the lock, and the bottom and master pins that are required to implement this scheme. We are utilizing a Schlage cylinder with ten depths (0 = most shallow, 9 = deepest cut). The table shows the pins as they would be inserted for each chamber and pin stack order. The diagram shows the actual pinning. This lock would have a total of 128 cross-keys that would open it. Note that in this example, the code 030929 would not actually be utilized for a Schlage with a

code 030929 would not actually be utilized for a Schlage with a MACS of 7.

MAISON KEYING SYSTEM: DEPTHS REQUIRED FOR EACH CHAMBER					
#1	**#2**	**#3**	**#4**	**#5**	**#6**
			9		
			7		9
			5		7
2	5	8	3	2	5
0	3	0	1	0	1



11_5.3 Master Keying Pin Tumbler Locks

11_5.3.1 Introduction

Pin tumbler locks can be effectively master keyed to six different levels, can contain sectional sub-systems and incorporate both schemes for a complex keying system. Master keying is generally done at the factory when locks are first produced for a customer; most combinations are generated by computer program within carefully defined guidelines for the selection of top level master keys. Software is so sophisticated today that all parameters relating to TMK bitting, levels of keying, tolerances, differs, adjacent cut specifications, cross-keying, and other customer requirements can be factored into the output.

Conventional pin tumbler locks are usually keyed to a maximum of four levels of complexity: **master, grand master, and great grand master.** In the simplest system, a number of locks with different change keys can all be controlled by one master key. In the more complex levels of keying, several different series of locks, all with their own submaster key, may have one grand or even great grand master key.

As detailed in the text that follows, there are a number of variables that affect the design, operation, capabilities and

security of any master key system. These concepts are examined in subsequent sections and must be understood in order to effectively analyze a system for security and for covert operations, in order to compromise the TMK as discussed in **chapter 31.**

11_5.3.1.1 Underlying Concepts

- **Method of progression: total position progression or rotating constant;**
- **Type of progression: one or two-step;**
- **Parity;**
- **Keyway design;**
- **Division of the key;**
- **Sequence of progression (SOP): shallow to deep, odometer method, scrambled;**
- **Levels of keying;**
- **Mechanical design of the lock;**
- **Number of chambers that can be progressed.**

11_5.3.2 Definitions

Specific terms have been developed by the locksmithing and manufacturing industry to describe locks, keys, keying levels, keying schemes, bitting, measurements, and associated hardware technology. The following reference provides a comprehensive glossary of accepted terminology.

Abbreviations for Locks and Keys within a Master Key System: See **Standard key coding system.**

Associated Change Key: A change key that has common bitting with the master key to which it belongs. In like fashion, the **associated master key** has common bittings with the change keys below it. In contrast, an **unassociated change key** does not have common cuts that relate it to a master key, and likewise for the **unassociated master key** to the change key.

Bitting List: A comprehensive list or inventory of all keys and their bitting codes that are associated with a master key system.

The list may be sorted by blind code, direct code, or key symbol.

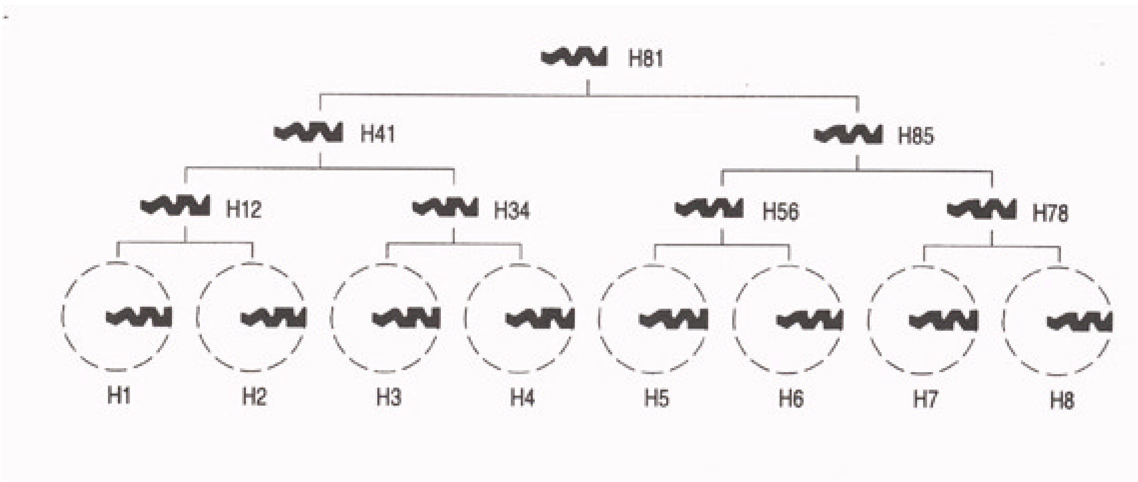
Bitting Position: The location of a cut on a key.

Block Master Key: Within a standard progression format, the one-pin master key for all bitting combinations that comprise a block.

Building Master Key: The key that can operate most, if not all of the locks within a building.

Build-up Pin: See master pins or top pins. The pin is used to "build-up" or make up the difference in height within a pin stack between the change key and control key shear line. The primary definition relates to interchangeable core locks such as Best, and Corbin and Russwin master sleeve cylinders. The build-up pin can usually be found immediately below the top pin.

Chamfer or Radius of Pin: The top of the bottom pin should be chamfered or radiused to conform with the surface of the plug to assure smooth operation. If the top of the pin is flat, it will catch or interfere with the turning of the plug.



Change Key (CK): The individual change key is the lowest level of keying for any cylinder within a keying system. Change key, guest key, servant key or similar term denotes the base unique individual combination of pins that will allow one or more locks (if keyed alike) to be opened by only one key. Such locks may also be controlled by one or more master keys. The two concepts are not mutually exclusive.

Figure LSS+1104 The change key is the lowest level of keying. One key fits one lock. Courtesy of HPC Interactive Learning Series.

cmk'd: Construction master keyed.

Complex Keying Systems: A *complex keying system* utilizes one or more levels of master keying and may also incorporate sectional keyway assignments for added security and organizational control. Systems implementing sectional keyways may also be referred to as **multiplex keying systems.** The Medeco M3 can implement advanced sectional keyways through the use of sliders for different keying levels.

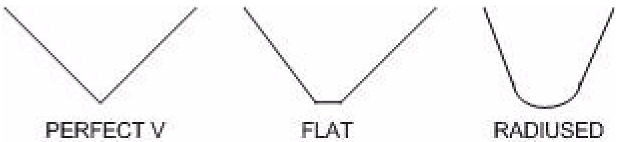
Complementary Keyway: This term usually refers to a disc or wafer lock that is part of a master key system. As described earlier in this chapter, the wafers are manufactured to provide two contact surfaces for different key sections: one to operate the lock as a change key, and one for the master key.

Constant Cut: This term refers to one or more bittings that are common and identical as to depth and position within different keys within a keying system. Such commonality can provide grouping between keys and levels. As shown in the detailed description of the rotating constant system, **figure LSS+1126**, one or more chambers in groups of cylinders have pins of the same length.

Construction Breakout Key: A special key that is employed by some lock makers to render inoperative upon project completion a cylinder that has implemented a construction master key system.

Construction Core: A removable core, usually keyed alike, that is utilized at a construction site during the project. Cores are removed at the conclusion of construction and replaced with ones that are keyed for the facility.

Construction Master Keying: A specialized keying technique used in new building sites to control the distribution and compromise of master keys during and after construction. It is a unique keying system that is designed for the convenience of workers, managers, and other persons who require free access to the site. Such systems will allow for the programming of a special tumbler combination for a master key that will only function prior to building completion.



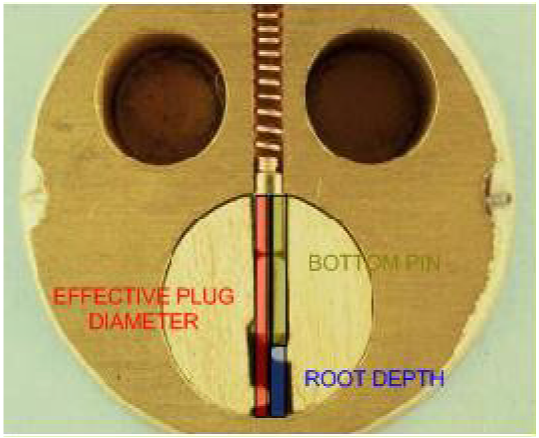
Controlled Cross Keying: When two or more change keys associated with one keying level and under the same higher level are allowed to operate one cylinder **by design**, then controlled cross-keying has been implemented. This would be demonstrated by cylinder XAA3 operated by AA4, but not by AB1. Cross-keying can present serious security issues, detailed in later sections. In contrast, **uncontrolled** cross-keying would exist in a situation where two or more different keys under **different** higher level keys can operate one cylinder. Thus, XAA3 can be operated by AB, AB1, etc.

Cross-Keys: "Cross-keying" can denote the introduction of multiple pin segments within the chamber of a master keyed cylinder that will create different combinations that will open the lock. Traditionally, the term referred to the different combinations that were created with the introduction of multiple pin segments. Many virtual shear lines can be created when master pins are introduced. The industry has refined the definition for cross-keying, as shown below. The correct nomenclature to define the composite combinations that will open a lock in a master keyed environment is "incidental master key."

Cross-Keying: *Cross-keying* is the intended or unintended and undesirable product of conventional master keying systems and results from the introduction of multiple pin tumbler segments within each pin chamber. For each master pin segment within a chamber, there is created another or virtual theoretical shear line. The result is a different key combination that will open the lock. To compute all the possible permutations, the number of pin segments are factored by the number of chambers. Thus, in a five-pin lock with three pin segments within each chamber, there would be 3^5 possible combinations, or 243 different keys that theoretically could open the lock. See the definition for **controlled cross-keying**, above. Locks employing **master rings** or **sleeves** can reduce the problem of cross-keying. However, if

chambers are double-pinned below the master ring or sleeve, then cross-keying can still occur.

Cut Root Shape: The geometric design or shape of the root or bottom of a key cut. The shape may be flat, V, or radiused.



Department Master Key: A master key that is designed to open many or all of the locks within a specific department.

Display Key: Within a hotel keying system, a special key that is designed to open one specific guest room, even if the lock has been set to prevent access by a normal key or master key. A display key may also be considered as a shut-out key.

Double Pin: The practice of double pinning means to insert more than one master pin in a pin stack within a given chamber. The practice is more fully explained later in the text, and is not the correct way to implement a master key system except in very limited circumstances, such as controlled cross-keying, master ring, and IC.

Effective Plug Diameter: The effective plug diameter is slightly less than the actual diameter of the plug. It is comprised of the lower pin tumbler and root depth to the bottom of the key blade. The effective plug diameter is affected by the blade radius and the shaping of the top of the bottom pin to conform with the curvature of the plug. The more that the radius of the blade and the pin tumbler conform to the plug, the closer will be the effective plug diameter to the actual plug dimension.

Engineer's Key: This is a multilevel master key utilized by maintenance personnel than opens locks within a master key system that contains three or more levels of keying, and which will operate locks that are each controlled under different master key levels.

Expansions Specification: A detailed analysis of a system's functionality requirements will dictate how many locks will be needed. The expansion specification defines the potential number of required combinations for each specialized keying level.

Floor Master Key: A master key that controls or operates most or all of the locks on a specific floor of a building.

Grand Master Key (GM): This term generally describes the second level of keying above the individual change key and one level above master key.

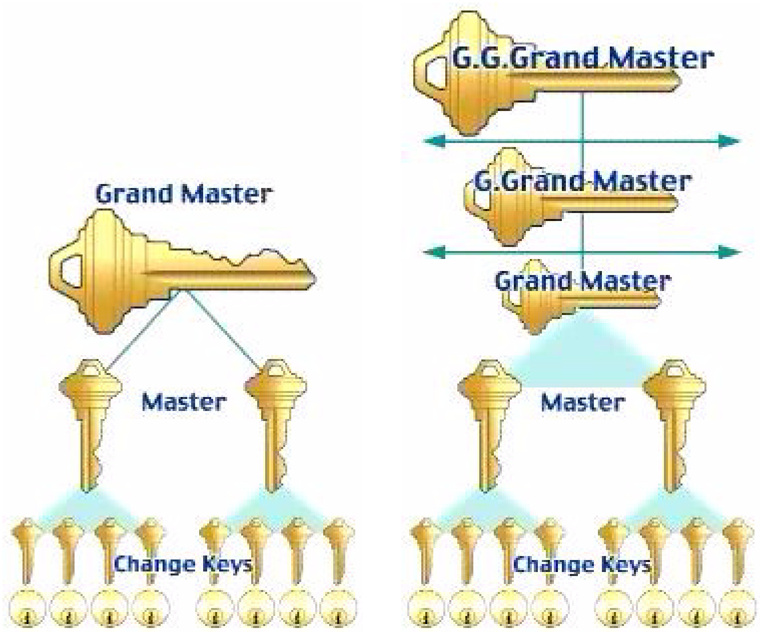


Figure LSS+1105 Great grand master key diagram. Courtesy of HPC Interactive Learning Series.

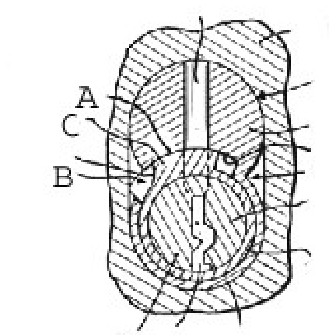
Great Grand Master Key (GGM): The GGM keying level defines the third step above the change key. It may also be referred to as the TMK. Generally, most systems will rarely be keyed above the great grand master key level, except in those instances where high-security hybrid locks, such as Medeco or the EVVA magnetic sidebar are employed.

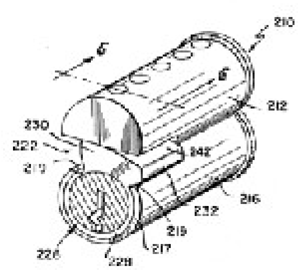
Guest Key: A guest key is the equivalent of a change key within a hotel master key system. It is designed to open one guest room when the lock is in the normal (not lockout) mode.

Horizontal Group Master Key: Within a standard progression system list, this is a two-pin master key for all combinations in all blocks in a line across the page.

Housekeeper's Key: A special master key within a hotel keying system that is designed to operate guest rooms as well as those areas that must be accessed by housekeeping staff.



Incidental Master Key: When a cylinder is combinated to a change key and a top master key, a key may be cut to a **virtual shear line;** a composite of bottom and master pin combinations in the different chambers. The matrix of bottom and master pins provide certain bitting combinations that were not intended to be used



within the system, but for which a key could be produced to open the lock. Incidental master keys are used in complex keying systems as block, row, horizontal group, vertical group, and page master keys. In a total position progression system that utilizes cylinders with six chambers and one master pin per chamber, there are a total of 41 incidental master keys, and a total of 64 keys that will open the lock. In this example, there would be:

1 page master key (PM)
16 row master keys (RM)
16 block master keys (BM)
4 vertical group master keys (VGM)
4 horizontal group master keys (HGM)

Individual Key: The simplest form of keying allows for one depth per bitting position, created by one bottom pin. In this configuration, only one key will open the lock.

Interchangeable Core Nomenclature: The **control cuts** (A) within the **control key**, raise the pins to the control shear line that is created by the **sleeve** (C), in order to remove the core by withdrawing the **control lug** (B).

Key Alike (KA): Two or more locks or groups of locks may be keyed alike within any keying system and at any level. This means that all such locks will have the same individual key combination. Any number of locks can be combinated alike so that one key will open them all. Locks can only be keyed alike if the keyways are identical or use the same keyway section within a multiplex system.

Key Bitting Array (KBA): The KBA provides a graphical method of defining every available bitting depth for each chamber in any pin tumbler lock within a master key system. It is based upon the

number of available depths, the keying scheme, number of chambers, and the spacing between depths (which in turn translates to a one or two-step progression).

Key Bitting Specifications: Each manufacturer provides precise specifications regarding all matters pertaining to bitting depth, spacing, cut angle, cut root shape, key cut profile, degree of rotation, and how bittings are applied to the key blank during the cutting process (bow-to-tip or tip-to-bow). Spacing will generally provide two dimensions: stop to the center of the first cut, and center-to-center between adjacent cuts. Depths are correlated to depth cut numbers and are generally computed from the bottom of the blade to the root of the cut, although some manufacturers have measured from a register groove on the side of the blank.

Key Cut Profile: The geometric shape of the composite cut, including the root design and cut angle.

Keyed Different (KD): One or more locks that may or may not be part of a keying system that are combinated differently from each other. It is the opposite concept of keyed alike.

Keyed Random: Duplicate bittings may occur if a cylinder or group of cylinders is selected from a limited number of locks that present only a few different key combinations of no specific order or progression.

Keying Schedule: A detailed listing or inventory of all keys and cylinders within a keying system that provides the specifications as to their quantity, markings and shipping instructions.

Keying Symbol: See standard key coding system.

Keying Levels: See **standard key coding system.**

Key Interchange: See the definition of cross-keying and incidental master key. This is an undesired and unintended condition that occurs when a key is able to open a lock for which it was not designed, and can be caused by poor tolerance, pinning error or mistakes in the definition of the KBA.

Key System Schematic: A diagram representing the hierarchy of keying levels, where locks and keys are defined through the use of letter designations (symbols), circles (for change keys), and boxes (for master keys). Interconnecting lines are used to

display the relationship between locks and keys within levels.

Levels of Keying: A uniform method of expressing levels of keying defines change key, key alike, maison keying, and master keying systems using the **standard key coding system**, below. A **two level** system, for example, allows for one or more change keys and one master key. Added levels of complexity can be defined, as shown in the accompanying table. Diagrams representing the standard key coding system are hyperlinked for each **level of keying**.

Level of Keying	Key Name	Level ID	Abbreviati
1	Change key	Level I	CK or k
2	Change key Master key	Level I Level II	CK MK
3	Change key Master key Grand master key	Level I Level II Level III	CK MK GMK
4	Change key Master key Grand master key Great grand master key	Level I Level II Level III Level IV	CK MK GMK GGMK
5	Change key Master key Grand master key Great grand master key Great great grand master key	Level I Level II Level III Level IV Level V	CK MK GMK GGMK GGGMK
6	Change key Sub-master key Master key Grand master key Great grand master key Great great grand master key	Level I Level II Level III Level IV Level V Level VI	CK SMK MK GMK GGMK GGGMK

Maid's Master Key: A limited-use master key within a hotel keying system that will allow the maid to access guest rooms and certain special areas such as linen closets.

Maison Keying System: A specialized keying system (generally in apartment complexes) that allows common-access locks to be operated by each tenant. In theory, it is the reverse of a master key system.

Master Key Changes: This term defines the number of useable combinations for change keys that are available under each master key.

Master Key System: Any keying system that allows two or more levels of keying. The term "master key" is also used to designate a two-level keying system (as opposed to grand master key, for example, which denotes a three-level system).

Master Pin: This is the preferred definition for the older term of **master wafer.** See also **build-up pin.** A master pin is a lower pin segment that is inserted into the pin stack to create an added virtual shear line to allow more than one key to open the lock. A master pin may be inserted in one or more chambers, depending upon system design, master keying scheme, and the number of master keying levels. In modern keying systems, there will rarely if ever be more than one master pin in any chamber, unless done to create intended cross-keys (or in master ring or IC locks). If more than two pin segments are present in any chamber, then many **unintended cross-keying** combinations can result. The practice is known as "double-pinning" and is more thoroughly explained later in the text.

Master Disc: See **master pin.**

Matrix Format: A high level method of displaying key combinations and assigning keysets through the use of a matrix rather than in a chronological list. See the detailed discussion in a later section.

Maximum Adjacent Cut Specifications (MACS): This term refers to the maximum degree of vertical separation that is permissible between adjacent cuts and which will allow the pins to move freely up and down as the key is inserted and withdrawn. If the adjacent cuts create too steep an angle, then the tumblers will bind, not seat properly, or form an imperfect geometric shape for the root. MACS rules will also limit the number of useable differs. Adjacent cuts that violate MACS cannot physically be cut.

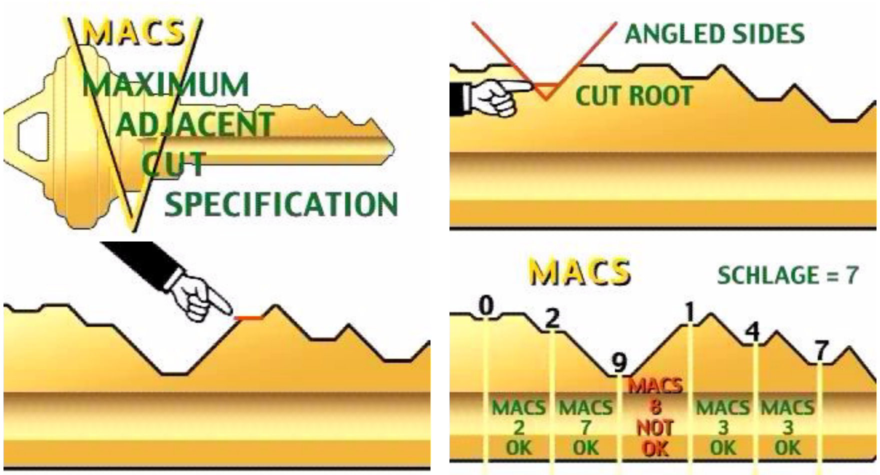


Figure LSS+1106 MACS specifies the maximum root depth and angle that will allow the proper insertion and removal of the key, and the proper root dimensions. By defining the maximum difference in depth between adjacent cuts, the manufacturer controls the ramp angles and root shape for optimum operation. In the diagrams, the proper angle of cut is shown. In the Schlage key with a MACS of 7, it can be seen that the difference between a "1" and a "9" cut is not allowed because the ramp angle causes a reduction of root dimension of the adjacent "1" cut. The diagram to the left of the Schlage key shows the proper amount of bitting that must be present for each root. Courtesy of HPC Interactive Learning Series.

Master Key (MK): A master key is generally defined as the first level of keying above the individual change key. It represents a second common key that will open all cylinders within a group.

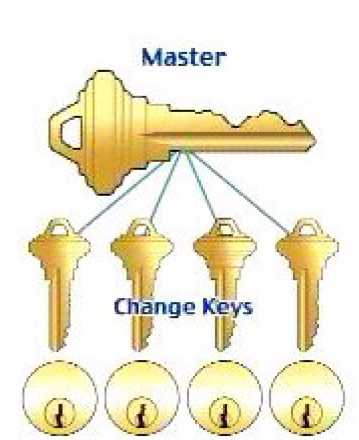

Figure LSS+1107 A master key is one level above the change key. In this diagram, the master key fits all four of the locks for which there is an individual change key. Courtesy of HPC Interactive Learning Series.

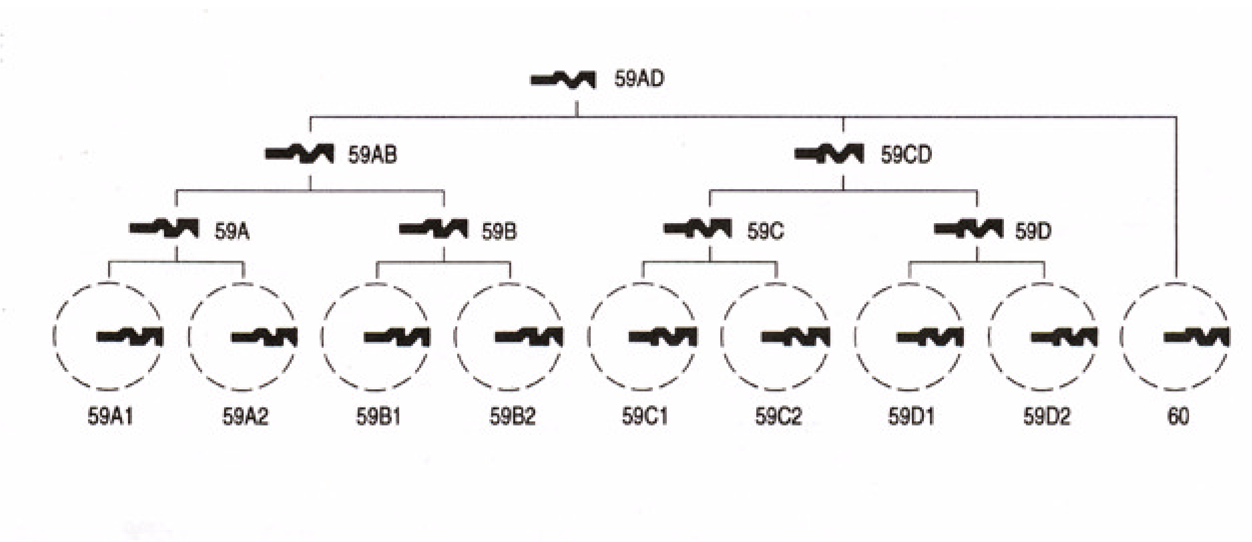
Master Sleeve or Ring: A ring is made in the form of a brass tube

to fit snugly around the plug and within the shell of the lock. The purpose of this device is to create a second physical shear line. The ring forms a plug with a slightly larger diameter. Certain pin segments are aligned to the second shear line created by this added ring. Cross-keying problems can be eliminated by this technique because **all tumblers** must be raised to the shear line created by the plug **or** to the sleeve. It is thus impossible to produce split combinations (cross-keying) that will open the lock as with conventional master keying, unless double pinning is used for higher keying levels.

Master Wafer or Master Pin: The middle segment(s) of a pin tumbler set, sandwiched between the top pin (driver) and bottom pin, that will allow the creation of multiple virtual shear lines. Each manufacturer assigns values for standardized lengths for both top pins and master pins. Master pins are usually flat-cut at each end.

Method of Progression: There are two primary *methods* of progression: **total position progression**, and **rotating constant.** These should not be confused with the type of progression: **single-step** and **two-step**. These terms, method of progression and type of progression, are often confused. They denote very different concepts discussed throughout this chapter.



Minimum Safe Increment: This term refers to the depth increments that are required for progression within a master key system. It is based upon the difference between effective plug diameter and actual plug dimension, and tolerance build-up. Cumulative tolerance errors, discussed elsewhere in this text, can result in key interchange and unreliable mechanical operation if a minimum increment between depths is not maintained.

The industry standard requires a minimum of .023" between each depth for master keying and thickness of master pins. This increment will control the available depths that can be written into the KBA and the resulting combinations that are produced by progression of each value in each chamber. Thus, if the manufacturer utilizes .015" steps, a two-step (.030") progression would be utilized. This means that **every other** depth is actually available for use in defining the master key system. It is critical that depth increments never be mixed between manufacturers.

MK'd Only: Master keyed only.

Multiple Gating: In lever tumbler locks, more than one gate for each tumbler is provided to allow master keying.

Multiplex Keying Systems: See **Complex Keying Systems.** The diagram shows a Corbin 59 series keyway system. 59AD will open every keyway in the system.

Odometer Method: In a progression systems, it describes a method of deriving (progressing) bitting combinations in ascending or descending order from right to left, resembling the action of an odometer in accruing mileage. The least significant digit is farthest to the right. The term also describes one of the methods of entering available depth increments into the KBA.

Operating Shear Line: The physical shear line within a pin tumbler lock that forms the gap or break between the shell and plug. It is the precise location where each pin tumbler within each pin stack in each chamber must split in order that the plug might rotate. It also identifies the lower shear line in a removable core lock and in a cylinder employing a master ring.

Page Master Key: In the standard progression format, it is the three-pin master key for all combinations listed on one page. A "page" is a notation of sixty-four change keys under one master key within the progression format.

Partial Position Progression: A hybrid system that contains some of the attributes of a total position progression and rotating constant system. In the PPP, one or more columns are held

constant, allowing the sharing of bitting values between the TMK, MK, and CK. The distinction between rotating constant and partial position progression is subtle yet simple. In RC, the "held" positions are rotated for new progressions; in the PPP, held positions remain constant. There is simply a common bottom pin that is used for the change key, master key, and TMK.

Positional Master Keying Systems: A positional master key system relies upon a different theory than the split tumbler found in conventional cylinder locks. These systems are used by Schlage wafer (obsolete), Kaba, Keso, Corkey, Schulte, Miwa, Showa, and other dimple and magnetic card locks.

Traditional master pins are not utilized; rather, detainers are placed within **one or more chambers**, following a defined keying scheme. Other chambers are left open or inoperative. The master key in a positional system is the **composite** of all of the change keys. In the conventional split pin system, by contrast, the master key is derived through a mathematical computation of bitting depths for each chamber.

Privacy Key: A special key that is used to open a lock that has been single-keyed. It may also be referred to as an **emergency key**.

Progress: To choose possible key bittings from the KBA for each column.

Progression: The logical or orderly sequencing of key bittings that are used within a keying system. The sequence of numbers is usually taken from a **progression column** that represents one bitting position within the key bitting array and occurs in some predetermined order. Each column is progressed to obtain added bittings. The number of columns provide the basis to define the number of bitting combinations that are theoretically available for a system. Progressions are defined by the number of columns that are utilized in the KBA and the commensurate number of pin chambers and depths that create all associated master keys. Of course, the number of pin chambers within the lock will ultimately determine how many chambers can be progressed, and how they are divided between master keys and change keys. If three pins are progressed and used for defining master key bittings, for example, then it is said that it is a three pin master key. The term that designates, for example, a "two-pin" or "three-pin" master key also relates to the hierarchy of master keys within a system, and which locks are associated to that keying level.

In our example, we shall assume that the system utilizes a two-step progression, and that there are four depths available for each position. (Originally, there were five depths in our hypothetical, but one depth was reserved for the TMK in a TPP system). The table shows the correlation between the number of positions progressed and the number of available key combinations. The table also defines the master key designation within the progression.

MASTER KEY DESIGNATION BY NUMBER OF PINS		
Master Key Name or Designation	Columns Progressed,	Available Combinations
Row master key **Block master key**	**1**	**4**
Vertical group master key **Horizontal group master key**	**2**	**16**
Page master key	**3**	**64**
16 groups of 4 pages	**4**	**256**
4 groups of 16 pages	**5**	**1,024**
TMK: 64 pages	**6**	**4,096**
	7	**16,384**

Progression List: A bitting list for change keys and master keys that is presented in a chronological sequence.

Progressive: A bitting position that is derived through a progression of available depths (rather than being held constant) would be considered as a progressive. The term also denotes the number of depths within a chamber that can be progressed. For example, the Corbin System 70 system has a total of six depths, with a depth increment of .028". Thus, a single-step progression can be utilized for generating master keys. There would be a total of five progressives available, because one progressive would be reserved for the TMK.

Random Master Keying: Any scheme for deriving master key combinations that is not based upon a logical progression of bitting depths and that does not correlate keying levels to each other.

Register Number: Most lock manufacturers will asign a code or

identification number to a master key system or to higher level keys within the system.

Root Depth: The measurement from the base or bottom of the cut (root) to the bottom of the blade of a key constitutes the root depth and would equal the bitting value.

Rotating Constant (RC) Systems: This is a common keying progression scheme for defining master key systems. It allows one or more TMK depth and positions to be shared with the change key and master key. It is an algorithm that establishes patterns of progressives that are rotated in different key bitting arrays. Within each different KBA, some columns are constant and some are progressed.

Row Master Key: The one-pin master key that denotes all combinations that are listed on the same line across a page within a standard progression format constitutes a row master key.

Sectional Keyways: A sectional keyway is one that is specially designed to be used in a **family** of similar keyways within a complex keying system. One or more sections will be included within the keyway family and will allow the repeat use of individual and master key combinations in the system without loss of security. They will block access to keys that are not defined within a specific keyway family. Note that if the wrong sectional blank is utilized when cutting a key, then the security of the system can be compromised because the key may allow access to more than one section in different locks in the system. It is typical for certain key shops to maintain a limited inventory of blanks. Thus, in Figure 11-7, the master keyway LN would open all other keyways. If the specific change key that utilizes section LA, for example, were cut on the LN blank, then the security of the system could be compromised if the bitting combination for the LA change key were repeated in other locks throughout the system, because LN would enter all of those keyways. The **Easy entrie** key machine, described elsewhere in this text, can create restricted sectional blanks that can bypass the inherent security in a multiplex system.

Selective Key System: A system that is designed so that every key can be a master key. Certain installations may require a limited number of keys and extensive cross-keying.

Selective Master Key: In certain systems, an unassociated master

key can be made to operate one or more specific locks throughout the system. These keys would act in addition to the regular master key and change key without creating cross-keying issues. They are created by double pinning and are a subset of the TMK.

Sequence of Progression: The specific order by which bitting positions are progressed to generate different change key combinations. The SOP is noted at the bottom of the KBA.

Simple Master Key System: A keying system that contains only two levels (change key and master key) can be referred to as a simple MK system.

Single-Step Progression: Depending upon the manufacturer, a one or two-step progression may be utilized for master keying. In the single-step system, every depth increment can be utilized to progress change key bittings in the KBA. Generally, the difference between depths must be a minimum of .023". If the minimum depth increment is less than .023", then every other depth can be used to derive combinations.

Spacing: The specification that provides the dimension from the shoulder or stop to the center of the first cut, and center of cut to center of cut for adjacent depths.

Split Pin Master Keying: The method that allows master keying of pin tumbler locks by introducing master pins in one or more chambers to create additional virtual shear lines.

Standard Key Coding System:(132) Originally developed by Thomas Hennessy at Emhart in the 1960s, the SKCS has been adopted by the lock manufacturing industry and practitioners to define and designate in a uniform manner all keys and locks within a master key system, according to a hierarchy of access. Key symbols denote **relationships.** Use of these letter and number designations (referred to as keysets) will allow any knowledgeable professional to determine the precise function and keying level of locks without any further information. The definitions can be likened to the symbols that are utilized by electrical and electronic engineers within a schematic. All SKCS symbols have been grouped within one table for easy reference. There are certain **rules(133)** that are followed with regard to the system in order to avoid confusion in large systems.

LSS204: Brian Chan on master keying rules

Standard Progression Format (SPF): An orderly and systematic method to list and relate each change key combination to all master key combinations in a master key system. The derivation of bittings is defined and grouped by segments called blocks, horizontal groups, vertical groups, rows, and pages. Each of these allow or provide for a specific level of access within the keying system.

Sub-Master Key: Within a keying system that has six or more levels, it is the master key level immediately under the level that is defined as "master key."

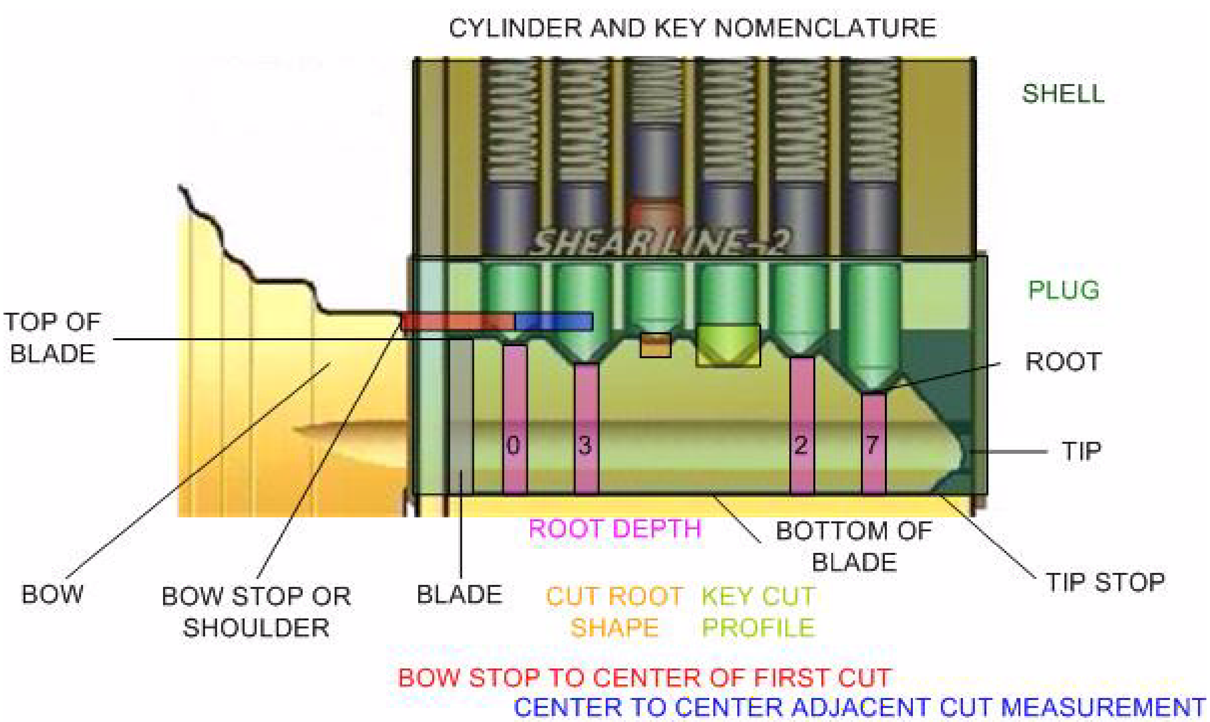
Theoretical Combinations: The number of combinations that can be derived from the available depths and number of chambers within a cylinder will provide the maximum number of different combinations that can be generated. The actual number may be greatly reduced.

Top level Master Key (TMK) or Top Master Key: This is the highest level within the keying system. It may be a master key, grand master key, great grand master key, or great great grand master key.

Total Position Progression (TPP) System: This is the most common master keying scheme. It relies upon a progression of useable depths, as defined in the key bitting array, to generate combinations for master key and change key levels.

Type of Progression: This term identifies whether a single-step or two-step progression is utilized in generating combinations within the KBA.

Uncontrolled Cross-Keying: See **controlled cross-keying**.



Vertical Group Master Key: Within a standard progression format, the two-pin master key for all combinations in all blocks in a vertical line, down a page.

11_5.3.3 Technical Specifications and Documentation

Master keying systems are described and defined in terms of accepted industry standards and specifications. In this section, the nomenclature and technical details of master keying systems are examined.

11_5.3.3.1 Nomenclature, Measurements and Tolerances

Basic measurements and tolerances of plug, shell, and key are important in order to understand their interaction and affect upon the design of a master key system. Manufacturer specifications for cylinders and keys will provide basic design criteria for a master key system in terms of the KBA, progression technique, and available combinations. Although described elsewhere in this text, the diagram below identifies all critical parts within a cylinder together with proper nomenclature. The manufacturer will assign values to each component that will form the basis of all master key systems. The relationship between each component and their measurement must be understood in order to properly design and implement a multilevel keying system. Tolerance build-up is directly related to specifications, and thus the minimum depth increment for progression must exceed the total tolerance error, or key interchange will occur.

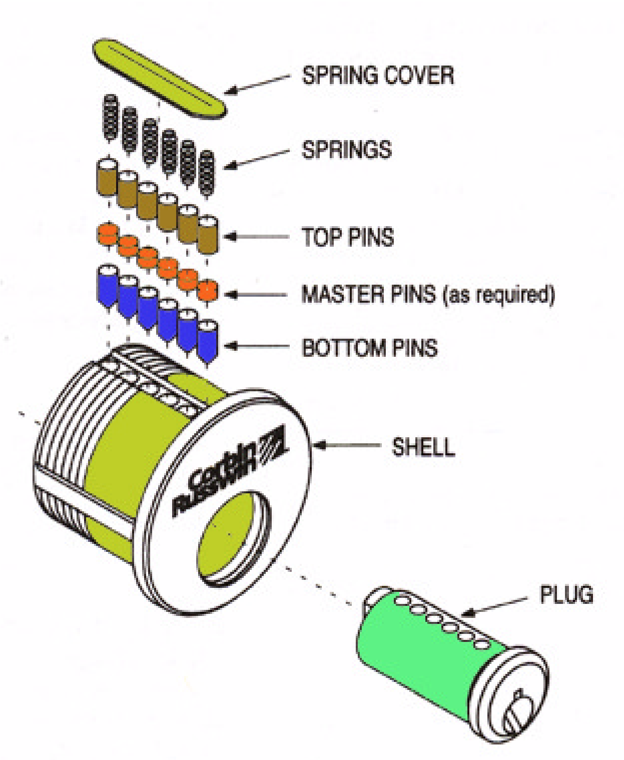


Figure LSS+1127 Identification of critical components within the cylinder. Various root depths are shown (0,2,3,7) for a Schlage lock (left).

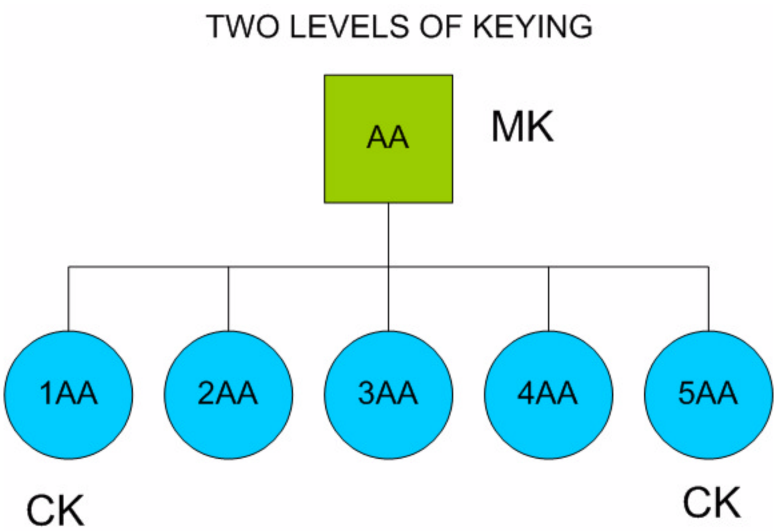
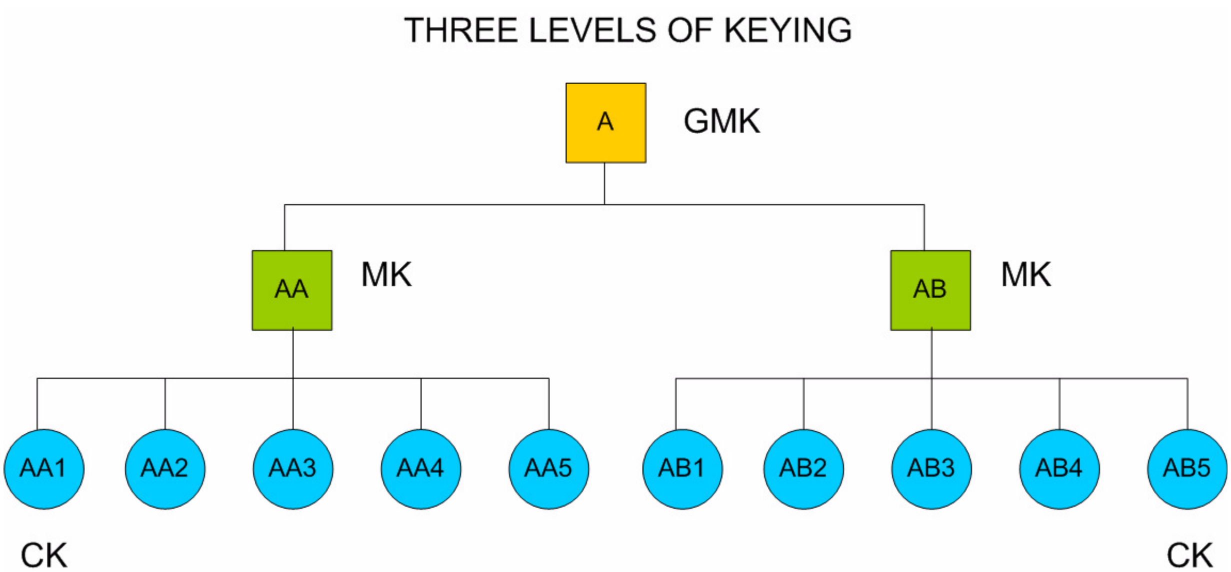
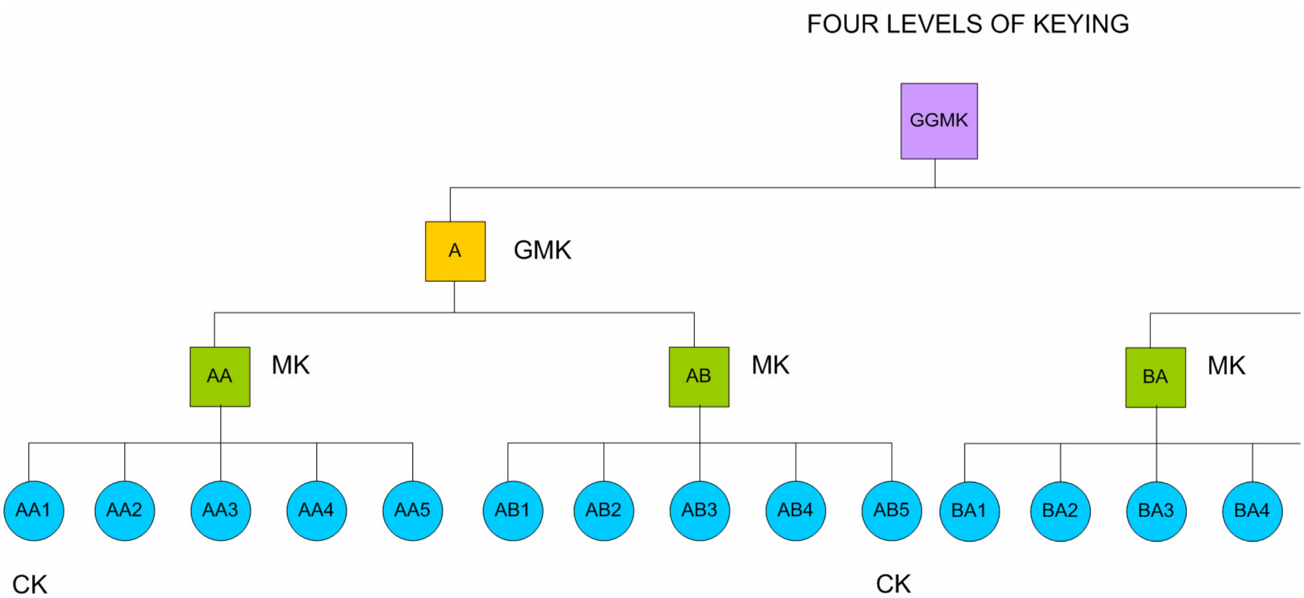


The components in the diagram are described in the preceding definition section of this chapter, and in **chapter 3**.



11_5.3.3.2 Levels of Master Keying



Master key systems are defined by an expansion specification that will delineate keying levels and associated cylinders. In this section, these concepts, as well as system documentation, definition of specific types of keys, and certain design limitations (MACS) are discussed. Pin tumbler keying theory is examined in the sections following this discussion.

Locks can be pinned for several levels of keying, depending upon the requirements of the location, as defined in the expansion specification. The lowest level is the change key. Generally, systems are not programmed for more than six levels (as defined elsewhere in this chapter). Diagrams of two, three, and four keying levels appear below. A five-level system is shown in the definitions of keying levels, above. Standardized coding (SKCS)

for each level is utilized in the diagram.

11_5.3.3.3 Expansion Specification

When designing a system, the starting point is the **expansion specification.** This delineates the total number of theoretical bitting combinations that are required by the system at each keying level. In essence, it defines system functionality in terms of the number of locks and key combinations. A comprehensive premises survey must be accomplished prior to planning any master key system and developing such a specification.

Consideration must also be given to any access control system that is to be implemented or that is already in use, because even the most sophisticated systems can provide a false sense of security. Electronic access control using a variety of technologies has become common in any installation that has secure areas. Unfortunately, most electronic systems have a mechanical lock that can be used as an emergency bypass in the event of failure of the main system. Therein lies the problem, because in almost every keying system that employs any form of access control, there is also a master key system. As detailed in subsequent sections, virtually every master key system is vulnerable to attack and compromise. In a successful attack, the access control system can be completely bypassed through the use of a top level master key.

The following primary issues must be resolved in planning any

master key system:

- **Different levels of access;**
- **Kind of installation;**
- **Floor plans;**
- **Information for every opening;**
- **Risks associated with master keying for a specific facility;**
- **A functional diagram of the entire system. This will dictate the structure of the system;**
- **Have spaces been grouped to reduce functions in terms of keying requirements;**
- **Have high security locks been integrated into the system? Is there a mixture of high security, old locks, new locks, or interchangeable core locks;**
- **Are access control devices presently in use or desired to be implemented into the system;**
- **How is the system to be administered and maintained;**
- **What key control measures will be implemented;**
- **Are there any mechanical issues involving the locks that have been selected for use in the system;**
- **What are the potential number of combinations that are presently and projected to be required for the system;**
- **What is the best approach to keying;**
- **Lock technology desired and needed for the specific installation;**
- **Number of locks;**
- **Number of change keys that are required under each master key;**
- **Number of group access levels or levels of keying;**
- **Identification of individual access requirements;**
- **Necessity to use sectional keyways;**
- **Desirability of restricted keyways;**
- **Security enhancements for the lock technology that has been chosen: sidebar, magnetic, electronic, master ring, other system;**
- **Total potential number of locks within each system;**
- **Potential for uncontrolled cross-keys or incidental**

master keys;

- **Nature and size of the business or entity in terms of personnel, potential turnover, and operational requirements;**
- **Typical requirements for certain types of installations. For example, hospitals will generally have different needs than primary and secondary schools in terms of keying levels and change keys under each level;**
- **Will the design of the system encourage key picking (the use of change keys to open an unintended lock by manipulation);**
- **Has the expansion specification been thoroughly defined.**

For systems integrating monitoring of door opening and closing and alarm functions using computerized-control, additional considerations may include:

- **Area access restrictions;**
- **Time of day and day of week restrictions;**
- **Delay on entry;**
- **Lockout capability;**
- **One-way entry: lock or unlock only;**
- **Audit functions.**
- **The type of master key system, and how mechanical locks are integrated into access control. Can the sophistication of the access control system be compromised with a key? If locks are not utilized in coincidence with access control protection, then the entire system can be compromised if the TMK is obtained.**

It is mandatory, to create an organizational flowchart and expansion specification for the following reasons:

- **Show the relationship between keys and locks and how they control access for each security level;**
- **Provide a uniform and effective method of graphically depicting the entire system;**

- **Offer better control of keys in the system;**
- **Explain the function as well as the use of each key;**
- **Identify potential key interchange and cross-keying problems that can be easily overlooked.**

From the flowchart, the building owner, management, or security staff can readily understand what the system will and will not do. In the context of a criminal investigation, it may be advisable to request a system flow chart to pinpoint access. It is standard practice to submit the master key system requirements to the factory for pinning of cylinders through keying specifications and a system matrix or listing of all assigned locks and keys. In the unlikely event that the system is developed on site, extra attention must be paid to cross-keying potential and key design.

The expansion specification provides an arithmetic definition of the combinations required for all of the locks in the system and can be considered as the logical extension of the Standard Key Coding System. Like the SKCS, the actual specification is noted by keying levels, and denotes the level, number of master keys and the number of associated change keys. The notation is written to define how many levels there are from highest to lowest order and the number of combinations required for each level. The method of notation is always the same. Expansion specification must take into account both **symmetrical** and **asymmetrical** systems. That is, some systems may have an unequal number of change keys under certain master keys.

Expansion specifications for symmetrical notation

- **Three or more levels of keying;**
- **The specification does not indicate that all of the possible master keys and change keys will in fact be required or used. It simply projects the maximum possible needs of the system;**
- **The expansion specification is often based upon a division of the key in the key bitting array to provide for the maximum number of keying levels and change keys that may be required. Note: such a "division" may be altered by the use of incidental master keys;**
- **The specification must reflect any change keys that are under a level not directly above them. Thus, change keys may be directly under a grand master key, but not under the master key directly below that grand master key. It should be noted that there will**

in fact be a theoretical master key combination above such change keys, but it may never be cut;

- **The number of theoretical combinations is the same for any level of master key. A system that is noted as 1-5-50 specifies one grand master key, five master keys, and fifty change keys under each master key. The system is said to be symmetrical because for each grand master key, there are five master keys, and for each of those five master keys, there are fifty change keys. In certain systems, however, this specification would be different for specific master key levels. In such case, the notation would be asymmetrical to denote the differences;**
- **The specification should anticipate the maximum number of change keys that will be required for any master key, now and in the future. An example would provide for a three level system (one grand master key, three master keys, and forty change keys). Remember, the specification is symmetrical, so if presently there is only a requirement for thirty change keys under two of the master keys, and forty change keys under the remaining master key level, then the specification would require that forty change keys be provisioned for each master key. The notation would be written 1-3-40.**

The table shows the relationship between the expansion specification for a symmetrical system and the standard key coding system. In our example, Roman numerals (I, II, III, IV, V, VI) are used to denote keying levels, and the arithmetic notation system.

SYMMETRICAL EXPANSION SPECIFICATION*	Level of Keying	Key Name	Level ID	Abbreviation	Key Symb
	1	Change key	Level I	CK or k	
	2	Change key Master key	Level I Level II	CK MK	1AA, 2AA AA
III-II-I	3	Change key Master key Grand master key	Level I Level II Level III	CK MK GMK	AA1, AA2 AA, AB, A
IV-III-II-I	4	Change key Master key Grand master key Great grand master key	Level I Level II Level III Level IV	CK MK GMK GGMK	AA1, AB1 AA, AB, A, B GGM
V-IV-III-II-I	5	Change key Master key Grand master key Great grand master key Great great grand master key	Level I Level II Level III Level IV Level V	CK MK GMK GGMK GGGMK	AAA1, AA AAA, AAB AA, AB A, B GGGM

VI-V-IV-III-II-I	6	Change key Sub-master key Master key Grand master key Great grand master key Great great grand master key	Level I Level II Level III Level IV Level V Level VI	CK SMK MK GMK GGMK GGGMK	AAAA1, A AAAA, AA AAA, AAB AA, AB A, B GGGM

***Note that the expansion specification is written from top level to lowest level, Our example utilizes Roman numerals to define each level. The actual notation format is in single integers.**

Examples of expansion specifications for symmetrical systems:

1-3-50: three level system, one grand master key, with three master keys under the top level, and fifty change keys under each master key;

1-3-5-35: four level system, one great grand master key, three grand master keys, five master keys, and 35 change keys under each master key;

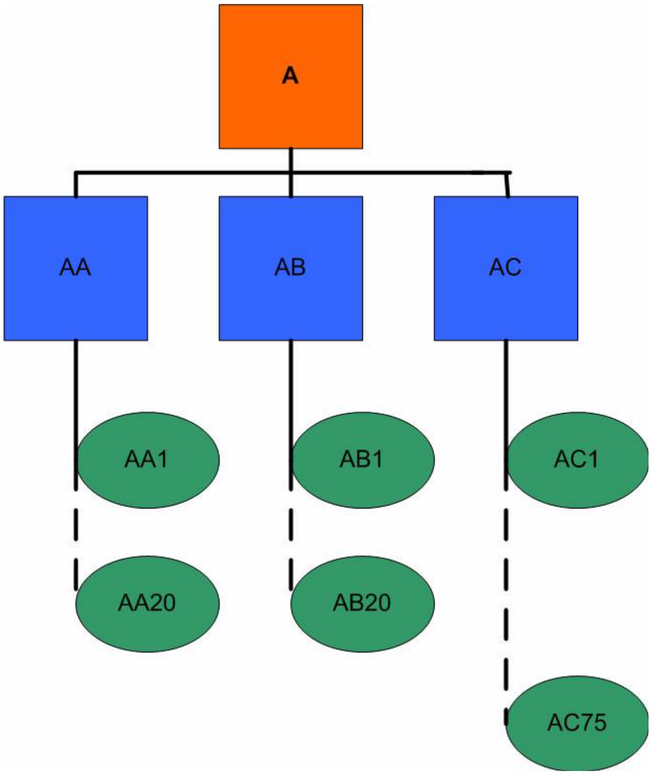
Certain systems may require change keys to appear directly under higher keying levels, such as grand master (GMK), or great grand master key (GGMK), rather than master key level. The method of notation is different to reflect this change. Remember, in symmetrical notation, integers are separated by dashes; the dashes denote keying levels. The numbers show the actual quantity of combinations for each level. For notation of change keys directly under higher keying levels, parenthesis are utilized. In order to indicate the association of change keys with a specific master key level, they are indicated by parenthesis immediately to the right of the keying level.

In the example above for our three level system with three master keys and fifty change keys under each master key, the notation was 1-3-50. Let us say, however, that we require ten change keys under the grand master key, as well as fifty change keys under each master key. This would be written as 1(10)-3-50. In this instance, the dash is utilized to distinguish keying levels. As with standard symmetrical notation, levels run from top level to bottom, left to right. The (10) is associated with the top level master key because **both** are to the left of the dash separating levels.

Examples of expansion specifications for symmetrical systems with change keys directly under higher levels:

1-100: Two level system, one master key, one hundred change keys;

1(10)-3-50: Three level system, one grand master with three master keys, each having fifty change keys, and one with ten change keys under the grand only;

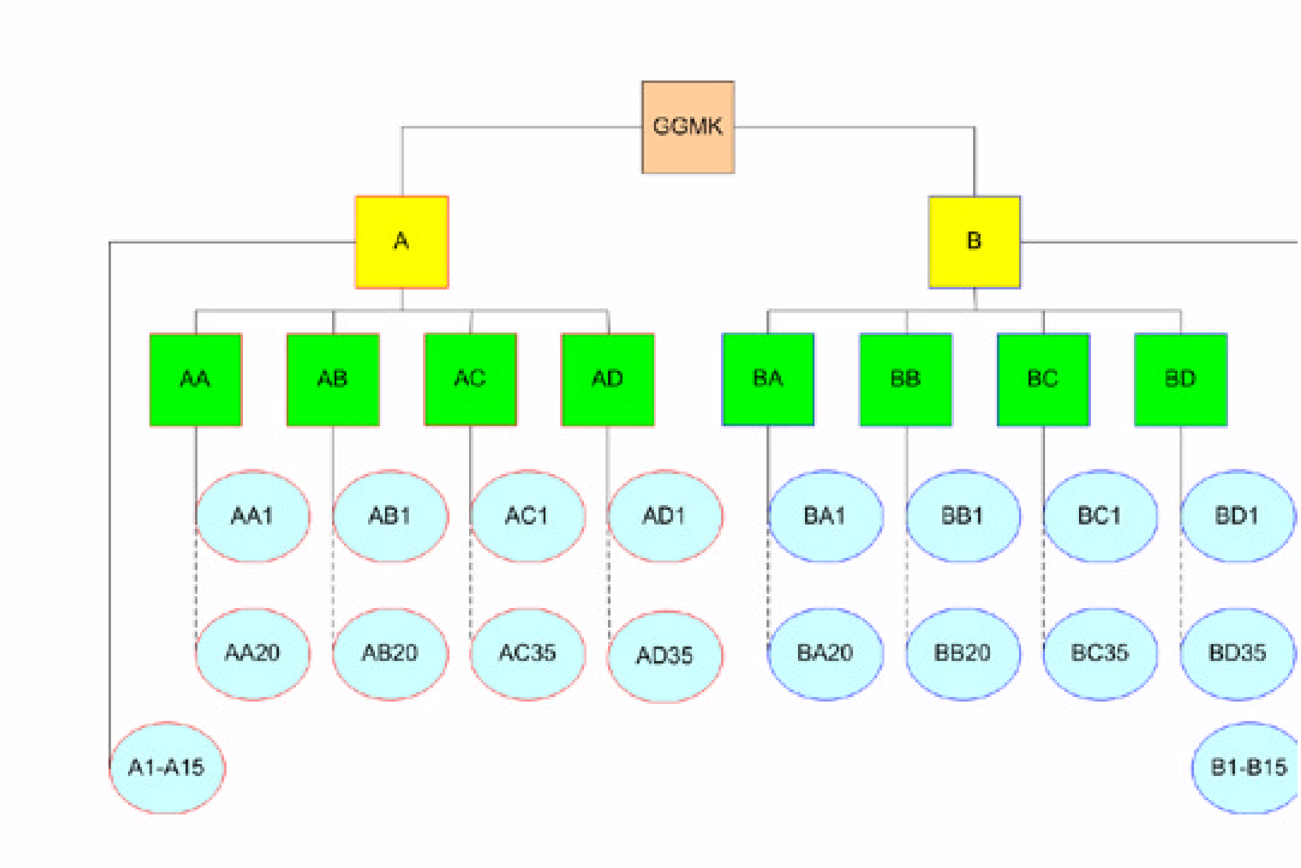


1(35)-5-10-50: Four level system with one great grand, with five grands, ten masters under each grand, fifty changes under each master, thirty-five change under the great grand only;

1(10)-4(20)-5-55: Four level system, GGMK with four grand masters, five masters under each grand, fifty-five changes under each master, ten changes under each great grand only, and twenty changes under each grand only.

1-15(28)-3-50: Four level system with one great grand, fifteen grands, three masters under each grand, and fifty change keys under each master, and twenty-eight changes under each grand only;

Expansion specifications for asymmetrical systems



An asymmetrical system is one in which there is an unequal number of change keys under each master keying level. Note the distinction in this scenario and the one above where there are change keys associated directly under a grand master or higher level, but not with the master key level directly above the change key level. Thus, for example, in a three level system with a total of three master keys, there may be two master keys each with twenty change keys, and one master key with seventy-five change keys. Again, parenthesis are utilized to associate master key levels with their change keys. Thus, the above cited example would be written as **1-(2-20)(1-75)**, where red indicates the grand master key, blue is the master key level, and green, the change key level.

Compound asymmetrical expansion specifications may also be written. These reflect systems that have different numbers of master keys and associated change keys, as well as change keys that are directly under higher levels of masters. The notation follows the same format with respect to the use of parenthesis and groupings.

Example of expansion specifications for compound asymmetrical system with change keys directly under higher levels

1-2(15)-(2-20)(2-35): Four level system with one great grand master, two grand masters each with four master keys, (two master keys with twenty change keys under each grand, and two master keys with thirty-five change keys under each grand), two grand masters with fifteen changes under the grands only. Each keying level is color coded (orange, yellow, green, blue) for ease in understanding, and line colors (red and blue) denote the association between keying levels

11_5.3.3.4 Master Keying Records and Documentation

Security, maintenance, and liability issues make it imperative that proper and comprehensive records be maintained for every master key system. The process begins with the first site survey and keying conference and continues to include the ordering and installation of hardware throughout the life of the system. The following documentation and processes are essential.

- **Site survey and keying conference. Compile complete and accurate data about the facility. This includes:**

- **list of all openings (doors, padlocks, overhead doors) and their function. Openings (not the doors) should be individually marked;**
    - **keyways;**
    - **number of chambers within each lock;**

- **verify that all hardware is operational;**

- **Hardware schedules(134). All hardware should be listed;**

- **Keying schedules. You can combine keying and hardware schedules, if desired, organized by lock. These must be kept updated and accurate to be of value;**

- **TMK Register and end-user register. The TMK and end-user registers provide critical information regarding all keys within a system. Registers should never be provided to the customer. The TMK register allows the locksmith to organize the bitting lists for all clients in order to prevent duplication of the TMK and the isolation of client systems geographically. These registers must be kept secure. Liability issues are detailed in chapter 37. The TMK register reflects the design of the top level master key and is based upon specific design criteria defined in this chapter.**

- **Progression and bitting lists. For security, there should be no customer identification associated with this information, but rather an indirect code that is only available to employees of the locksmith with a need to know. The lists must be secure and accurate. Remember, the failure to develop comprehensive records can cause the reuse of combinations by error, possibly incurring liability.**

- **Authorizations and key inventory records. In high security systems, there must be strict procedures for the distribution of restricted blanks and duplicate keys.**

11_5.3.4 General System Design Rules

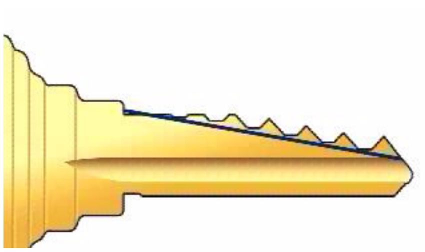
Every manufacturer establishes different standards for bitting depth and spacing, as well as pin lengths. These guidelines must be followed and will define:

- **How many depth cuts are available, and how they are numbered;**
- **The maximum allowable vertical increment between adjoining cuts (MACS);**
- **How the tumbler cuts are spaced on the blade of the**

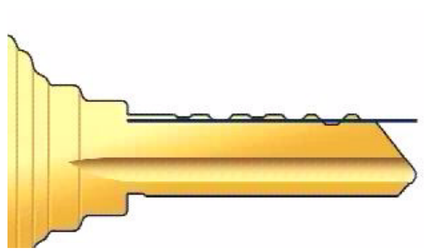
key;
- **The minimum depth increment;**
- **Whether a one or two-step progression system is utilized in a master key system.**

Failure to adhere to rules relating to master keying can result in loss of security, mechanical problems that can lead to operating failures, cross-keying difficulties, and broken keys.

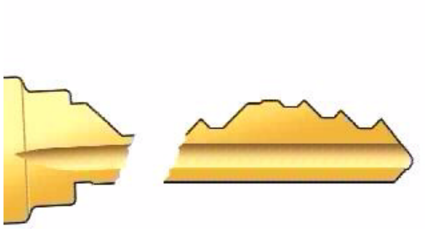
11_5.3.4.1 Change Keys and Master Keys



Within any master key scheme, all keys must have the same keyway or sectional keyway system, acceptable bitting patterns must be developed, and standard depth cuts must be utilized. Note that master key systems can be expanded through the use of different sectional keyways.



All keys in a master key system should be designed to incorporate certain characteristics to maintain security. The basis, in large measure, is reliant upon the mechanical parameters of the lock and its capability to offer a significant number of **real** rather than theoretical differs or different keying combinations. Jiggling of a key should not result in opening the lock. Although any key combination can be utilized as a master key or TMK, there are certain accepted guidelines that are based upon the keying scheme that generally include the following requirements:



- **With respect to the design and layout of individual combinations, at least one very deep cut may be desirable, so long as it is not placed near the bow of the key, thereby causing structural weakness. Within the TMK, at least one cut that is deeper than any within the change key will prevent jiggling. It is also advisable to use one very shallow cut to avoid change keys being altered to a master key combination;**
- **There should be a mix of depths so that not all cuts are shallow or deep. A stair-step pattern of cuts should not be made because they can allow a key to be improperly withdrawn from the lock during rotation of the plug and will also make the lock easier to pick;**
- **No more than three adjacent cuts in any key should be of the same depth, nor should there be more than four cuts of the same depth in any one key. This requirement will not be an issue with even-odd parity;**

- **Strict adherence to Maximum Adjacent Cut and depth-cut specifications is imperative to prevent overlapping of V cuts;**
- **The accepted standard minimum depth-cut difference or increment is between .023" and .028" for master pins. Any increment less than .023" will require a two-step progression;**
- **Nickel silver blanks should be used whenever possible due to their strength. They are usually supplied with high security cylinders;**
- **Refer to cuts as shallow or deep, not high or low;**
- **Use factory OEM pins. Do not utilize old or filed pins, and be certain that all pins are chamfered for smooth operation;**
- **Never file pins or plugs;**
- **In master key systems that were implemented more than forty years ago, manufacturers typically established the master key cuts lower than or equal to the change key depths to facilitate manual pinning of the lock. Within Corbin locks, for example, a master key code of 80008 would be common, with all change keys having bitting higher than those values. This practice should be avoided.**

LSS204: Brian Chan discussing old style master keying and pinning.

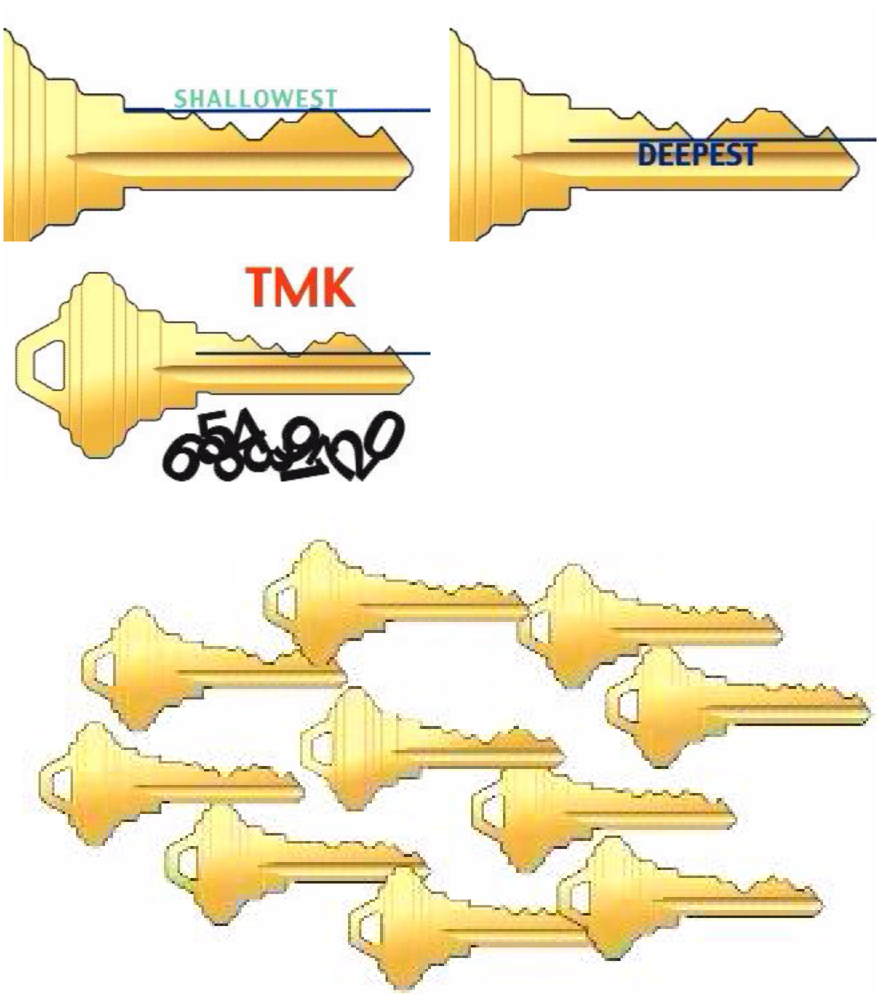


Figure LSS+1112 Keys must be designed to avoid stair-step or sequence patterns, all cuts close to the same depth, and very deep cuts close to the bow of the key. In addition, the system should be calculated so that the master key has at least one deeper and shallower cut than the change keys, if possible. This will avoid the potential for filing or modifying change keys to work as master keys. Master keys should also be normal in appearance, and have no special attributes that would identify them as a special or master key. Master keys should be carefully planned and not have random patterns. Courtesy of HPC Interactive Learning Series.

There are very specific rules with regard to depth and spacing in complex master key systems. These relate to adjacent cut depths, the thickness of master pins, and the design of the master keying levels. If MACS and other rules are not followed, the result will be a decrease in security and potential mechanical malfunction.

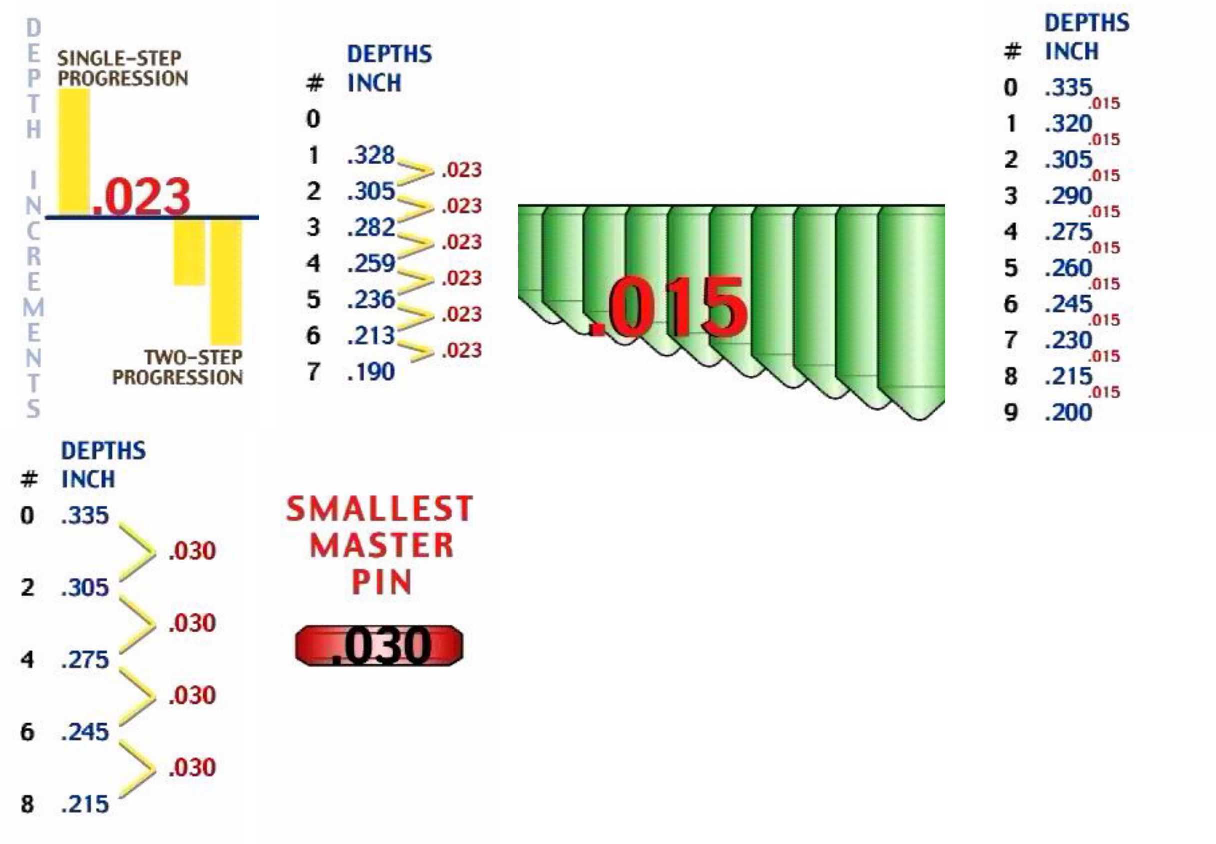

Figure LSS+1108 This series of diagrams represents the different approaches to depth levels by manufacturers. Some manufacturers, such as Schlage, utilize a constant difference of .015" between cuts, while others utilize .023" or greater. Depending upon how many bitting depths are created, the master key system will utilize single-step or two-step progression to set the depth coding for master key levels. A master pin must be at least .023" thick. If the manufacturer utilizes .023" as the difference between pin lengths, then there will be a greater number of different depths available for use in the KBA and generation of combinations. In contrast, if there is only 0.015" difference between cuts, then in a ten depth system (0-9 in the example), there will only be five positions that are available for insertion into the KBA. Courtesy of HPC Interactive Learning Series.

0	0	**0**	0	**0**	0
1	**1**	1	**1**	1	**1**
2	2	**2**	2	**2**	2
3	**3**	3	**3**	3	**3**
4	4	**4**	4	**4**	4
5	**5**	5	**5**	5	**5**
6	6	**6**	6	**6**	6
7	**7**	7	**7**	7	**7**
8	8	**8**	8	**8**	8
9	**9**	9	**9**	9	**9**

Figure LSS+1109 This chart represents the reduced number of available depths for a master key system. Only half of the total available depths can be used in this progression. This chart refers to Figure LSS+1108 (above) wherein Schlage utilizes .015" steps between each depth. A two-step progression (every other depth) is required. Thus, only five of the ten available depths can be used to define master and change keys. In this example, there are 5^6 or 15,625 differs available. This number would be further reduced by other rules. Courtesy of HPC Interactive Learning Series.

11_5.3.4.2 Maximum Adjacent Cut Specification (MACS)(135)

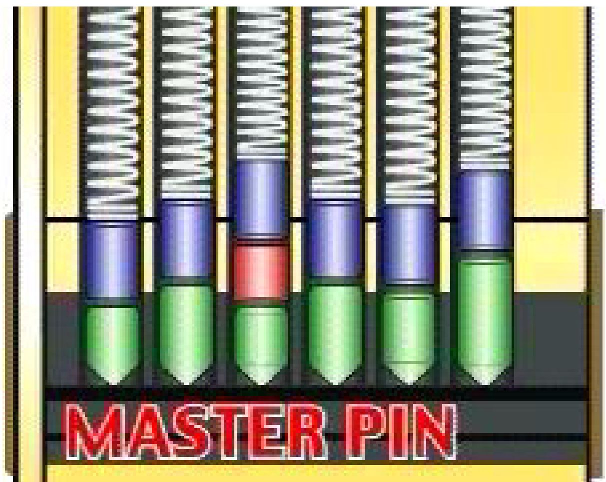
As described elsewhere in this chapter, MACS is a concept that relates to the mechanical design of a specific cylinder and the interaction of the key, bitting design, depth, and tumblers within adjacent chambers. The violation of manufacturers specifications can lead to improper and erratic operation and lockouts. The following statements can be made regarding maximum adjacent cut specifications:

- **MACS relates to a physical limitation on how a key can be cut and shaped;**
- **Not all theoretical combinations are practical or useable. Although a combination may be available, it may also violate MACS and not be useable;**
- **Forbidden combinations will usually violate MACS;**
- **A MACS violation is generally undesirable because of its physical characteristics. Thus, a deep cut next to a shallow one is not allowed;**
- **Violation of MACS for some products will allow the adjacent**

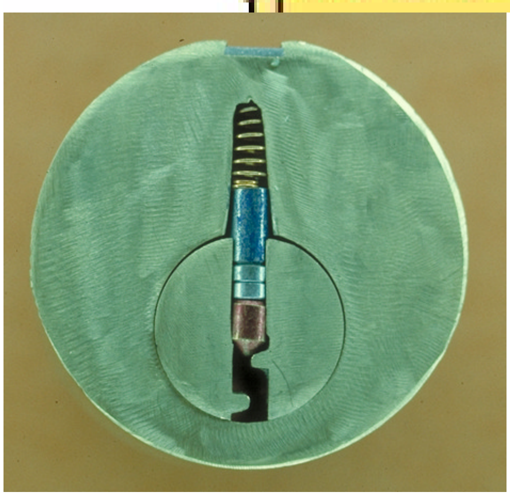
depths to be utilized in extreme cases, but not desirable;

- **MACS can prevent a key from being cut. However, the bitting code can be used in the system;**
- **In designing a master key system, each progressed column must be examined for MACS violations;**
- **MACS is computed based upon each manufacturers specifications. Schlage, for example, provides for a MACS of greater than 7. Thus, adjacent cuts of 92 would be acceptable, but 91, 90, 80 would not be allowed;**
- **MACS is calculated by subtracting the value of adjacent cuts;**
- **The angle of cut is also factored into the MACS equation;**
- **The calculation of MACS can be affected when computed from bow to tip, or tip to bow, depending upon manufacturer.**

11_5.3.5 General Pin Tumbler Master Keying Theory



This section deals with traditional pin tumbler locks having one physical shear line between the plug and shell. A later section examines keying and decoding of interchangeable core locks and master ring locks that contain two physical shear lines.



Master keying involves the segmenting of pin tumblers, thereby allowing keys with different individual combinations to create more than one virtual shear line. The pin tumbler lock is adaptable for simple to complex keying systems because of the use of pins with varying lengths. The ability to alter and create different lengths through the introduction of pin segments, using one or more master pins in all or some of the pin chambers, is the essence of master keying.

In a cylinder with only one change key, all of the pins are raised and split at the shear line upon insertion of the correct combination. Within the master keyed lock, in contrast, there is created another level or split. Usually one master pin is used for this splitting. The methodology of implementing a master key system can be quite complex and generally involves one of two accepted techniques: total position progression (TPP) or rotating constant (RC). Both of these algorithms have been designed to minimize cross-keying by limiting the number of virtual shear lines that are created and to increase security.

In the TPP scheme, every pin stack has only one defined bitting

position for the top master key, and that depth is never used in that position for the change key. In the RC method, the depth for one or more specific pin stack positions can be shared between the change key and master key, but the positions may rotate for a group of locks. Each of these schemes presents its own security issues, however, which are discussed in a subsequent section.

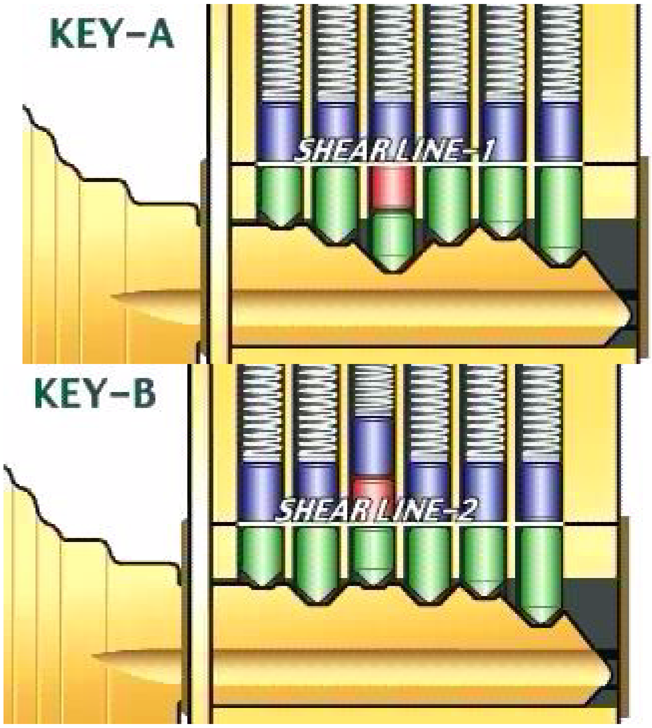


Figure LSS+1110 In this series of diagrams, the master pin is shown in the third chamber position. A different shear line is created for a top master key (A) and a change key (B). When one master pin is utilized in each chamber, a complex keying system can be created. Courtesy of HPC Interactive Learning Series.

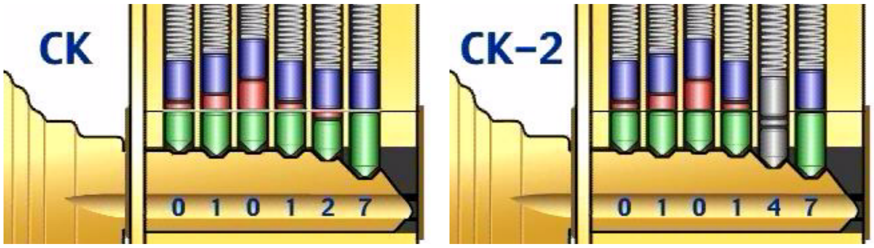

Figure LSS+1111 In this illustration, CK (change key) 010127 opens the lock by creating a combination shear line with both lower pins and master pins. CK-2, however, will not open the lock, as pin number 5 does not break at shear line. Courtesy of HPC Interactive Learning Series.

Four different theoretical keying examples will be presented to illustrate how master pins are utilized, followed by a discussion of master keying schemes. Note that in **example 4**, we do not take into account recognized master keying schemes or levels. These issues are considered subsequently. The cross-keying problems that are shown would largely be eliminated in any master key system that was defined through TPP or RC schemes. Rarely, if ever will there be more than two lower pins (bottom pin and master pin) in any chamber. The exceptions would involve master ring locks, the intentional cross-keying of cylinders, and maison keying, discussed elsewhere. Otherwise, the result of keying a cylinder in the manner shown in **example 4** would create a serious loss of security and is not considered as acceptable practice. The example is illustrative of the issues that occur in maison keying with regard to cross-keying and incidental master keys. These examples are presented merely as an introduction to the concept of split pin master keying, allowing the creation of virtual shear lines and the use of the combination of lower and master pins to derive combinations. This will become especially relevant when we examine complex multilevel master key systems that utilize incidental master keys. Other issues, such as one and two-step progression, parity, MACS, and key design have not been considered for this discussion.

Keying Example 1

In our first example, the plug for a Corbin five-pin tumbler lock, having a change key with the code 75126 and a master key with a code of 80008, must be set up. These are direct reading codes: a "1" cut being a very shallow depth, a "0" the deepest possible cut. If just the lower pins for the change key were present, they would allow the plug to rotate only when

combination 75126 is introduced. If the master key is inserted, all of the change key tumblers are going to be **beneath** the shear line for the combination of 80008.

To allow the master key to work, more pin segments are added to increase the length of each pin. This creates another shear line (virtual shear line) for combination 80008. In order to **make up the difference in length** between 75126 (our imaginary change key) and 80008 (the master key), added pin segments must be placed in each chamber. The composite combination of these added segments would be 15982.

In our example, the combination of the change key plus the master pins must equal the master key pin lengths. Thus,

7 5 1 2 6 Change Key
+ + + + +
1 5 9 8 2 Master Pins
----
8 0 0 0 8 Master Key

Keying Example 2

In a slightly different example, the master key is coded 21135 and the change key 50347. In this case, the master key has cuts that are shorter than the change key. Thus, the following mix of tumblers would be used:

2 1 1 3 5 Master Key
+ + + + +
3 9 2 1 2 Master Pins
----
5 0 3 4 7 Change Key

Keying Example 3

In this example, some of the change key cuts are lower, and some are higher than the master key cuts. Thus, our change key has a combination of 26335, and the master key has a combination of 80114. Note, however, that some of the pin lengths are added and some are subtracted.

2 6 3 3 5 Change Key

+ + - - -
6 4 2 2 1 Master Pins
----
8 0 1 1 4 Master Key

The **actual order** of pin stacking for each chamber in this example would be:

1 2 3 4 5   Pin Position within Plug

6 4 2 2 1   Master Pins
2 6 1 1 4   Lower Pin set

In the above example, the first two bottom pins and the last three **lower and master pins** combine to form the individual change key combination. Likewise, the master key combination is formed by using the combination of both lower tumblers in the first two chambers, and the last three bottom tumblers only.

Keying Example 4

In the **grand master** system, we have **three** separate keys that will open one lock: the change key, the master, and the grand master key. In TPP or RC systems, such complex keying may be accomplished with only two bottom pins; there is no necessity to add more master pins to create additional virtual shear lines. In locks with master rings, however, pin segments are added at the ring shear line for each required combination. However, to demonstrate the disastrous result that would occur from the addition of more master pins within a conventional lock, the following example is offered. This also illustrate how complex the job of keying would be in comparison to utilizing accepted industry practice with TPP or RC. It is important to note that the same bad result will occur in maison system where multiple pin segments are employed to allow the operation of many keys in one lock. This is a prime example of intended cross-keying.

In our example (that does not rely upon TPP or RC methodology), more master pins are added to create the **grand master** key. Let us assume that our change key is 13308, our master is 75126, and our grand master is 80008. A total of **108 keys** would be created for this lock if it was pinned as shown below (3 x 3 x 3 x 2 x 2).

1 3 3 0 8 Change Key
+ + - - -

```
6 2 2 8 2  Master Pins
---------
7 5 1 2 6  Master Key
+ + +
1 5 7 - -  Master Pins
---------
8 0 0 0 8  Grand Master Key
```

11_5.3.6 Incidental Master Keys, Cross-Keying, and Key Interchange

The concepts of incidental master keys, cross-keys, and key interchange relate to the creation or use of keys that are intended to open one lock, but are able to actually open more than one cylinder. These three concepts are interrelated and are discussed throughout this chapter. Each can have a serious impact upon the security of the keying system and therefore must be thoroughly understood.

11_5.3.6.1 Incidental Master Keys

Incidental master keys are the intended consequence of keying a system that is defined by the total position progression or rotating constant method. They are inherent in split pin master keying systems. TPP or RC schemes rely upon the creation of incidental master keys in order to provide for complex keying levels and access. The charts in sections **11_5.8.2** standard progression format, and **11_5.8.3** matrix format provide an amplification of why incidental master keys are vital to any complex system and how they are utilized.

In a six-pin lock with a total of ten depths per position, and using two-step progression, there are theoretically 10^6 or 1,000,000 combinations. There are actually only 15,625 (5^6) permutations. When one depth is removed for the TMK, there remains **4^6** or 4,096 combinations. **This leaves 11,529 theoretical incidental master keys per system in this example.** The number of incidentals is reduced in a rotating constant system because the number of master pins that are required is less than in a TPP system.

As can be seen in the chart in **11_5.8.2,** incidental master keys are a composite of the change key and TMK bittings. In the true total position progression format, there are always two lower

pins in each chamber: a bottom pin and a master pin. In a lock with six chambers, we therefore must create a total of 64 (2^6) permutations. Other than the change key and master key, all others (total of 62) are incidental master keys. Depending upon the complexity of the system, these incidentals comprise the row, block, horizontal group, vertical group, and page master keys. Remember, split pin master keying allows different keys to work in the same cylinder; this is the basis for the TPP and RC systems.

In the standard progression format listing in **11_5.8.2**, we choose combinations of lower pin segments to create these incidental master keys. Thus, the first VGM 030107 in the chart is actually a composite of the first three positions that define the master key AA, the fourth position (1) which is common to all of the change keys in the vertical group, and the fifth and sixth positions (07) which is common to the TMK. This (incidental) **v**ertical **g**roup **m**aster key is a composite of the lower pin segments that make up the bittings of the master key, change key, and TMK, and will open sixteen locks. As can be seen, any combination of bottom pins and master pins can be utilized to create incidentals. That is how complex keying systems can be created with just two lower pin segments, rather than several master pins in each chamber.

In another example to further illustrate the point, the ninth block master 030167 will open four locks associated with it: 030161, 030163, 010165, and 010169. This is accomplished by using the first three positions for AA master key (030), the fourth and fifth positions of the change key (16), and the sixth position (7) of the TMK. A close examination of these codes reveal that where the bitting values remain constant in every lock (030 in the first three positions and 16 in fourth and fifth positions), those constants are utilized as part of the incidental master key. However, it can be seen that the sixth position in this example utilizes all four available depths (1,3,5,9), and thus the TMK value of 7 is chosen as the constant. Another way of stating this is that the TMK value is always utilized to replace a progressed value for the change key or master key.

Incidental master keys can be defined as those combinations that result from the selection of a composite of pin segments to create keys that will open one or more locks in one or more keying levels. The following master keys are incidental and created by virtue of the use of master pins:

Row master key: A row master key represents the "C" column (fourth position or first change key progressive) that is substituted with the fourth position of the TMK. It is also a one-pin master key, and will open the four locks associated with its row. There are sixteen row master keys per page.

Block master key: The common depth for all combinations within a Block of four locks. This is the first five positions and the TMK sixth position (A). A BM wil operate any cylinder that is on the TMK and is within the block. It is referred to as a one-pin master key because there is one pin different from the change key in that block. One TMK position is utilized as a substitute for the progressed position of the change key. There are sixteen block master keys per page.

Vertical group master key: This is a two-pin master key because two progressed pins are substituted with the TMK values. In this case, the fifth and sixth positions (B,A) are substituted with the TMK values. There are four vertical group master keys per page.

Horizontal group master key: This is a two-pin master key that will open sixteen locks in four blocks by substituting the fourth and sixth positions (C,A). There are four horizontal group masters per page.

Page master key: This is a three-pin master key because the fourth, fifth, and sixth positions (C,B,A) are substituted with the TMK values. There is one page master key for 64 locks where the division is three chambers for the master key and three chambers for the change key (six pin lock), with a two-step progression. The first three positions (F,E,D) are always constant for each page. The last three positions (C,B,A) repeat 64 patterns for each page. There are therefore 64 change keys per page (4 x 4 x 4).

Groups of pages: There are also incidental master keys for groups of pages. Thus, there are sixteen four-pin master keys that will operate sixteen groups of pages. There are four five-pin master keys for four consecutive groups of sixteen pages. And, of course, there is one TMK that will operate all sixty four pages.

11_5.3.6.1.1 Selective Master Keys

Selective master keys are employed in large systems where high

level access is required across different keying levels. The SMK will be programmed to open most, but not all of the locks within the system, thereby distinguishing it from a true TMK. Engineers and housekeeping supervisors are often issued selective master keys because they have a need to access most, but not all areas. From the standpoint of functionality, the design of a SMK can be compared to a master key for keyed alike groups of cylinders. Generally, the selective master key will open locks under different master keys in a system having three or more levels of keying.

A selective master key (SMK) may be considered as a subset to an incidental master key and as a modified alternative to the TMK. They can, in effect, be turned on and off for any lock, and they do not create key interchange. In order to implement selective master keying, one progressive is sacrificed: its code will differ by one depth (in one position) from the top level master key (through double pinning). There is usually only one SMK in a system because of the requirement to sacrifice one progressive. In the **diagram**, the engineers key is identified as AA1 and can open most of the locks under both AA and AB levels.

There is a difference between **selective key systems** and a **selective master key**. Selective key systems are utilized in Europe and provide that every key can be a master key. This would occur in a system wherein there are a limited number of keys and extensive cross-keying requirements. Extra master pins are utilized, making the locks extremely vulnerable. This security issue is in part offset through the use of sidebars and large numbers of pins.

11_5.3.6.2 Cross-Keying: Intended and Unintended

Cross-keying, whether intended or not, can occur in all split-pin master keying systems. Physically, it results from the use of more than one master pin within a chamber. Each time another pin segment is introduced, more virtual shear lines are created, resulting in additional combinations that will open the lock. In certain systems, it is desirable to have change keys open more than one lock. Certain cylinders would be intentionally pinned to accomplish this result. In other instances, unintended cross-keys or key interchange can be created through pinning or system design errors. Cross-keying issues may be largely eliminated in recognized keying schemes that prevent the TMK combination from

being used in any change keys.

In the controlled cross-keying scenario, two or more keys under the same master key level and same higher level will operate one cylinder by design. In such event, security and system expansion is limited. If more than a few cross-keyed cylinders are utilized within a keying system, then many keys may operate such cylinders. The diagrams represent two typical scenarios that employ cross-keyed cylinders. In the first example, four private offices (2AA-5AA) are accessed and shared by a common reception area (1AA). The individual change key to each private office must also access the common area but the key for the common area cannot open any of the private offices. In this instance, **X1AA is operated by 2AA-5AA and AA.**

In the second example, a dormitory lounge serves three individual rooms. There is no change key (X1X) for the lounge, but each of the individual room keys must be able to enter the common access door. The lounge **X1X can be opened by AA1-AA3, AA, and A.**

If uncontrolled cross-keying is implemented by design, then two or more keys under different higher levels of master keying will open one cylinder. Thus, **XAA1 also operated by AB, AB1.**

The following issues and design rules must be considered with regard to cross-keying in any system:

- **Cylinders are cross-keyed, not the keys that fit them;**
- **It is not normal for two or more keys to operate one cylinder. Thus, careful planning of the system is mandatory;**
- **All cross-keyed cylinders must be documented, together with an explanation of what is controlled by each key. Show ALL keys that operate each cylinder; A cross-keyed cylinder with no dedicated change key is denoted by X1X;**
- **X indicates a cross-keyed cylinder;**
- **Cross-keying requires the use of added master pins, resulting in a loss of security;**
- **Cross-keying issues must be analyzed and planned from the inception of a system;**
- **Cross-keying will result in a loss of combinations. Therefore, the number of locks that are intentionally cross-keyed must be minimized;**
- **All locks that are cross-keyed should have combinations that are close to each other or consecutive within the progression**

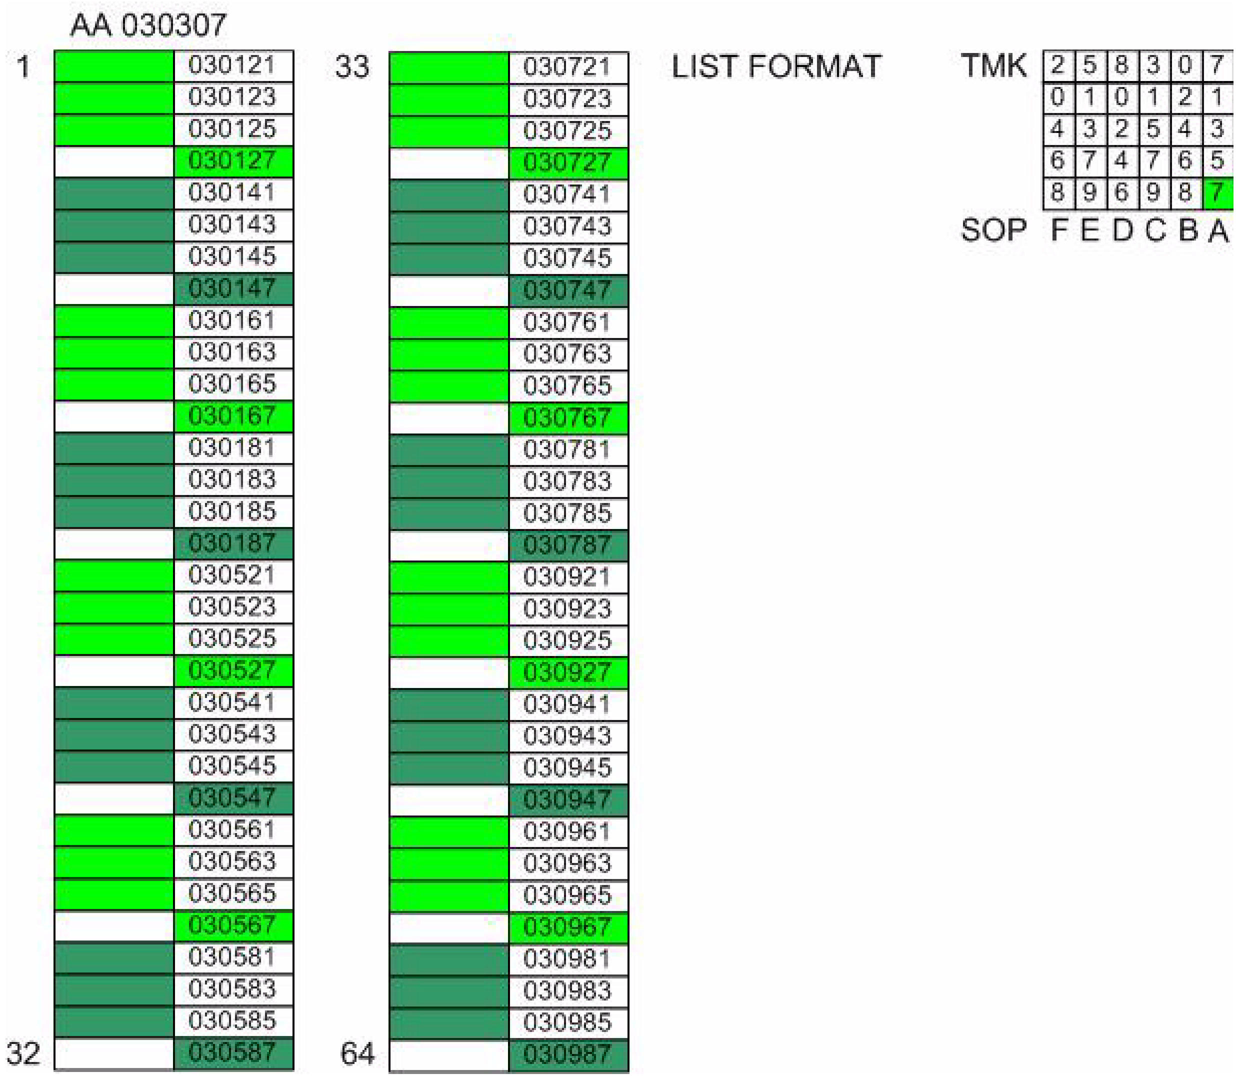
list: the more identical cuts, the better. Conversely, the greater the number of different cut values that are selected will result in greater loss of available combinations;

- **System expansion will be limited if more than a few keys operate one cylinder and more than a few cylinders are cross-keyed within a system;**
- **Cross-keying is undesirable and should be avoided;**
- **A loss of security will result from cross-keying;**
- **If poorly executed, key interchange will result;**

Although cross-keying is not a recognized system, it must be defined because the condition can create a subsystem of keys to open unintended locks. Cross-keying, if unintended, is an error inherent in master key system design. It results in the creation of extra and unintended key combinations outside of the system. Such permutations are generally unknown and may allow an unauthorized key to open a lock for which it was not designed.

Cross-keying is perhaps the greatest threat to security in conventional master key systems. The problem occurs because of the increased number of tumbler splits that are created in order to allow keys to open locks where such action would not normally occur. A cross-key condition is simply the addition or subtraction of tumbler lengths that occur between the change and master key levels. For example, in a five-tumbler lock with one change key and one master key, there are thirty-two possible cross-combinations (2^5) or different keys **that will all open the lock.** They can also be referred to as incidental master keys. Let us say that the code for the change key is **33308,** the master key is **80096.** The incidental master keys would be as follows:

33308 30308 83308 80308
33306 30306 83096 80306
33398 30398 83306 80398
33396 30396 83398 80396
33008 30008 83396 80008
33006 30006 83008 80006
33098 30098 83006 80098
33096 30096 83098 80096



Every one of the above listed keys will open our hypothetical lock. If this system required added master pins in one or more chambers to intentionally cross-key a cylinder, then the number of combinations would dramatically increase. It can be seen that

the addition of extra master pins can substantially reduce the security of both the lock and system in terms of its resistance to picking, impressioning, key interchange and use of unauthorized keys.

11_5.3.6.3 Key Interchange

Key interchange means that a specific key will open one or more locks for which it is not intended. The error can subject the locksmith to liability in the event of a loss resulting from unauthorized access. Key interchange will occur when an error is made in defining the KBA, thereby creating one or more incidental master keys from a progression that repeats values incorrectly. An example is shown below where common depths have been used in the TMK and change key. Remember: never is the same depth shared between the TMK and CK in the total position progression system.

In the progression list in the example, an error has been made in the sixth position of the KBA. The available depths should have been 1,3,5,9. However, a 7 was substituted for 9, with the consequence that sixteen incidental master keys have been created which would open a total of 48 unintended locks under master key 030307. Note that each incidental master key is shown in green, with the three associated locks that can be opened by that key in the same color.

Key interchange between systems in different facilities or locations can also occur when single-step progression is utilized because the available pool of differs (combinations) are the same for all systems that share a common keyway, even though there are more theoretical combinations in the single-step system than in a two-step progression (and parity is not utilized). It is imperative that the locksmith maintain an accurate TMK register to insure that key interchange between client-systems does not occur.

Poor tolerances and cumulative tolerance error within a lock can also contribute to key interchange by allowing the creation of a greater window or gap for the shear line. This could occur from

the filing of the plug, filing of pins, or use of worn components. The ability for key jiggling in such a case is also increased, allowing unintended keys to open a lock.

11_5.3.6.4 Design of the Top Level Master Key (TMK)

Stringent rules govern the design of the top level master key (and control key for an interchangeable core system) if proper system security is to be maintained. As a result, there are few acceptable combinations that are actually useable for the TMK for any manufacturer. As noted elsewhere in this text, it is imperative that accurate and timely records, in the form of a **TMK register(136)**, be maintained by any locksmith who defines the TMK for any system. This is vital in order to avoid conflicts between client systems which could lead to a breach in security and subsequent liability. The maintenance of proper records will:

- **Eliminate the potential for reuse of TMK combinations in different systems that are serviced by the locksmith, especially within the same geographic area;**
- **Reduce the likelihood of key interchange between systems, especially those that utilize the same keyways;**
- **Provide a method to geographically isolate systems;**

The following design rules apply when defining the top level master key.

- **The combination is not chosen at random;**
- **Reasonable criteria must be applied to the TMK definition;**
- **No declining stair step patterns. For example, 02468 can be removed in an unlocked position. The combination 020402 can not be removed in the rotated position;**
- **Do not use uniformly deep or shallow cuts. Uniform patterns are easy to pick and manipulate and are subject to key jiggling;**
- **Keys should not be designed where the depths run in a straight line and have little cut-to-cut variation, thereby reducing pick resistance and pull-out capability of the key;**
- **There should not be extreme cut-to-cut variation that can cause excessive wear on locks and keys;**
- **There should be no deep cuts near the shoulder or bow of the key that can result in metal fatigue and breakage;**
- **Combinations must be chosen that eliminate the potential that**

change keys can be altered to the TMK. For example, the combination of 67876 would not be acceptable. This particular combination also exemplifies the problem of pull-out, low pick resistance. The TMK must contain one cut that is shallower than all others to prevent this practice;

- **Be certain to verify the relationship between key sections between systems to avoid a conflict;**
- **Never use published or pre-written master key systems;**
- **Do not replicate keying systems for different customers;**
- **Do not design the system based upon uniformity or predictability;**
- **Do not use off-the-shelf keys as the TMK;**
- **Alter the parity for added security. A lower level master key in one system may be the same as the TMK in another system. This can also be true of a change key. Changes in parity can prevent this problem. Thus, OOEEOE 512894, EOOOEE 817326, and EEOEOE 627415;**
- **Certain manufacturers may utilize different key sections for master keyed systems as opposed to stock products;**
- **Employ moderate deep-to-shallow cut-to-cut design so as to appear as a normal key and reduce the potential for MACS violations;**
- **Utilize the shallowest cut in one position so that all of the depth cuts utilized in the change key will be deeper, thereby preventing physical alteration. Note that the change key may be modified to replicate an incidental master key, but not the TMK;**
- **Make one of the cuts the shallowest possible to minimize the capability to modify the change key. This will provide added pick resistance in a rotating constant system and will also prevent key jiggling or manipulation;**
- **Manufacturers such as Schlage may not utilize the most shallow cuts (0,1,2) for stock products. In such a case, it would be far easier to decode the master key and top level master key by visual inspection;**
- **Be aware that some manufacturers may write uniformly deep or shallow cuts for the TMK, making them far easier to compromise.**

11_5.3.7 Improving Master Key Security

In all conventional systems, master keying generally reduces security. Depending upon the system, the higher the level of

keying, the lower the security. Although master keying will offer simplified organization and greater convenience, there are many considerations affecting security that are involved in planning, implementing, and monitoring any specialized keying system. The master key scheme that is chosen can also have a significant impact upon security. The basic rule: **master keying systems are not recommended if there is an alternative.**

Unless the proper procedures and guidelines promulgated by the manufacturer are adhered to, serious degradation of system security will result. Issues involving tolerances, differs, adjacent cut specifications, keyway design and control, and generation of bitting combinations will all affect the potential for the system to be compromised by cross-keying issues, key interchange, change key modification, extrapolation of the TMK, and picking.

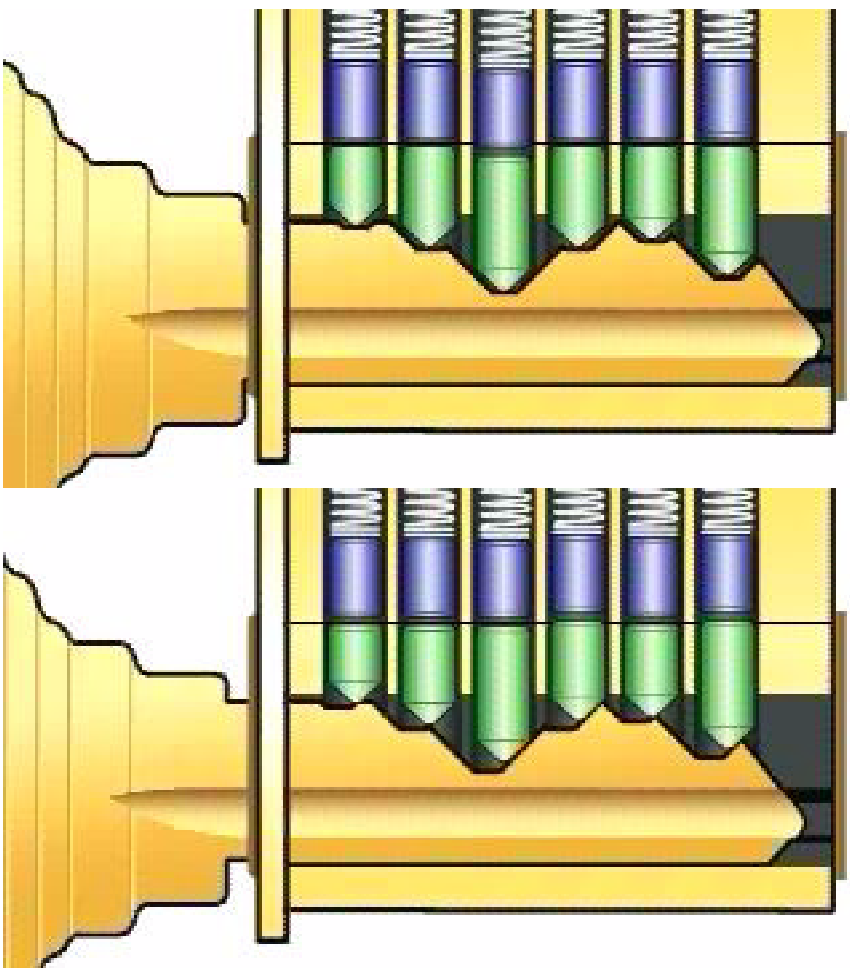


Figure LSS+1101 If master keys are not properly designed and differs calculated, then there is the potential that a change key can be jiggled to raise pins to shear line in a lock that was not intended to be opened by that specific change key. The practice is called "key-picking." Courtesy of HPC Interactive Learning Series.

For any system that is to be master keyed, careful planning is a necessity. Most master key systems have a life of between five and fifteen years, although many are in place for a much longer period. Unless proper control procedures are implemented, it is a sure bet that the system will be compromised long before the end of its projected life.

11_5.3.7.1 Security Considerations

Any conventional master key system is subject to compromise or bypass through a variety of techniques that are in large measure dependent upon the design of the system, the scheme employed to define master and change key levels and combinations, and mechanical enhancements that increase resistance to picking and similar forms of covert attack.

Although the master key for these types of systems cannot be derived from the inspection or decoding of one single change key, the code for master keys may be determined through the analysis of several change keys, depending upon the algorithm that was utilized to define the system. If a significant sample of change keys is obtained and either a total position progression or rotating constant scheme was used to define the key bitting progression, then it is possible to extrapolate the TMK bittings through a process of elimination and reverse engineering. This assumes that significant data is available about the lock so that a hypothetical KBA can be constructed that provides all possible bitting values based upon a one or two-step progression. Each change key is evaluated for each chamber and depth code. In a true TPP system, the TMK values will never be used in a change key. Thus, the value of the TMK bitting for each position can be deduced, based upon a computation of all of the values that are present in the change key samples. Whatever depths remain are possible TMK values.

In addition, as explained in **chapter 31**, a very simple method exists to extrapolate and decode all master key levels within a system. This technique presents a serious threat to the security of any installation where one or more master keys will open all of the locks. It is important that the reader thoroughly

understand the fundamentals of master keying theory contained in this chapter in order to properly analyze, define, and protect any system for which he is responsible. Remember that the unauthorized compromise of the top level master key can eliminate the security of an entire facility.

The security of any master key system is based upon the following factors:

- **Design of the TMK;**
- **Type of master key scheme (TPP, RC);**
- **Numbering sequence that is established in the KBA. It may be ascending order (shallow to deep), descending order (deep to shallow), sequential incrementing (up or down) from each TMK bitting (odometer), or pseudo-random value selection and progression;**
- **Limited number of people with access to master keys;**
- **Security of physical keys and key codes;**
- **Security policies with regard to all individuals that have access to any key that opens a lock that is master keyed. This issue relates to rights amplification, and the ability to compromise the system by modifying or altering a change key to work as a master key;**
- **Design of change keys to prevent their modification to allow them to act as master keys through filing of bitting positions, or of building up certain positions;**
- **Secondary locking system for enhanced security against cross-keying, key interchange, picking, key jiggling, decoding, and other methods of entry. Means include the use of master rings, security tumblers, sidebars, magnetics, integration of microprocessors, sectional keyways, and the addition of extra master pins to make decoding and extrapolation more difficult. Note that the addition of master pins will severely reduce the security of the lock, however, and thus should be carefully considered because the problems that are created far outweigh any security advantage. An analysis was completed by Matt Blaze at AT&T Labs regarding the insertion of extra master pins to make decoding more difficult, and the increased likelihood of key interchange in doing so;**
- **Proprietary keyways. See the discussion regarding the Easy Entrie key machine;**
- **Effective key control;**
- **Control of locks within the system, and monitoring for**

tampering or removal. People often talk about key control, but rarely discuss lock control. This concept is very important;

- **Control of extra cylinders in inventory;**
- **Background investigation on all individuals who work on, handle, duplicate, re-key, or maintain locks within the system;**
- **Adherence to master keying rules in design and determination of the bitting progression;**
- **Design of bitting pattern of change keys and master keys;**
- **Number of differs that are available;**
- **Key jiggling may be an issue in locks that employ sidebars;**
- **Sidebars will generally not affect the decoding of locks for the TMK.**

In an ideal master key system, the following rules would virtually prevent the compromise and bypass of any conventional system:

- **Nobody has access to a top level master key except one person;**
- **The TMK is difficult to replicate;**
- **The TMK cannot be extrapolated from the change key by physical inspection and decoding of one or more keys or locks;**
- **Nobody can gain unauthorized access to a cylinder for the purpose of disassembly, removal, or decoding;**
- **The TMK is difficult to derive and decode through any bypass process, including:**
    - **Decoding as defined herein;**
    - **Use of the Falle pin-lock pin-and-cam decoder system;**
    - **Use of the Falle original pin lock decoder system that employed shim wires;**
    - **Shimming of a cylinder with depth keys;**
    - **Use of a change key to extrapolate the TMK;**
- **Blanks are not available;**
- **Bittings are extremely difficult to replicate or cut. Unique sidebar codes, keyways, or other techniques that are only active for master keys or change keys, and for which no information can be derived from the individual change keys (regarding master keys). The Medeco M3 can provide this level of security.**

Several techniques and mechanical designs have been employed within conventional locks to increase the security of master keyed cylinders. These include use of a **master ring**, double keyways, sectional keyways, and double-throw bolts that can only be actuated by the master key. High-security locks will offer higher tolerances in concert with security enhancements, thus providing a greater number of useable combinations. The Medeco Biaxial and M3 locks, for example, can offer a very high number of key combinations in complex keying environments due to the ability to both lift and rotate tumblers in several positions. See the discussion of the Medeco M3 system in **chapter 17.** Mechanical security enhancements may provide added protection against certain forms of surreptitious entry, but may be of limited value with regard to the security of the master key system.

11_5.3.7.2 Security Procedures

The major threat to the security of any system is the compromise of master keys. When this occurs, every lock is vulnerable. For this reason, it is essential that procedures be implemented to insure the continued integrity of a master key system. The procedure to extrapolate the TMK from virtually any conventional master key system is discussed in **chapter 31.** It is important to understand accepted master keying schemes and to properly implement them in order to reduce the risks from this procedure.

The following checklist details the security issues that must be considered in the planning, as well as the investigation of potential compromise of a master key system.

- **Record the location and code of all locks that are master keyed;**
- **Record each key that is issued;**
- **Issue master keys only to those with a valid need;**
- **Restrict access, view, ability to copy, or possession of master keys to authorized personnel only;**
- **Maintain all spare master keys in a locked, controlled access cabinet;**
- **Conduct routine key and lock audits;**
- **Know your locksmith or person/organization responsible for changing, repairing, or rekeying locks. Instruct staff as to individuals who are**

authorized to work on locks;

- **Establish a procedure for providing clearance for outside workers to do maintenance and perform other duties that will require access to secure areas. Do not loan keys to such individuals without a proper policy of identification and background checks;**
- **Removable plug or construction locks should be employed in new facilities so that keys may be changed prior to acceptance of the building;**
- **Restrict access to blank keys;**
- **Do not stamp direct codes on keys or designations such as M, MK, GM, GGM;**
- **Any lock that is accessed by non-employees should not be master keyed. Restrooms, garages, storage areas, HVAC, vending, pharmacies, communications facilities, fire control equipment, elevator control areas, mail and package delivery areas, telephone and utility closets, pools, waste systems, and other areas should have only one change key (not master keyed) to minimize the ability of unauthorized individuals to extrapolate and decode the TMK;**
- **In some installations, locks in primary entrance areas should not be master keyed;**
- **Key codes should not be stored on a computer that is connected to a network or accessible to the internet;**
- **The design of the TMK should follow accepted guidelines, not be easily distinguishable, not permit easy alteration of a change key and should allow a high yield of master keys and change keys;**
- **Critical areas that contain weapons, explosives, nuclear materials or sensitive information should not be master keyed.**

11_5.3.7.3 Hardware and Security of Master Key Systems

The use of quality high-security locks can increase security in the master key environment. This results from the use of recognized keying schemes, maintenance of high-tolerance (creating more useable combinations), sidebar technology, restricted sectional keyways, protected profiles, and other

enhancements. It must be noted, however, that high security locks may be subject to compromise with regard to the TMK, and that merely using such locks does not guarantee added security **for the master key system.** Such systems may make the generation of test keys more difficult, but the addition of a sidebar will not frustrate the process. Sidebar codes will remain constant for virtually every system and can be easily replicated in the decoding process. Virtually **any** lock that relies upon multiple virtual shear lines for master keying can be compromised through extrapolation and decoding.

Unless the manufacturer restricts availability of its key profiles through patent and copyright protection, distribution safeguards and stringent key control, high security locks offer no advantage. Recent controversy regarding the decoding of master key systems has alerted security managers to the ease with which such systems can be compromised. That subject is treated in depth in this chapter, and in **chapter 31**.

The only way to protect a master key system from compromise through the extrapolation and decoding process is to insure that the key profile is secure. Sidebars, security pins, and other security enhancements are relevant to a discussion of picking, decoding, and impressioning, but have little significance when considering the ability to extrapolate the TMK code of the lock through sampling techniques discussed in this text. In the author's view, only those high security locks that make key generation extremely difficult would be capable of frustrating the compromise of the TMK in a conventional master key system. Locks in that category would include the Medeco M3, the Evva 3KS and MCS, and to a limited extent, the Abloy Disklock, Schlage Primus, Assa, and Medeco Biaxial. The ability to silicone impression and copy a key containing a sidebar code may make such compromise even easier. The replication of certain restricted blanks using specialized key machines such as the Easy entrie can also be a simple process.

Protected profiles and other enhancements can reduce the likelihood that a master key system can be compromised through the decoding and extrapolation process in many ways. The task can be made more difficult to:

- **Duplicate a key;**
- **Generate a key by code;**
- **Obtain or produce blank keys;**

- **Decode different depths on a sample key to determine:**
    - **depth coding and available depths;**
    - **master key schemes and sequences;**
- **Simulate different depths in order to sample each chamber;**
- **Obtain information regarding special bitting codes for master and change keys.**

11_5.3.7.4 Misconceptions Regarding Master Key Systems and Security

LSS204: Brian Chan on assumptions regarding master keying

There are many misconceptions regarding master key systems and their security. The discussion that follows is preliminary to the material presented in **chapter 31** regarding the compromise of conventional master key systems through extrapolation, and provides a foundation for understanding methods of bypass.

ASSUMPTION: A master key can be visually decoded from one key.

FACT: A master key cannot be deciphered or extrapolated from the inspection and measurement of one change key. Depending upon the keying scheme, a system can be evaluated and potentially compromised from the inspection of a significant sample of change keys, in order to provide information regarding depths that are common to several keys for one or more specific chambers, and to allow reverse engineering of the system. Depending upon the grouping and progression of change keys, the level of master keying, and the implementation of security enhancements to the system, the ability to extrapolate a master key may be problematical at best.

ASSUMPTION: A master key can be derived from the analysis of one change key.

FACT: A top level master key can be extrapolated from the analysis of one cylinder associated with that TMK, and the use of one change key for that lock.

ASSUMPTION: There are master keys that will globally open all locks.

FACT: Only in the movies. There is no universal master key, except perhaps a brick that is utilized to smash a window! The closest thing to a universal key would be for a warded lock, but even that would depend upon keyway and bullets or wards.

ASSUMPTION: Master key cuts are not repeated on all keys within a group, section, or progression on change keys, and thus, no relevant information can be obtained from the analysis of change keys.

FACT: If enough samples are available, certain patterns will emerge that may provide information as to one or more bitting positions that are utilized within the master key algorithm. This is particularly true within a rotating constant system where one or more values of the TMK will be shared with the master key and change key

ASSUMPTION: A change key cannot easily be converted to a master key.

FACT: This is a process known as "rights amplification" and will allow the alteration of a change key so it can be used as a master key. If the system is engineered properly, at least one cut of the master key will be both shallower and deeper than any change key cut, thus preventing the practice, although the deeper cut has several functions.

ASSUMPTION: In order to decode a master key, it is required to analyze more than one cylinder through disassembly.

FACT: As detailed in chapter 31, this is not necessarily true. If a change key is available, a system can be decoded without the need to disassemble a cylinder, either through sampling or shimming. In the alternative, the possession of a change key can make the disassembly and decoding of a master keyed lock quite simple and can insure the correct derivation of the master key or TMK.

ASSUMPTION: In complex multilevel master key systems, there will often be more than two master pins in several chambers, thus creating many cross-keys and a corresponding difficulty in deriving the correct code for the top level master key.

FACT: In the properly designed master key system, there will never be more than one master pin in each chamber. In the

rotating constant system, there may only be master pins in a few chambers, depending upon the number of differs required in the system, and rotation patterns applied to the KBA. In master ring and IC systems, there can be more than one master pin in each chamber to accomplish keying for more than three levels, or where control keys are master keyed.

ASSUMPTION: It is required to disassemble a lock in order to derive the master key.

FACT: Disassembly is not required in conventional master key systems in order to derive the top level master key. See chapter 31 for a detailed discussion of extrapolation through the use of the change key. A cylinder can also be shimmed with depth keys to determine its coding without the necessity of disassembly.

11_5.3.7.5 Sidebars and Security

Manufacturers throughout the world produce a variety of sidebar locking systems. Although Medeco was the original inventor of this technology as applied to pin tumbler locks, it is now prevalent in pin tumbler, disk, and lasertrack locks. The use of a sidebar does not mean that the lock is rated for a high security installation; it simply indicates that either the primary or secondary locking mechanism utilizes an indirect locking method described elsewhere in this text. Indeed, some sidebar locks are suitable and rated for high-security applications; others are not. Some locks utilize one sidebar in conjunction with a traditional shear line; others utilize it in conjunction with rotating magnetic disks. Some locks employ two sidebars for increased resistance to picking and other forms of covert attack.

In the context of master key systems, sidebars may increase the number of theoretical combinations that are available and reduce or eliminate the problem of cross-keying and key interchange. However, the presence of a sidebar in most cases does not increase the security of the system in terms of extrapolation and decoding of the top level master key. The design of the key and how it interacts with the active locking components will determine whether it actually increases the security of the lock against surreptitious entry.

There are many different sidebar schemes described in this text. Each is slightly different in design, mainly to circumvent prior

art that is already protected by patent claims. All sidebars, regardless of mechanical configuration, accomplishes the same result: to provide a means to prevent rotation of the plug through an independent means that cannot be directly affected by the application of tension applied to the plug. Assa, Abloy, Medeco, Schlage, Bilock, Ikon, Evva, and other manufacturers utilize sidebars in conjunction with pins, discs, sliders or wafers that must be moved to the correct position in order that the sidebar can retract into the plug.

Other systems employ a modified technology that provides a direct link between the key and sidebar. Although technically these manufacturers are utilizing a mechanical design that acts like a sidebar, in fact the same level of security is not attained. An excellent example is shown below.

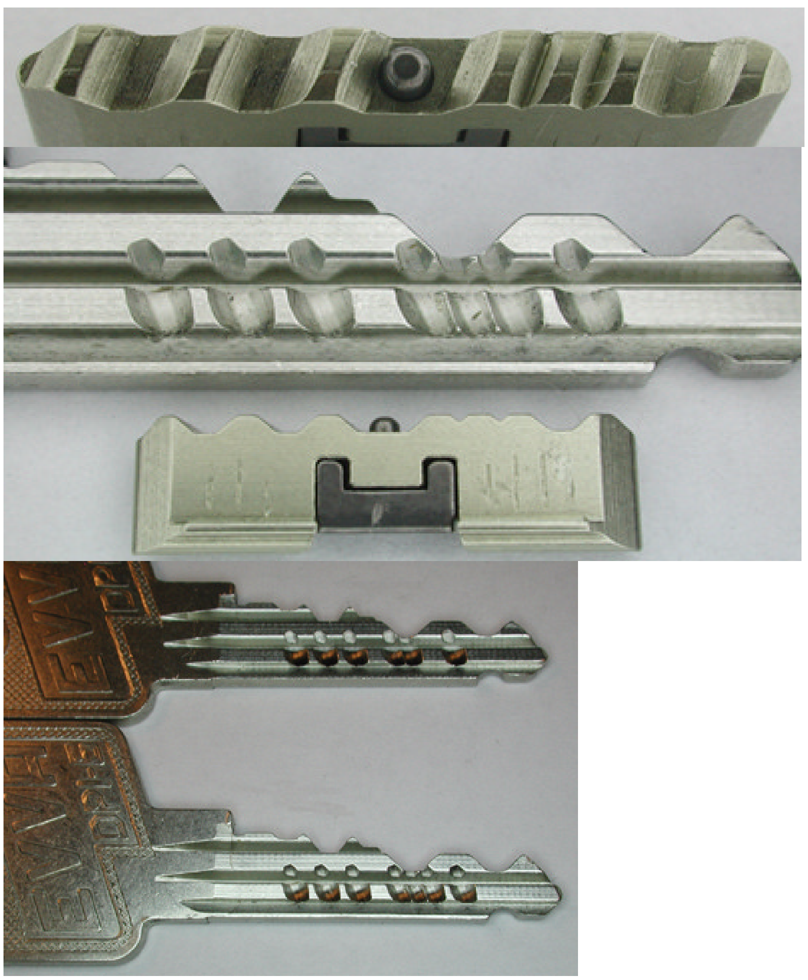

Figure LSS+1128 Evva DPI series dual sidebar lock, showing two different

milling codes.

This series of photographs shows a recent introduction by Evva (Austria) of their DPI series dual-sidebar lock, utilizing the same technology as their 3KS lasertrack system described elsewhere in this text. One sidebar is controlled by the traditional bittings on the key; the other by the side millings. Shown is the mating sidebar that is the reverse image of the side cuts on the key. Note the two different sidebar patterns in the photograph (right). This system resembles that which is utilized by Assa with one significant difference: the Assa design relies upon secondary pins that must be raised to the correct height to match the predefined sidebar code. In the Evva DPI series, there is a direct link between the key and sidebar insert. Thus, if all of the side bittings are milled out, the sidebar can be retracted into the plug. Only one point must be raised to correspond with the movable piece in the center of the sidebar insert. A spring-biased pin that protrudes from the shell will catch if this piece is not equal to the dimensions of the outer edge of the sidebar insert. The relevance of this is clear: an examination must be conducted to determine the action of all sidebars in **any** lock that is installed in a high-security system to insure that its function is consistent with the desired level of security.

11_5.4 Master Key System Algorithms

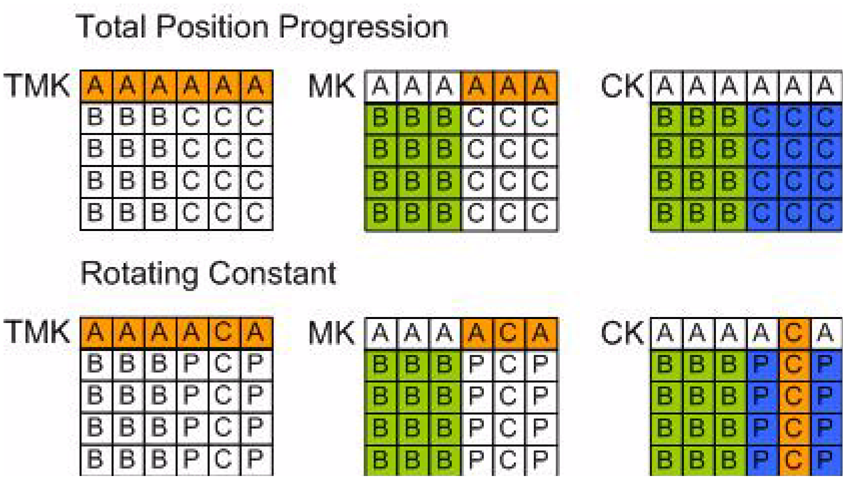
11_5.4.1 Introduction

There are two recognized schemes for planning, defining, and generating secure bitting combinations for a master key system: **total position progression** and **rotating constant.** A variation of the TPP is the **partial position progression** system. Each of these has advantages and drawbacks and are explored in the following text. This treatment is not intended as a treatise on master keying, but rather a required primer to allow the reader to fully understand the security implications of each technique. This will provide the necessary foundation of keying theory to allow for a competent analysis of bypass potential, countermeasures to system compromise, and the requisite knowledge to allow the bypass of master key systems.

11_5.4.2 Planning the Master Key System

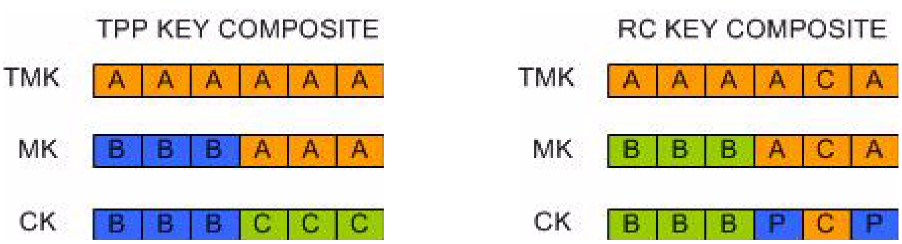
Regardless of which progression scheme is selected for generating individual bitting combinations, it is imperative that complete data is gathered and evaluated in order to asses the user access requirements for the system while maintaining security. The following issues must be analyzed and factored into the design of the system in order to choose the master key scheme that will yield the greatest number of secure combinations:

- **Number of locks;**
- **Levels of master keying;**
- **Complete analysis of access levels through the development of an expansion specification;**
- **Physical design of the TMK;**
- **Number of change keys under each master key;**
- **Consideration of the optimum approach to layout of the master key system;**
- **Available lock technology, required integration with current systems, and desires of the user;**
- **Size of the system in terms of the number of locks, access points, and interaction of master keying levels;**
- **Available security enhancements;**
- **Number of available differs, determined after generating a Key Bitting Array;**
- **Which master keying scheme will be selected;**
- **What rules apply for the generation of master and change keys;**
- **Manufacturers specifications with regard to depth and spacing, as well as the following issues:**
    - **Tolerance;**
    - **Number of chambers within the lock;**
    - **MACS;**
    - **Rules and limitations;**
    - **Differs;**
    - **Keyways available;**
    - **Sectional keyways;**
    - **Keyway protection;**
    - **Ability to duplicate;**
    - **Integration of high security locks with conventional profiles;**
    - **Access levels;**
    - **Conventional or positional master key system;**



- **Required security;**
- **Cross-keying issues;**
- **Standard or non-standard bitting depths;**

• Use of single or two-step progression in the generation of bitting codes. This will be dependent upon the actual difference between each bitting depth. The accepted rule requires that any difference between individual depths of less than .023" requires a two-step progression system. This means that every other depth can be factored into the key bitting array. If there is more than .023" between cuts, then every depth can be utilized in the KBA. There are exceptions to this rule, such as the Best A4 system;



11_5.4.2.1 Levels of Keying and Method Selection

Decisions with regard to whether total position progression or rotating constant is utilized will in part be based upon the required levels of keying, the number of master keys and associated change keys. A summary comparison of the two systems with a view toward analyzing the math involved in computing theoretical and practical combinations for each method should prove helpful for the discussion that follows with regard to specific master keying techniques.

A graphic comparison of total position progression and rotating constant is shown to highlight the differences inherent in the progression schemes. The diagrams are amplified in subsequent sections for greater understanding. A six pin cylinder is shown, with a 3:3 key division. The coding for the diagrams is: **A** = TMK, **B** = master key, **C** = change key, **P** = progressed, and **C** = constant.

Keys within a master key system, whether total position progression or rotating constant, are formed by a composite of progressives from the KBA, as shown below. In fact, it can be seen that rotating constant can be looked at as a subset of total position progression. Rotating constant **is** a total position progression system but always has at least one change key value that is shared with the TMK.

In the diagram of the TPP composite, the top level master key is formed by positions assigned in the KBA that cannot be utilized by the change key. Although in some instances one of the chambers may be held constant in a total position progression system (referred to as partial position progression), this is not the rule. In such a rare event, the values of A would be shared by the MK and CK. The master key is a composite of BBBAAA. In the example, the first three positions are progressed to derive a total of 64 possible master keys. All master keys will utilize the remaining three chambers AAA of the TMK. The change key is a composite of BBBCCC. BBB and CCC are progressed separately and then combined.

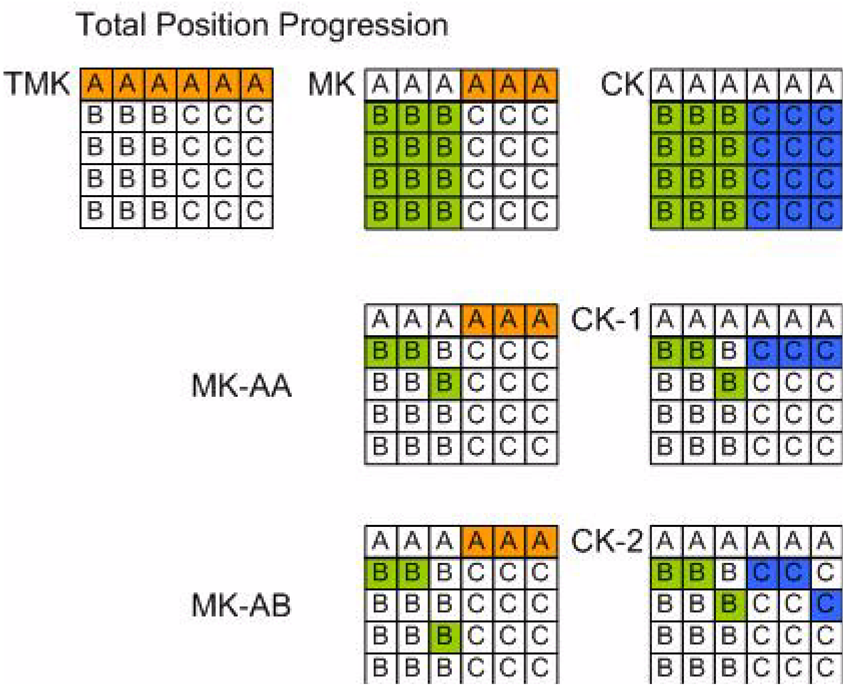
In the TPP diagram above, the relationship between the TMK, MK, and CK is clearly defined by color:

- **The TMK can never have any of the same elements as the change key;**
- **The MK always shares cuts with the TMK;**
- **The MK shares cuts with the CK, complementary to those shared with the TMK;**
- **A+B is always a constant, based upon the key division;**
- **B+C is always a constant, also based upon the key division;**
- **A is never a part of C and C is never a part of A;**
- **B is always a part of A and C;**
- **The number of chambers and positions value for A, B, C is constant;**
- **Each chamber is dedicated for a specific progression (master key or change key) based upon the division of the key;**

The rotating constant scheme also defines the TMK, but slightly differently than with the total position progression system. In the RC method, one or more positions are held constant between the TMK, MK, and CK, and other positions are progressed. Patterns, as shown in subsequent sections, define the matrix of all constant and progressed positions for locks in which one to seven chambers are to be rotated. In other words, the pattern matrix defines how many chambers are to be rotated, and within each pattern, which are to be progressed and which are to be held constant.

There are two distinct concepts that distinguish RC from TPP. In TPP, we divide the key and fix the number of positions that will be available for progression for the master key and change key portion of the key. In the RC approach, as with the TPP, we also define how many chambers will be available in the division of the key for the MK and the CK. However, based upon a matrix of all of these possibilities, we choose different patterns of constant and progressed positions. The term "rotate" actually indicates that the relationship between constant and progressed positions, as well as the number of positions to be so affected is based upon a pattern matrix. Simply stated, within the total position progression scheme, the sequence of progression is fixed; in the rotating constant method, the sequence of progression can be said to change. Unlike the TPP system, positions within the SOP may or may not be progressed, depending upon whether they are held constant or not. Generated combinations are based upon **which** positions are progressed. In the TPP, this relationship **never** changes, once established.

In the RC system, the constant positions will appear in the TMK, MK, and CK, as shown. In the example, utilizing two chambers that are progressed and one that is held constant, the top level master key is comprised of AAAACA; the master key is BBBACA. The change key is made up of BBBPCP. The key division is 3:3, meaning that three chambers are progressed for the master key and three chambers are utilized for the change key. However, the difference (and similarity) between the TPP and RC method is clear. Rotating constant will utilize different rotational patterns for the change key and master key, if required. Although the first pattern in our example is PCP (indicating **P**rogress or **C**onstant), it could just as well have been PPC, CPP, CPC, PCP, or expanded to include one or more of the master key positions. This is one critical difference between total position progression and rotating constant: the positions that can be progressed will rotate, whereas in the TPP, once the key is divided, they are fixed. Note, however that the **number of positions** that are progressed and held constant cannot be varied. A series of key bitting arrays shows actual progressions for different patterns.

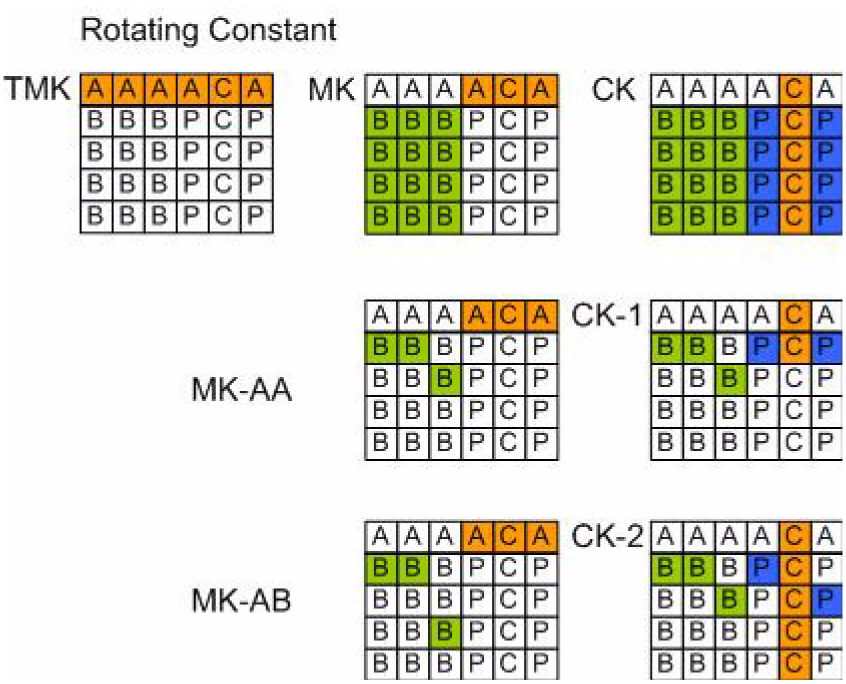


In the diagram of the RC key composite, one or more values of the TMK (A) will always be part of the MK (B) and the CK (C). However, the **position** of the constant and progressed chambers for B and C will not be constant.

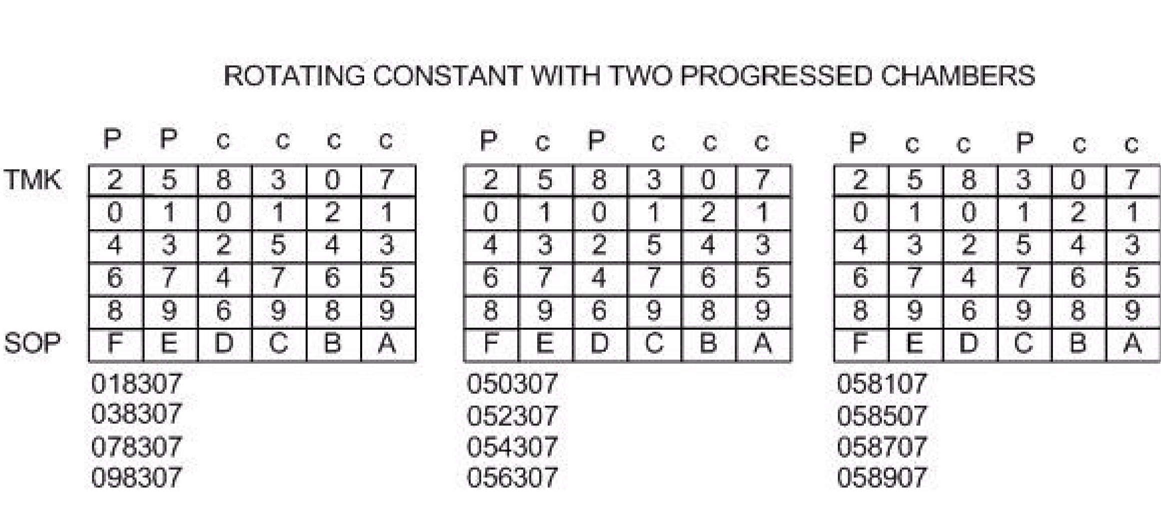
Total Position Progression:

- **TPP defines how many progressives, most commonly in powers of 4 or 5, are computed from the depths available in the key bitting array;**
- **The number of levels of key -1 defines the key division;**
- **The number of positions within the KBA must match the requirements of the expansion specification in terms of key division;**
- **In the TPP system, the chambers are progressed in a sequence, based upon the Sequence of Progression (SOP);**
- **In TPP, the key is divided between the master key and change key to derive a sufficient number of combinations for each, based upon the expansion specification;**
- **The division of the key, once set, never changes;**
- **The key division is a composite of two progression subsets: MK and CK:**
    - **which positions are progressed for the MK and CK are**

predefined;



- **the only constant is the TMK: these values are never progressed;**
- **key combinations are derived by the addition of the products of the individual master key and change key progressions. In other words, progress each subset separately, then the two subsets are combined to make up the key;**



Rotating Constant:

- **Rotating constant is almost never employed in a system that has more than three keying levels;**
- **The makeup of the key in a rotating constant system can be defined by the key division and the pattern of constants and progressed positions;**
- **Within a selected pattern, progressed chambers can never be constant and vice versa. This is the essence of pattern progression;**
- **At least one of the TMK values (depending upon selected pattern) will be shared between all three keys (TMK, MK, CK);**

- **Rotating constant, for two levels of keying, will produce more changes than a TPP system;**
- **Division of the key may not be altered once established, or key interchange will result;**
- **Rotating constant system has fewer master pins than a TPP system and is more secure;**
- **Less key interchange possibilities;**
- **More difficulty in picking;**
- **A rotating constant system is more applicable for two levels of keying or a small three level system;**
- **Rotating constant is based upon the number of progressives. The key division is established -1; Patterns are utilized to determine how many positions must be progressed and held;**
- **Within a rotating constant system, which chambers are constant cannot be easily derived from the analysis of a few keys unless in the same group;**
- **In the RC scheme, the position of the constant will change, based upon the selected pattern;**
- **The number of chambers that are constant and which are rotated are set;**
- **Define the chambers to be rotated and which of those chambers will be held, pursuant to the pattern selected;**
- **In both the RC and TPP systems, the design of the change key and master key have common elements. In the TPP scheme, the TMK is a composite of the TMK and MK bittings. The chambers that are progressed for the change key are different that those for the master key, based upon the division of the key. Only in RC, the change key and master key may share common values with the TMK;**
- **More depth increments are available in the RC system.**

11_5.4.2.2 Dividing the Key and System Paradigms

A key division is simply a logical method to derive master key and change key permutations. It is necessary to define the key bitting array in terms of the number of required combinations that will be available for master keys and for change keys and

the number of keying levels. The requirement to generate a specific number of master keys and change keys is dictated by the expansion specification that is provided for the proposed system. The KBA must be "divided" because the columns (progressives) for the MK and CK are acted upon separately, then combined to make a composite key as shown in preceding sections.

The principle for the division of the key is the same for both the total position progression and rotating constant systems. In the diagram below, two separate divisions are shown: 2:4 and 3:3. In the 2:4 example, two columns are allocated for the master key and four are designated for the change keys. This means that a total of 16 combinations for master keys and 256 combinations for change keys could theoretically be created. In the 3:3 example, the KBA is divided equally, so that there would be 64 theoretical master key combinations and 64 change key combinations available for each master key. Note that in both examples, there is a total of 4,096 theoretical combinations for all keys. In a second example for a five pin lock, the KBA is divided 2:3, with one position not progressed. This may be referred to as a **partial position progression** and is a hybrid between TPP and RC.

A key can be divided in any desired manner so as to produce the required number of combinations. However, there are only so many ways to accomplish such division, and there are only so many theoretical combinations available for a given lock and KBA. The derivation of combinations is based solely upon the number of chambers within the lock and the minimum depth increment established by each manufacturer, which in turn controls whether a single or two-step progression is utilized. If a manufacturer, for example, establishes a minimum depth increment of .015" and has ten available depths, there will be five depths for each progressive that are actually available (one for the TMK and four for progression). A key can be divided so that a specific number of chambers are dedicated to each keying level.

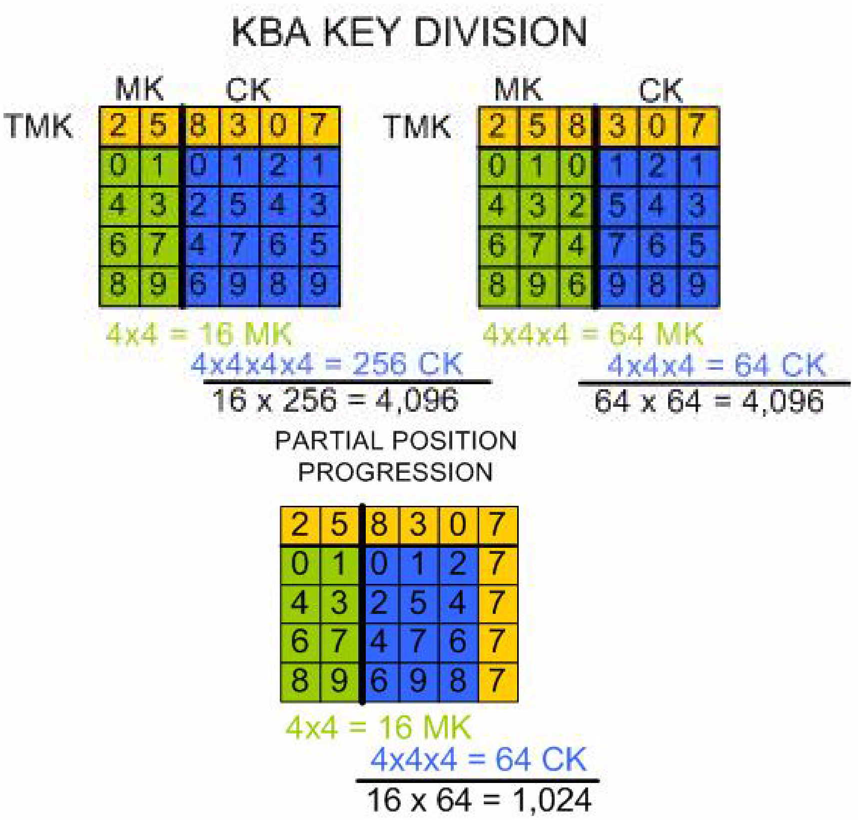


Figure LSS+1129 KBA division for TPP and partial position progression.

11_5.4.2.2.1 System Paradigms

The tables provide a matrix of theoretical combinations that can be generated within a total position progression system utilizing cylinders containing five, six, and seven pins for one and two-step progression. In the KBA key division table, the number of progressives assigned to each keying level is shown for a two, three, and four level system. In the lower portion of the table, the total number of theoretical combinations are calculated for single and two-step progression.

KBA DIVISION OF KEY

MATRIX OF CHAMBERS DEDICATED TO EACH KEYING LEVEL
TOTAL THEORETICAL COMBINATIONS

LEVELS	5 PIN DIVISION	6 PIN DIVISION	7 PIN DIVISION
	DEDICATED CHAMBERS	DEDICATED CHAMBERS	DEDICATED CHAMBERS
GGMK-GMK-MK-CK	1-1-3 1-2-2 1-3-1 2-1-2 2-2-1 3-1-1	1-1-4 1-2-3 1-3-2 1-4-1 2-1-3 2-2-2 2-3-1 3-1-2 3-2-1 4-1-1	1-1-5 1-2-4 1-3-3 1-4-2 1-5-1 2-1-4 2-2-3 2-3-2 2-4-1 3-1-3 3-2-2 3-3-1 4-1-2 4-2-1 5-1-1

11_5.4.2.3 Key Bitting Array: Computing and Defining Useable Combinations and the Concept of Progression

The progression of available depths as defined in the key bitting array is the basis for deriving theoretical combinations that can be used in a master key system. The concept of progression simply relates to an orderly process for sequencing a set of numbers in a specified order to obtain the greatest number of available combinations without repeating any of them. It is designed to prevent key interchange. Progression, as will be further explained, utilizes the KBA as a grid to organize the available numbers (depths) for progression. There are two **methods** of progression: total position progression and rotating constant. There are two **types** of progression: one-step and two-step. The method is in part determined by the number of specified keying levels and the number of combinations that are required for each level.

The type of progression is controlled by the hardware manufacturer and is a function of the number of available bitting depths and increment between each depth. This will in turn determine whether a one or two-step progression may be utilized. The industry standard is a minimum depth increment of .023" to allow for the use of every available depth (for single-step progression). Thus, a lock wherein the manufacturer determines that the incremental difference between each depth is .015" would require a two-step progression in order to exceed the .023" rule.

The number of theoretical and actually available differs for a

master key system must be determined in order to assure a sufficient number of change keys and master keys are available for each level. The computation is achieved through the creation of a key bitting array (KBA). As shown, this is a table that defines all of the available bitting positions for each chamber, and is dependent upon the keying scheme that is utilized. Described elsewhere in this text, the theoretical number of differs is computed by taking the number of available depths, raised to a power that is equal to the number of chambers. Thus, in a six pin Schlage lock where the manufacturer has defined ten individual depths per chamber, there would be 10^6 or 1,000,000 theoretical combinations. As will be shown, however, there are far fewer actual differs for this lock, due to factors described below.

Factors that will reduce the number of available combinations include:

- **Cross-keying;**
- **Too many levels of keying;**
- **Construction master keying;**
- **Selective master keying;**
- **Use of interchangeable core cylinders;**
- **Mixing high-security, master ring, and conventional cylinders within one system;**
- **Use of Brink or block out function cylinders.**

The relevant criteria that will determine the actual number of available differs include:

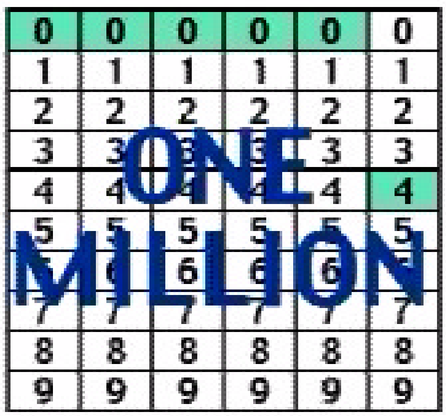
- **Master key scheme that is selected;**
- **Number of depths and chambers that are available for the specified lock;**
- **Spacing between depths, as defined by the manufacturer;**
- **Whether a one or two-step progression must be utilized in defining the available depths that can be used to formulate the master key system;**
- **Maximum adjacent cut specifications, as defined by the manufacturer;**
- **Rules regarding the use of the same depth for adjacent cuts;**
- **Rules regarding unusable bitting patterns.**

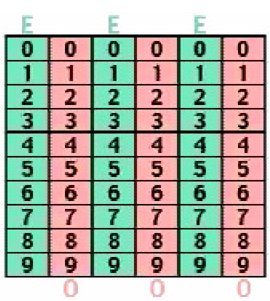
There are different parameters to define the KBA which are

examined for both TPP and RC schemes in the text that follows. The attributes of a key bitting array are summarized in the table below.

- **The KBA is a graphic display of all possible or theoretical bittings;**
- **Theoretical bittings are available but may not be useable;**
- **The KBA controls the progression of the available depths;**
- **The KBA, if properly devised, will eliminate the potential for key interchange within the system but not from keys of a different system;**
- **The KBA allows an orderly progression of numbers;**
- **How the individual available depths are entered into the KBA will determine their output as combinations and specifically how the sequence of numbers appear. Ths is based upon whether the digits are entered in odometer, shallow to deep, or random style;**
- **The KBA is defined by three critical factors: the TMK combination, method of progression, and type of progression;**
- **The KBA is "divided" based upon the number of required master keys and change keys. That division corresponds to the division of the key;**
- **The KBA has four major components: the TMK line, the master key and change key division portions, and the sequence of progression (SOP) line at the bottom of the array;**
- **In a total position progression system, there will be no TMK bittings in any column that is progressed. This is not the case in a rotating constant system;**
- **Columns are progressed in the same way that an odometer advances its wheels: from right to left (depending upon the sequence of progression);**
- **If the KBA utilizes depths in a two-step progression, the concept of parity is also introduced to further prevent key interchange between systems;**
- **Parity within a column is maintained between the TMK bitting value and the remaining values to be progressed;**
- **The progression order of bitting values as they are applied to the key (left to right or right to left) must match those provided by the manufacturer for cutting the key (bow to tip or tip to bow);**
- **The KBA format is the same for TPP and RC systems, however in the rotating constant system, only progressives from selected positions are utilized.**

Regardless of which keying scheme is employed, every lock has a theoretical number of differs or different key combinations that are available. In the example shown below, a Schlage lock has ten depths available in six chambers. Thus, there are 10^6 or 1,000,000 theoretical differs for this lock.





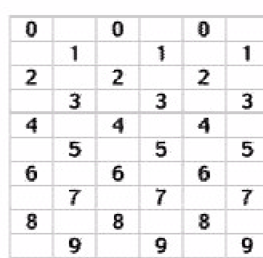


Figure LSS+1113 shows a key bitting array of the total number of theoretical differs for a six pin lock with ten depths. Minimum depth increment is not considered. Courtesy of HPC Interactive Learning Series.

In most keying schemes, odd and even depths are alternated between chambers in set parity patterns. When parity is implemented, the actual number of differs is reduced because all depths cannot be utilized in every chamber; only odd or even. The number is further diminished if the manufacturer utilizes incremental spacing between depths that is less than .023". In such case, every other depth will be utilized in a two-step progression system, as depicted below. In a two-step system, there is no loss of combinations with the implementation of parity, because it is inherent in the system.

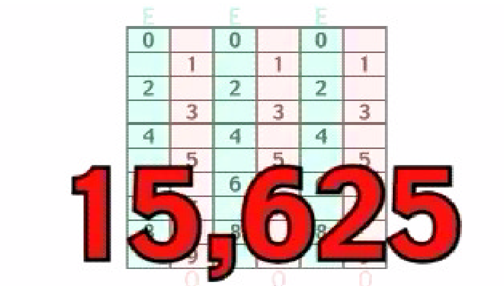

Figure LSS+1114 is a representation of the KBA for a two-step progression, with even-odd numbering in adjacent chambers. Courtesy of HPC Interactive Learning Series.

From 1,000,000 differs, our useable number of combinations for a master key system in a six pin lock has been reduced to a total of 5^6, or 15,625. This number results because there are now only five depths that are available for each chamber. However, the actual number will be far less than that, as will be seen when we examine the way in which combinations are produced.

- **The use of different keyways can expand the number of theoretical combinations within a multi-sectional system. There are certain general rules regarding the use of keyways:**
  - **Each individual keyway can be divided differently with respect to master and change keys;**
  - **If all keyways are divided in the same manner, the number of combinations for any one level can be expanded by multiplying by the number of keyways utilized.**

11_5.4.2.3.1 Sequence of Progression

LSS204: Brian Chan on the Sequence of Progression

The concept of sequence of progression (SOP) relates to the order that individual columns (chambers) are progressed within the key bitting array to derive combinations. The SOP is generally indicated as a series of letters that are positioned at the bottom of the KBA: they are read and progressed in ascending order from the least significant letter on the right. When the SOP is altered from a standard configuration such as **FEDCBA** as shown below, confusion can result if the concept is not fully understood. If the SOP of **FEDCBA** were changed to **FEDCAB**, for

example, that code would indicate that B, then A, then C would be progressed for the change key if the division was 3:3. It does not mean that columns B and A are transposed, for if that were the case, then either the combination of the TMK would be altered, or the bitting values under each TMK position would be wrong.

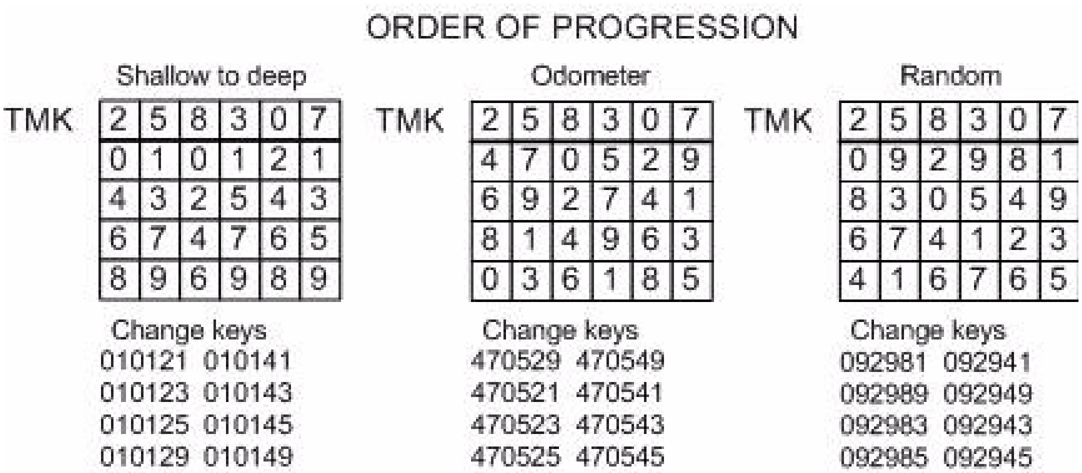
Depending upon whether total position progression or rotating constant is selected, the SOP will have a unique meaning relating to each method. If TPP is chosen, then the values within each column within the KBA are acted upon in a specified order. In the diagram below, the order is defined as **FEDCBA.** This code is read from right to left and indicates that column A is progressed first, then B, and C for the change key if the KBA was divided 3:3. Whether TPP or RC, the columns are always progressed **below** the first horizontal row that indicates the TMK bittings. Of course, the TMK values are never progressed. The **order of progression** or how the depths within a column are arranged, must also be defined for each KBA.

TMK	2	5	8	3	0	7
	0	1	0	1	2	1
	4	3	2	5	4	3
	6	7	4	7	6	5
	8	9	6	9	8	9
SOP	F	E	D	C	B	A

In our example, the progression for FEDCBA and FEDCAB for the first five change keys would read:

SEQUENCE OF PROGRESSION EXAMPLE	
FEDCBA	**FEDCAB**
010121	010121
010123	010141
010125	010161
010129	010181
010141	010132

In the rotating constant method, the sequence of progression becomes somewhat more complicated because the order is in part determined from a pattern matrix that defines the columns that



are to be progressed. Once the pattern is selected, the sequence of progression can be chosen.

11_5.4.2.3.2 Order of Progression

The bitting values within each column of the KBA can be initially entered in one of three recognized ways: **shallow to deep**, **odometer style**, or **scrambled**. The latter two modes are recommended. Why is this important? The arrangement of bitting values in the KBA will define their output as they are progressed. Once the TMK values are established, the remaining available depths are entered into each column (excluding the TMK value). From these, all available combinations will be derived. In our example KBA (using Schlage two-step), the TMK is defined as 258307. For the first column, the available values for progression would be 0,4,6,8. So, how do we actually enter those values in the KBA under the TMK? Logically, they would be entered so as to minimize the potential for error, in ascending order, as they are shown in the above example. As a result, the derived combinations would progress from shallow (0 cut) to deep. The problem with this method is one of predictability, key manipulation, reduced resistance to picking, and possible derivation of master key sequences by examining change keys. Values for the TMK may also be extrapolated.

Our bitting values of 0,4,6,8 for the first column could also have been written as a logical sequence from the TMK value of 2, in what is referred to as odometer format. As shown in the example below, this sequence would progress as the wheels in an odometer. The values would appear as 4,6,8,0 in the KBA. The values may also be scrambled or entered randomly. Thus, for example, they could be inserted into the table as 6,0,8,4.

The way in which the KBA is originally defined will affect the resulting combinations as they are progressed. Examples of the three methods of writing the KBA are shown below, together with output combinations for the first eight change keys.

11_5.4.2.3.3 Parity

Parity is another variable that can be utilized to reduce key interchange on the same keyway and between master key systems. It alters the relationship between the available depths for adjacent chambers, and provides an orderly way to define the KBA. Parity provides added security with regard to the use of keys from another master key system. In a lock with six chambers, there are a total of 64 different parity combinations, shown in the table below. Any of these can be selected for the KBA. Comparable to a virtual keyway, the use of different parity for each system that a locksmith defines in his geographic area (where such system has the same keyway) will minimize the potential that keys from one system can be used to access another. In other words, parity can minimize the key interchange between master key systems that utilize the same keyway. Parity patterns are chosen that do not have four adjacent chambers with the same odd or even value. Rather, patterns are preferred with no more than two adjacent values.

PARITY TABLE FOR SIX PIN LOCK (2^6 COMBINATIONS)						
EEEEEE	EEOEEE	EOEEEE	EOOEEE	OEEEEE	OEOEEE	OOEEEE
EEEEEO	EEOEEO	EOEEEO	EOOEEO	OEEEEO	OEOEEO	OOEEEO
EEEEOE	EEOEOE	EOEEOE	EOOEOE	OEEEOE	OEOEOE	OOEEOE
EEEEOO	EEOEOO	EOEEOO	EOOEOO	OEEEOO	OEOEOO	OOEEOO
EEEOEE	EEOOEE	EOEOEE	EOOOEE	OEEOEE	OEOOEE	OOEOEE
EEEOEO	EEOOEO	EOEOEO	EOOOEO	OEEOEO	OEOOEO	OOEOEO
EEEOOE	EEOOOE	EOEOOE	EOOOOE	OEEOOE	OEOOOE	OOEOOE

EEEOOO	EEOOOO	EOEOOO	EOOOOO	OEEOOO	OEOOOO	OOEOOO

Note: E=Even O=Odd

11_5.5 Total Position Progression (TPP)

Total position progression is the most popular method for deriving master and change key combinations. It provides an orderly means to generate sequential bitting patterns to insure that incidental master keys and cross-keying issues are minimized, and that the system provides sufficient change keys under each master key level. Perhaps the most critical feature of the TPP is its ability to protect the TMK bitting positions and depths from reuse. In the ideal system, **none** of the TMK values are ever utilized within a change key, although in some systems, one chamber may in fact share a common pin length for the TMK, MK, and CK (may be referred to as **partial position progression**). TPP systems are favored for three or more levels of keying because of their ability to generate sufficient combinations. Other attributes of the total position progression system include:

- **A master pin is placed in every chamber;**
- **The change key and TMK values are different in every position, unlike the rotating constant system;**
- **The key can be divided so as to make available any number of positions for master key levels and reciprocal positions for the change key combinations;**
- **Every column is progressed in the TPP format;**
- **The change key and master keys are derived solely from progressed columns;**
- **The master key and TMK share one or more common values;**

The KBA in a TPP system provides several functions that are required to assure a successful implementation:

- **The KBA defines combinations and numeric progressions for all combinations;**
- **Prevents rule violations;**
- **Insures system security;**
- **Defines master key cuts and positions, and prevents their use in change keys;**

- **Provides an organized method for calculating and generating required combinations for master and change keys;**
- **Defines the number of master key and change key progressives;**
- **Defines all possible depths for all chambers, which equals the global number of differs based upon manufacturers data. This is based upon a one-step or two-step progression;**
- **Allows for system diagramming of all bitting positions and eliminates the potential for duplicate bitting assignments;**
- **Reduces MACS violations by defining the KBA with MACS violation at the bottom of the sequence. This process is referred to as casting.**

The following example will provide an overview as to the steps required in order to generate a master key system utilizing the TPP system. Our hypothetical system utilizes Schlage locks having six chambers and ten available depths, as shown in the diagrams above. We shall require one top level master key (TMK), with ten individual master keys under the TMK, and 40 change keys under each master key. TPP allows us to generate each keying level in an orderly fashion. In our example, the required procedure is as follows:

- **Define a grid that shows all useable differs;**
- **Define the KBA for a three level system (1 TMK, 10 MK, 40 CK), taking into account the manufacturers specifications;**
- **Determine the division of the key, based upon the expansion specification;**
- **Determine the code for the TMK;**
- **Calculate the number of positions that must be progressed at the MK and CK levels in order to provide the required number of combinations;**
- **Progress each column for the desired number of permutations.**

Using a grid for graphic representation, we first define all possible depth increments for each chamber as shown above. We then remove those depths and positions that cannot be used. Recall that if the manufacturer defines a minimum depth increment less than .023", then we must utilize every other depth in our KBA. Because Schlage employs a .015" change, we use 0,2,4,6,8 for even depths, and 1,3,5,7,9 for odd depths, based upon a two-step progression. In such cases, even and odd are alternated between chambers, based upon the selection of a parity code. In this instance, we have chosen EOEOEO.

Next, we choose the code for the TMK. In this case, we selected **258307**. In our KBA, we originally determined that our Schlage lock allowed for five depth positions in six chambers. In the TPP system, we can never allow any depth or position of the TMK to be utilized in a change key. Thus, we must eliminate those positions from our key bitting array. In the charts below, all possible depths are shown on the left, while the useable depths are shown on the right. Note that the TMK depths have been removed on a chamber-by-chamber basis. Thus, 2 may never be used in the first chamber, 5 in the second chamber, 8 in the third chamber, 3 in the fourth chamber, 0 in the fifth chamber, and 7 in the sixth chamber. We are now left with 4^6, or 4,096 useable differs.

2	5	8	3	0	7	TMK
0		0		0		
	1		1		1	
2		2		2		
	3		3		3	
4		4		4		
	5		5		5	
6		6		6		
	7		7		7	
8		8		8		
	9		9		9	

2	5	8	3	0	7	TMK
0		0				
	1		1		1	
		2		2		
	3				3	
4		4		4		
			5		5	
6		6		6		
	7		7			
8				8		
	9		9		9	

2	5	8	3	0	7	TMK
0	1	0	1	2	1	Key Bitting Array
4	3	2	5	4	3	
6	7	4	7	6	5	
8	9	6	9	8	9	

4,096

We next define a progression sequence by setting up a grid having three rows: one for each level of keying.

	CHAMBERS					
GMK						
MK						
CK						

	CHAMBERS					
GMK	H	H	H	H	H	H

Figure LSS+1115 illustrates a key bitting array for a three level master key

system. Courtesy of HPC Interactive Learning Series.

For the TMK, we must never use any of those depths in our progression for other keying levels. Thus, we place an "H" (Hold) in each grid position corresponding to the chambers of the top master key. We then must determine how many MK positions are required to progress the required number of master keys. In our example, we need a total of ten separate bitting combinations. It can be seen that there are four available depths for each chamber. We therefore must use two of the chambers to obtain the needed permutations for our progression. This would provide a total of 16, or 2^4 combinations. So, we must **P**rogress two of the chambers. We show this by placing a P in two of the chamber positions, as shown in the grid.

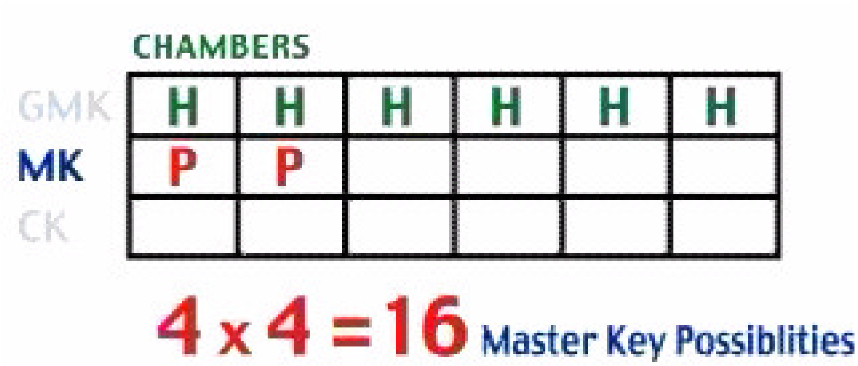


Figure LSS+1116 is a key bitting array for the master key level, with two chambers progressed in a TPP system. Courtesy of HPC Interactive Learning Series.

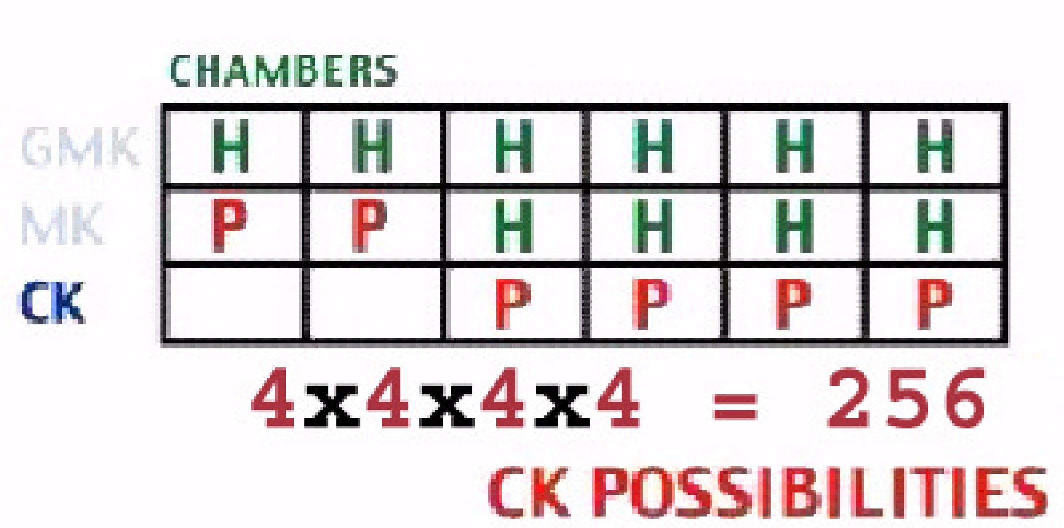
Next, we determine how many chamber positions we must progress in order to meet our requirement for 40 change keys. We need three chambers, or 4^3, which will yield a total of 64 permutations. Because this is a true TPP system, we actually show four columns that can be progressed. In the following section, we will construct this table in a **partial position progression** format with only three of the columns progressed for the change key and one that is held.



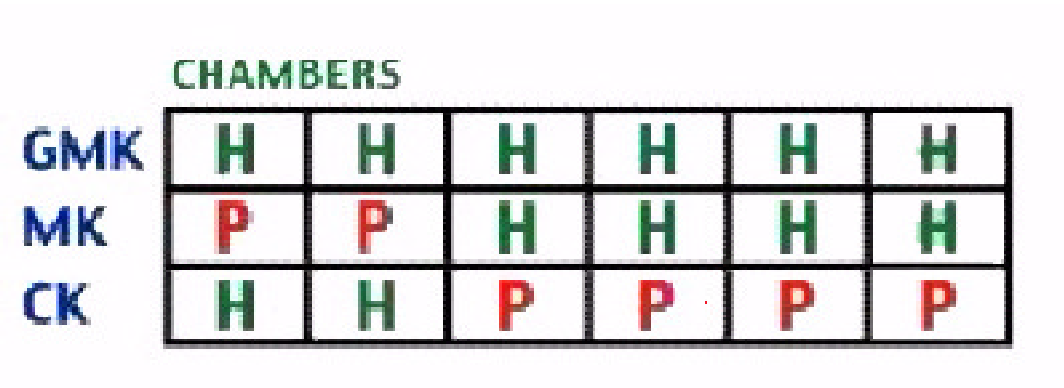


Figure LSS+1117 shows a key bitting array for a change key with four chambers progressed in a TPP system. Courtesy of HPC Interactive Learning Series.

This matrix allows us to progress each of the MK positions to create the required number of master keys (P1, P2). The change key chambers for a TPP system would utilize (P3, P4, P5, P6) and are likewise progressed under each of the master key levels. Each bitting code for the change key is a composite of all chambers, in sequence, as shown in earlier diagrams.

	CHAMBERS					
GMK	H 1	H 2	H 3	H 4	H 5	H 6
MK	P 1	P 2	H	H	H	H
CK	H	H	P 3	P 4	P 5	P 6

Figure LSS+1118 is a key bitting array showing the progression of master key and change key chambers. Courtesy of HPC Interactive Learning Series.

We can deduce the following information and rules from these grids with regard to the derivation of combinations for each keying level:

- **The TMK has a code of H1 H2 H3 H4 H5 H6. The TMK can have no other combination of depths;**

- **The MK has a code of P1 P2 H3 H4 H5 H6. Each master key is a composite of the progressed chambers and "held" positions of the TMK;**

- **The CK has a code of P1 P2 P3 P4 P5 P6. It is a composite of the progressed positions of the MK (P1, P2) and CK (P3, P4, P5, P6). Note: as will be shown, the CK would have a combination of P1 P2 P3 P4 P5 H6 in a partial position progression system if the last chamber were held constant;**

- **We can only progress one progressive at a time, within each division;**

- **We never progress the TMK chambers;**

- **The MK and CK levels, as defined by those chambers that are progressed, create the progression sequence. The chambers at the CK level are progressed against the chambers at the MK level, as will be shown in a later table;**

- **Each master key has a specific number of change keys that can be associated with it as a result of the division of the key. In**

the above example, there are a total of 16 possible master keys (4 x 4), and 256 (4 x 4 x 4 x 4) change keys that can be created under each master key. Remember, each change key has its associated master key code as part of its combination. This prevents a master key or associated change key from opening a lock under a different master key or group of locks;

- **The top level master key bitting code can never appear as part of any change key bitting in the total position progression system;**

- **There are a maximum of two lower pins in any chamber for any system, unless intentional cross-keys or selective master keys have been created (in which case the chamber is double pinned). This means that there can only be two depth positions that can be at shear line for each chamber: the change key depth, and the TMK depth;**

- **It can be seen that there are a maximum of two virtual shear lines in chambers 1-6.**

Derivation of master key codes can be easily understood from the charts below. Two of the chambers, P1 and P2 are progressed in order to meet the requirements of our hypothetical system (10 master keys). P1 and P2 are progressed in sequence and in ascending order, and replace the bitting codes H1 and H2 from the TMK. The progression, as shown, utilizes the first available depth in each chamber. For chamber 1, a 0 cut is utilized, while in chamber 2, the first cut is a 1. Thus, the first MK progression is 01. The least significant chamber in the sequence is always progressed first. This follows the same rule as with a base ten numbering system that we are all utilizing for counting. That is, we assign the value of a digit in a number sequence based upon its position. Thus, the number 25 actually is a code for 2 times 10 and 5 times one (one being the least significant digit). We add to the least significant digit to increment the value. The same rule applies when we progress the pin depths for each chamber.

In our example, P2 is the least significant chamber in sequencing the MK bitting. So, we take the least significant digit (P2) and increment it against P1, until there are no more possibilities (depths) available. We then begin the sequence again, only this time, we increment P1 to the next available depth, which happens to be 4. We repeat the progression with P2. When we have

exhausted the depths available for P2, we increment P1 to the next available depth, which is 6. We repeat the process by incrementing P1 to the last available depth which is 8, and then we repeat the sequence, using each of the available depths, in P2. In this manner, we are able to generate a total of 16 different master keys, all with unique codes.

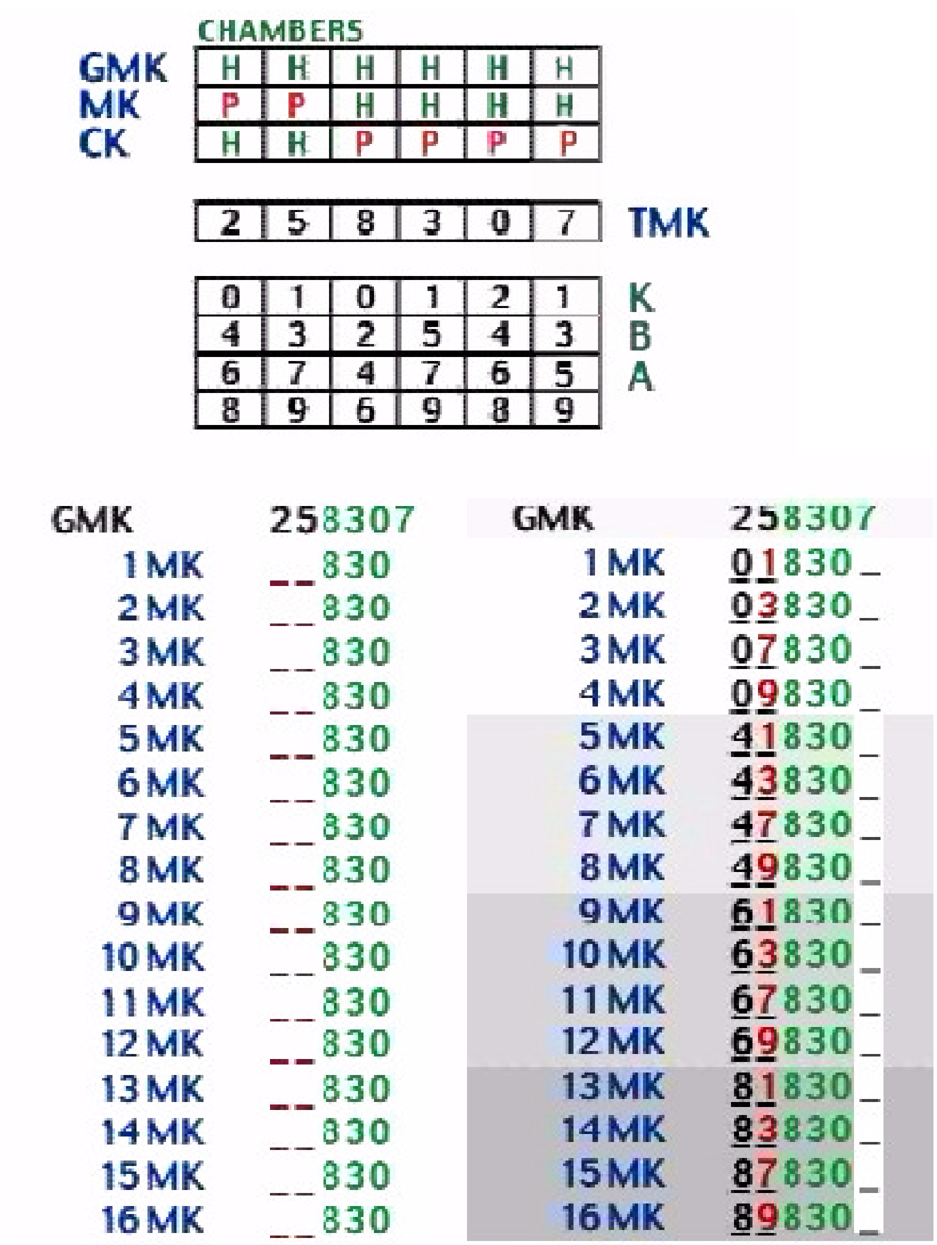

Figure LSS+1119 shows the progression in a TPP system for sixteen master keys.

Random assignment of symbols is not considered in the diagram. Courtesy of HPC Interactive Learning Series.

Next, we must define our change keys. Recalling our requirements in the example, a total of 40 change keys must be created for each master key. In the charts below, there are a total of 4^3, or 64 individual change keys that are progressed from chambers P3, P4, and P5. Although we only required 40 change keys for our example, there would be 24 available for system expansion. The change keys for each individual master key will contain the first two positions (P1 and P2) of its associated master key.

In the tables, the progression for 1MK is shown. Note that the sequence is identical with that shown for the MK level: the least significant digit is first sequenced (P5) through all possible depths that appear in the KBA (shown in red). Then, P4, then P3 is sequenced to generate a total of 64 combinations, each of which will only be controlled by 1MK. No other master key can access this group of locks, because no other master key has 01 (chambers P1 and P2) as its first two depths. Remember, the code for 1MK is only associated with the 40 change keys under its control. A new progression will be generated for 2MK, 3MK through 10MK. In our example, ascending progression values are selected for the bitting of each key. This progression can be modified to increase the security of the system and to make it more difficult to predict or extrapolate either change key or master key sequences or individual values. Also note that we have not entered a value for P6 at this time. We shall do so in the next section, dealing with partial position progression.

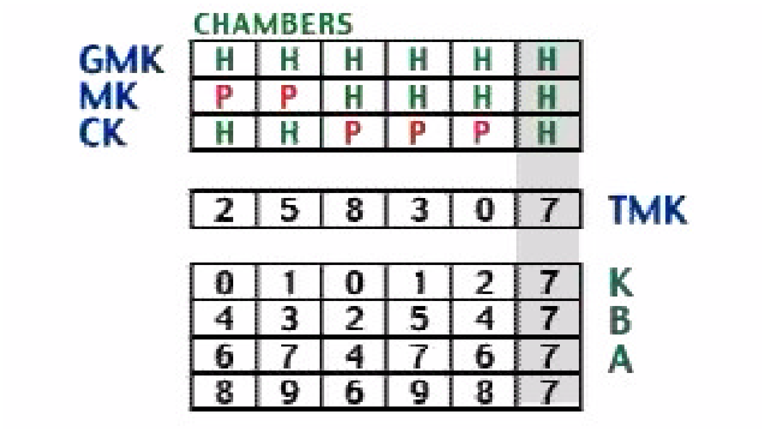
We can define a logical construct with regard to the change key and master key bitting position, and their relationship to the TMK bitting. This becomes extremely important to the discussion in **chapter 31**, with regard to the extrapolation of the top level master key bitting. Using the definition of each chamber at the MK and CK level that is marked for progression:

The TMK bitting for chamber 1 must be P1 or H1;
The TMK bitting for chamber 2 must be P2 or H2;
The TMK bitting for chamber 3 must be P3 or H3;
The TMK bitting for chamber 4 must be P4 or H4;
The TMK bitting for chamber 5 must be P5 or H5;
The TMK bitting for chamber 6 must be P6 or H6.

Any chamber that is progressed, regardless of whether it is at the MK or CK level:

Can only have two depths;
P1 can never equal H1

```
P2 can never equal H2
P3 can never equal H3
P4 can never equal H4
P5 can never equal H5
P6 can never equal H6
```



11_5.6 Partial Position Progression

Although not often discussed in master keying texts, a partial position progression system shares some of the attributes of both the total position progression and rotating constant schemes. It is employed in some systems where one chamber if held constant and its position never rotated. Often, a locksmith may create a PPP system, believing that it is in fact a rotating constant. Practically speaking, it is a theoretical difference, but deserves mention because it is sometimes employed.

Partial position progression can be considered as a subset of total position progression and a hybrid between TPP and RC. In the PPP scheme, not all of the columns in the KBA are progressed as with total position progression. The PPP shares a characteristic of rotating constant, in that one or more chambers is held constant. However, unlike RC, those progressives that are constant are **not rotated**; they are fixed at the time of the division of the key.

The distinction between PPP and RC can be understood by analyzing the difference in change key combinations between total position progression and partial position progression formats. It will be noted in the KBA (below) that the sixth column is held rather than progressed, and the value of the TMK (7) is shared between the TMK, MK, and CK, as with the rotating constant method.

	CHAMBERS					
GMK	H1	H2	H3	H4	H5	H6
MK	P1	P2	H	H	H	H
CK	H	H	P3	P4	P5	H6

We can now deduce the following information and rules from these grids with regard to the derivation of combinations for each keying level in partial position progression:

- **The TMK has a code of H1 H2 H3 H4 H5 H6. The TMK can have no other combination of depths;**

- **The MK has a code of P1 P2 H3 H4 H5 H6. Each master key is a composite of the progressed chambers and "held" positions of the TMK;**

- **The CK has a code of P1 P2 P3 P4 P5 H6. It is a composite of the progressed positions of the MK and CK;**

- **We can only progress one progressive at a time within each division;**

- **We never progress the TMK chambers;**

- **The MK and CK levels, as defined by those chambers that are progressed, create the progression sequence. The chambers at the CK level are progressed against the chambers at the MK level, and added to the held positions;**

- **Each master key has a specific number of change keys associated to it, by virtue of the fact that the MK and CK codes are interrelated. Thus, there is no possibility that a change key code can inadvertently be used in a lock located in an area for which it is not authorized;**

- **The top level master key code can appear as part of either the master key or change key;**

- **There are a maximum of two lower pins in any chamber for any system, unless intentional cross-keys or selective master keys have been created (in which case the chamber is double pinned). In those chambers that share a TMK value, there will only be one lower pin. This means that there can only be one or two depth positions that can be at shear line for each chamber: the change key (or master key) depth, and the TMK depth;**

- **It can be seen that there are a maximum of two virtual shear lines in chambers 1-5, and one shear line in column 6.**

- **Any chamber that is not progressed can only have one depth. That chamber will always be constant. The change key bitting will always equal the TMK bitting. Thus, H6 (or other chamber) will always equal the TMK bitting.**

- **It can be seen that there are a maximum of two virtual shear lines in chambers 1-5, and one shear line for chamber 6 (because this chamber is not progressed, so the bitting in this position is the same for all three levels of keying.**

- **In our example, the sixth chamber is not progressed at any level because it is not needed. That is, there are sufficient permutations available by using two chambers at the MK level, and three chambers at the CK level. If we had needed more than 64 different change keys, then we would have used the sixth chamber and made available a total of 256 or 4^4;**

In our example, the sixteen master keys under 1MK are derived as shown. Note that the sixth column is a constant 7, which is the same value as the TMK. The 64 change keys are sequenced as shown and they also contain a constant value in the sixth column with the TMK.

11_5.6.1 MACS Violations and Useable Combinations

This section will provide an example of theoretical and practical combinations that are derived through the progression method and the affect that maximum adjacent cut specifications can have with regard to the generation of useable combinations. The subject of MACS is also examined in section 11_5.3.4.2.

In our example, we have defined a system with 1 TMK, 10 MK, and 40 CK for each master key level. However, certain of the combinations at the MK and CK level may not be utilized due to **MACS(137)** violations. Schlage establishes a MACS of 7 and is shown in our example. Therefore, any two adjacent cuts that exceed a difference of 7 cannot be used. Even-odd depths between chambers will prevent the occurrence of a combination of 1 and 9, but will not prevent 0 and 9. It can be seen that **4MK** begins with 09, and thus, all of this master key level and associated change keys must be removed from the system. Likewise, the values of the

second chamber (P2) of MK levels 8, 12, and 16 is **9**, so all change keys with a third chamber (P3) value of **0** must be eliminated. MACS is a physical cutting limitation for keys. Although a lock can be keyed to a MACS violation, the physical key will not functional properly in that lock. MACS does not affect security, just the physical operation of the key. MACS losses will depend upon the design of the TMK and parity.

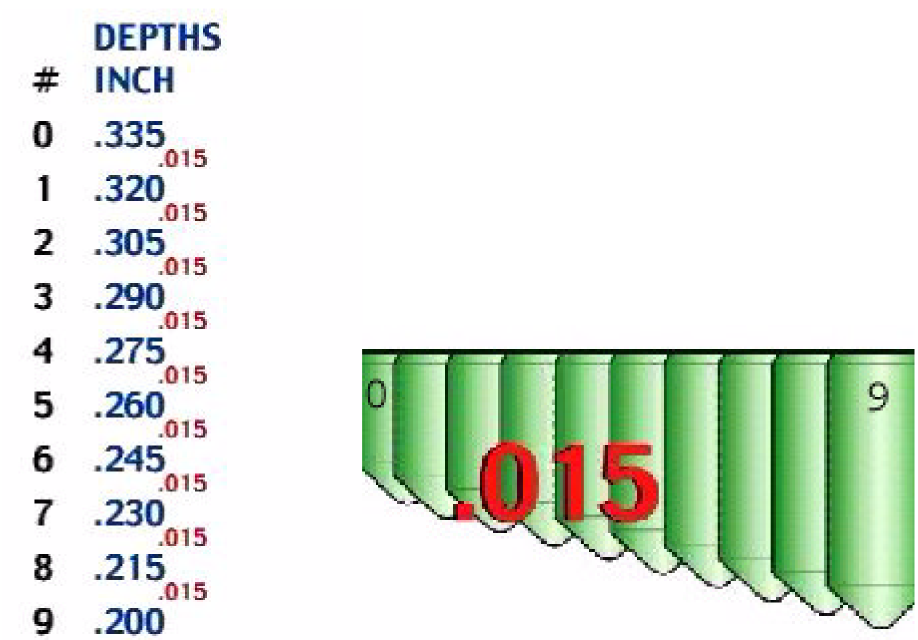
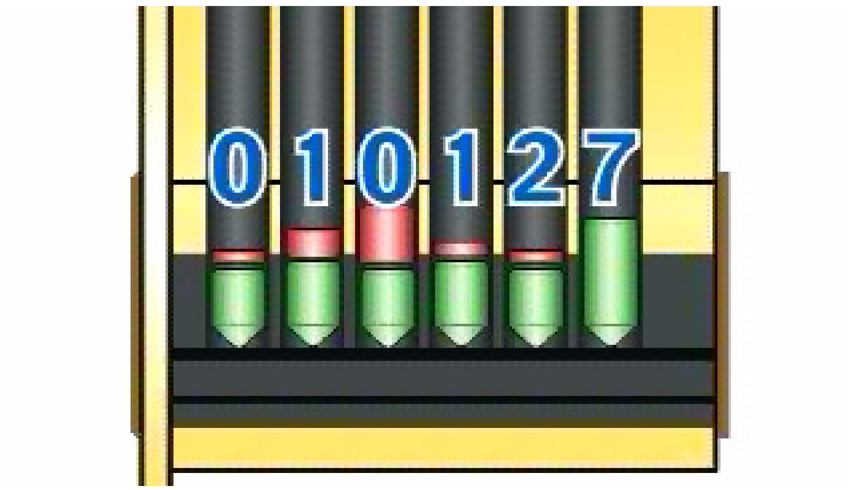
11_5.6.2 Pinning the Cylinder

Each cylinder must be populated with bottom pins, master pins, and top pins. This is done in a specific order (for each chamber) so that all combinations work as intended. Many manufacturers also utilize balanced drivers to insure that the overall pin stack height (top pin, master pins, bottom pin) is of a constant length. This practice will insure that a comb pick cannot be employed, that springs are not crushed, and that there is sufficient vertical movement of the pins. See the discussion regarding balanced drivers elsewhere in this text.



We shall use a change key with a combination of 010127 and the TMK with 258307. A chart of all Schlage depths is shown below, together with a graphic representation of pin depths, showing that a "0" cut has the most bitting and thus requires the shortest pin. Remember, bitting is measured from the base of the key blade to the root of the cut, and is inversely proportional to the length of the corresponding pin.

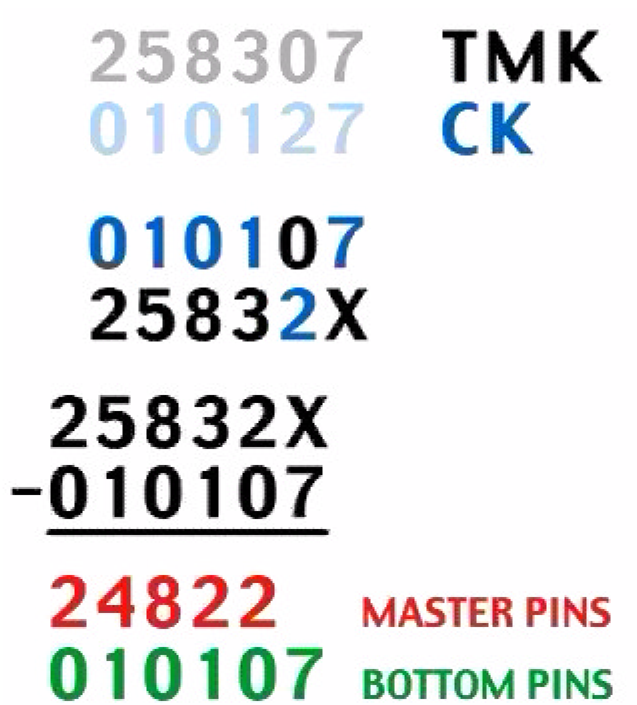


In order to properly place bottom pins and master pins into each chamber so that change key, master keys and top level master key will break at shear line, we compute the total length of the pin stack exclusive of the top pins. This means that the shallowest cut for each chamber plus a master pin must equal the deeper cut for each position. In our example, the change key has a code of 010127, and the TMK has a code of 258307. It can be seen that the first cut of the change key, "0" is the shorter of the two depths (2 is .030" longer than a 0 cut) and therefore "0" must be the bottom pin in chamber one. An additional length of two bitting depths (.030") is required to make up the difference for the TMK depth of 2 in the first chamber, so we add a number two master pin with this value to the pin stack. Now both a 0 and 2 will break at shear line. We repeat this procedure for each chamber so that both the change key depth and master key depth will split at the shear line.

The following procedure is followed to determine pinning for each chamber:

- **The shorter bitting value must always be loaded first and appear as the bottom tumbler;**

- **Notate the TMK bitting directly above the CK bitting on the chart;**
- **Transpose the smaller of the two numbers on the top in a second sequence;**
- **Eliminate duplicate numbers for each chamber. That means, for example, that if depth 7 is utilized in chamber 6, write it only once;**
- **Create a pinning chart, placing the shorter row of numbers on the bottom;**
- **Calculate the difference for each chamber between the shorter and longer pins. This value will be the master pin for each position and should appear above the first row of numbers in the pinning chart;**



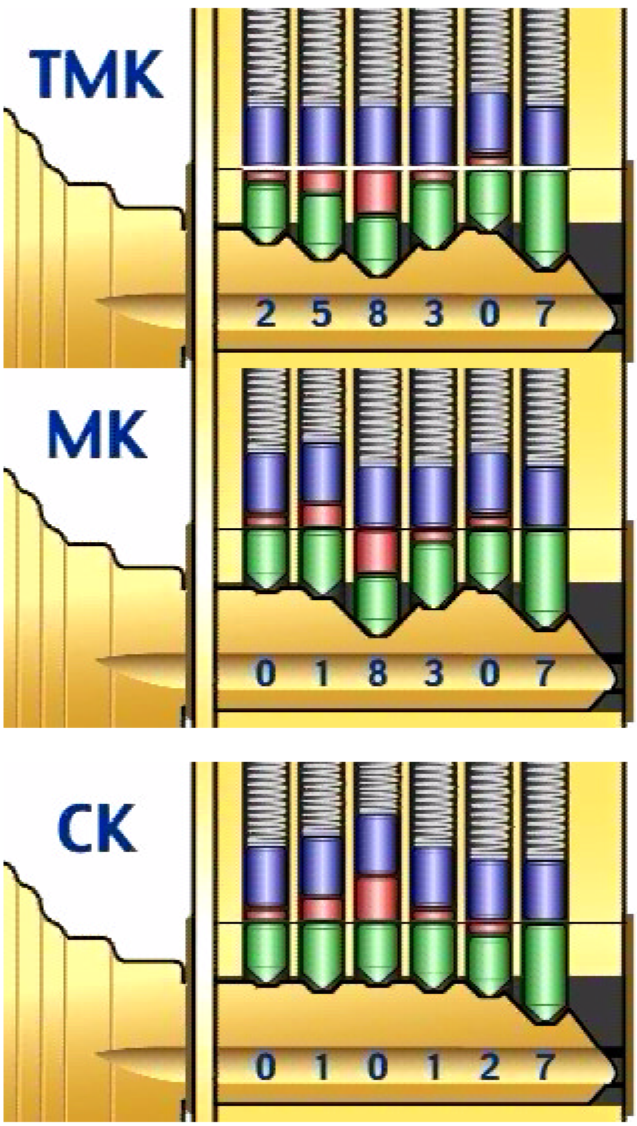


Figure LSS+1122 graphically illustrates the pinning of a master keyed cylinder, and the resultant cross-keys. Courtesy of HPC Interactive Learning Series.

When the cylinder is pinned properly, the TMK, master key, and corresponding change key will break at shear line. Note that a master key for another group will not open the cylinder. In our example, the following codes are all active for the cylinder

shown below: 258307 (TMK), 018307 (1MK), 010127 (CK associated with 1MK). Change key code 010147, however, will not open this lock because the pinning is incorrect for this combination, even though the combination is associated with the 1MK group. It can be seen that various composite pin combinations (incidental master keys) allow master keying schemes to operate one lock. In each of the examples, a combination of lower pins and master pins are raised to shear line and allow the plug to turn with three different keys. It can also be understood that there are a total **32 different combinations(138)** that will open this lock. Adherence to the keying scheme prevents any other keys in the system from matching these unintended cross-key combinations.

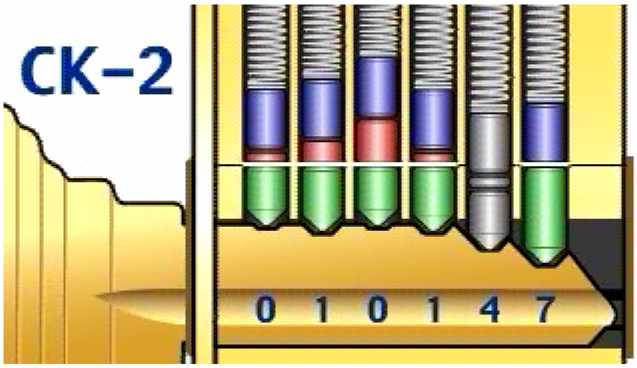

Figure LSS+1123 shows the different shear lines that are created when pinning a master key system. Courtesy of HPC Interactive Learning Series.

11_5.6.2.1 Verifying Cylinder Pinning

LSS204: Brian Chan on the use of system keys.

Brian Chan (UC Berkeley) has developed a method to rapidly pin and verify multiple cylinders for Best IC and other systems. The technique can minimize pinning errors and the time that is required for each lock. It will also eliminate the need to cut change keys to test each cylinder. Accelerated pinning can be likened to mass production techniques introduced by Eli Whitney (cotton gin manufacturing) more than 150 years ago during the Industrial Revolution. In a TPP or RC system, locks are grouped and identified by chambers having the same bitting values. Thus, all locks are loaded for each chamber having the same pins, rather than populating each lock for all chambers, as is the customary practice. For the second part of the process, verifying correct pinning, Chan eliminates the normal requirement to test each cylinder with its change key, master key, and TMK.

There are two types of common pinning errors: use of the wrong length pin and reversal of pins within a pin stack. If an error has been made with respect to placement of the correct bottom pin or master pin for a specific chamber, then most likely neither the master key nor TMK will function. If, for example, a pin with a depth of "3" rather than a "2" was inserted into the first chamber, then neither the CK, MK, or TMK would work.

The second type of pinning error is more difficult to identify and occurs when one or more pins are reversed within a pin stack. An example will demonstrate the problem. If the 1 and 3 pins are reversed in the fourth chamber, it can be seen that the change

key will not operate the lock, but the master key and TMK will. If the insertion order for a pin stack is reversed in chambers three or four, both the master key and top level master key would work. Only the change would fail to operate the lock. If such errors occur, the usual practice would be to dump all pins and start over.

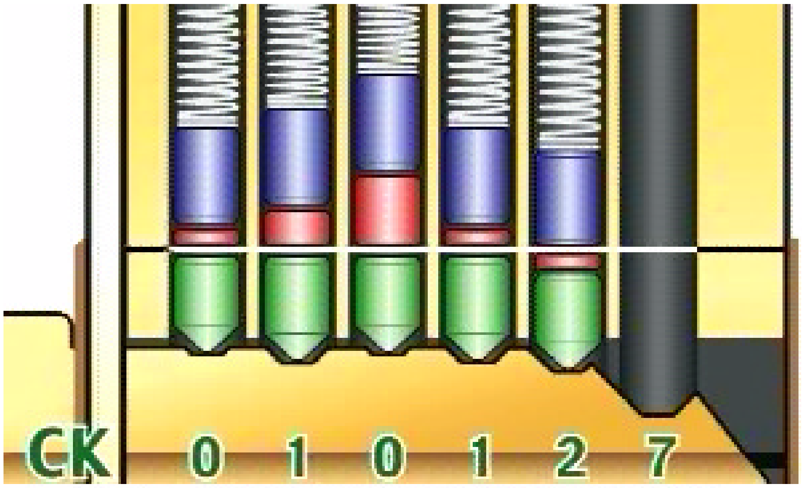
In our hypothetical master key system, the TMK has a value of 258307, the 1MK of 018307, and CK1 of 010127. Correct pinning of the cylinder would be as follows:

258307	**Top level master key**
018307	**#1 Master key**
010127	**#1 Change key**
24822-	**Master pin**
010107	**Bottom pins**

In order to determine which chamber(s) have been pinned in error, a method must be devised to individually test each pin stack. "System keys" are cut by Chan to exploit the composite combinations (incidental master keys) that are created by the multiple shear lines required for the different keying levels. This technique allows the isolation of each chamber to easily find pinning errors. The system keys for testing all locks within our hypothetical system would be coded to correspond with the available values that have been defined in he KBA for each chamber. In our example, we must test for all chambers. Because there are four available values for each chamber, we require a total of twenty system keys to test every lock.

The values for the system keys to test all progressives are shown in the chart below.

SYSTEM KEYS FOR TMK 258307		
T1-0	**058307**	**P1 bitting 0**
T1-2	**258307**	**TMK BITTING NOT USED**
T1-4	**458307**	**P1 bitting 4**
T1-6	**658307**	**P1 bitting 6**
T1-8	**858307**	**P1 bitting 8**



T2-1	**218307**	**P2 bitting 1**
T2-3	**238307**	**P2 bitting 3**
T2-5	**258307**	**TMK BITTING NOT USED**
T2-7	**278307**	**P2 bitting 7**
T2-9	**298307**	**P2 bitting 9**
T3-0	**250307**	**P3 bitting 0**
T3-2	**252307**	**P3 bitting 2**
T3-4	**254307**	**P3 bitting 4**
T3-6	**256307**	**P3 bitting 6**
T3-8	**258307**	**TMK BITTING NOT USED**
T4-1	**258107**	**P4 bitting 1**
T4-3	**258307**	**TMK BITTING NOT USED**
T4-5	**258507**	**P4 bitting 5**
T4-7	**258707**	**P4 bitting 7**
T4-9	**258907**	**P4 bitting 9**
T5-0	**258307**	**TMK BITTING NOT USED**
T5-2	**258327**	**P5 bitting 2**
T5-4	**258347**	**P5 bitting 4**
T5-6	**258367**	**P5 bitting 6**
T5-8	**258387**	**P5 bitting 8**

If an error is detected in the operation of a specific lock, the pinning chart is consulted to determine the bitting values for P3, P4, and P5. The test key for that chamber (T3, T4, or T5) and bitting would be used to test the operation of the lock. Based upon our previous discussion, we know that the change key bitting is a composite of the master key and change key progression. Thus, when the test key for a specific bitting value within a chamber is inserted, there are only two virtual shear lines: the change key and the TMK. If pinned correctly, the lock must open when the key is cut to the TMK or CK value. The master key division and associated depths for each individual master key portion can be tested in similar fashion with systems keys that are a composite of the master key and TMK depths.

This procedure provides further insight into the discussion in **chapter 31** with regard to the decoding and extrapolation of the TMK from the change key. In the verification of pinning described above, we know the bitting values of the change key and top level master key. We are seeking to determine whether the bitting depth that has been assigned to a specific lock and chamber for the change key matches the actual length of the pin. Conversely, when we are attempting to derive the TMK from a target lock, we know the correct value of the change key and that the lock has been pinned correctly. We do not know the bitting of the TMK, and will utilize the **change key** to determine the value of the TMK bitting. By using all system keys for each chamber, we are able to reverse the verification procedure and learn the specific value for the TMK for each position.

11_5.7 Rotating Constant Progression System (RC)

The application of rotating constant to master keying was first introduced by Yale in the 1800s. Much like the total position progression scheme, the rotating constant algorithm relies upon an orderly progression of available depths, derived from a key bitting array grid. The most critical difference is in the programmed use of one or more chambers having the same bitting depth in all keying levels, the use of constants, and in their rotation. It will be recalled in our hypothetical system for PPP that the sixth chamber was "held" and was therefore common to the TMK, MK, and CK. TPP systems will not allow this to occur, but in some situations, it can be the case that one chamber is common to all keying levels. The RC system is based upon a similar premise. In this system, at least one bitting value is held constant within a chamber, then its position is rotated in different progressions. The differences between TPP and RC can be graphically illustrated.

TOTAL POSITION PROGRESSION

2	5	8	3	0	7	TMK

0	1	0	1	2	1
4	3	2	5	4	3
6	7	4	7	6	5
8	9	6	9	8	9

Figure LSS+1124 shows the KBA for the total position progression system, but is equally applicable to a PPP system if the sixth progressive is held, as shown in the lock diagram. Note that the sequence of progression (SOP) is not shown in the key bitting arrays. Courtesy of HPC Interactive Learning Series.

In our PPP example, we held the sixth chamber constant between all keying levels. In TPP systems, however, this would not be the case, and all six chambers would be progressed as shown in the above KBA.

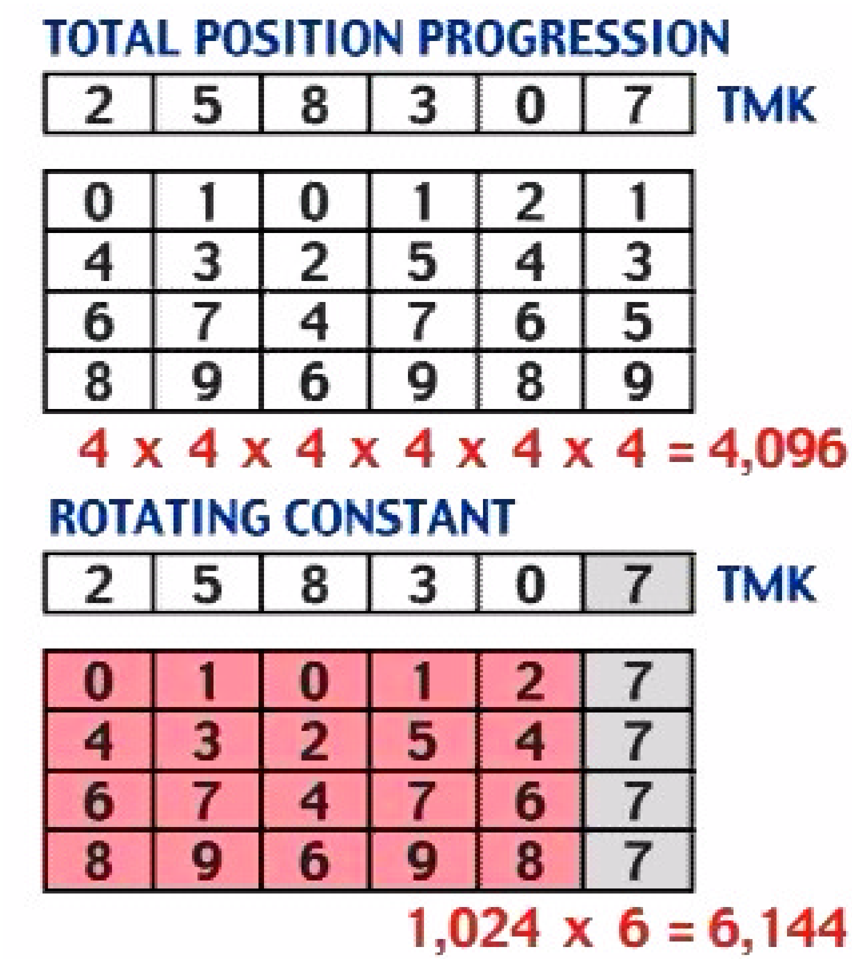


Figure LSS+1125 shows a comparison in KBA tables between a total position progression and rotating constant system. The RC table would also work for PPP, but the total number of theoreticals would be 1,024. Courtesy of HPC Interactive Learning Series.

In our hypothetical six pin lock when each chamber is held constant and the other five are progressed, a total of 6,144 combinations can be created, as shown in the charts below. Contrast this with a total number of possible differs of 4,096 in the TPP system.

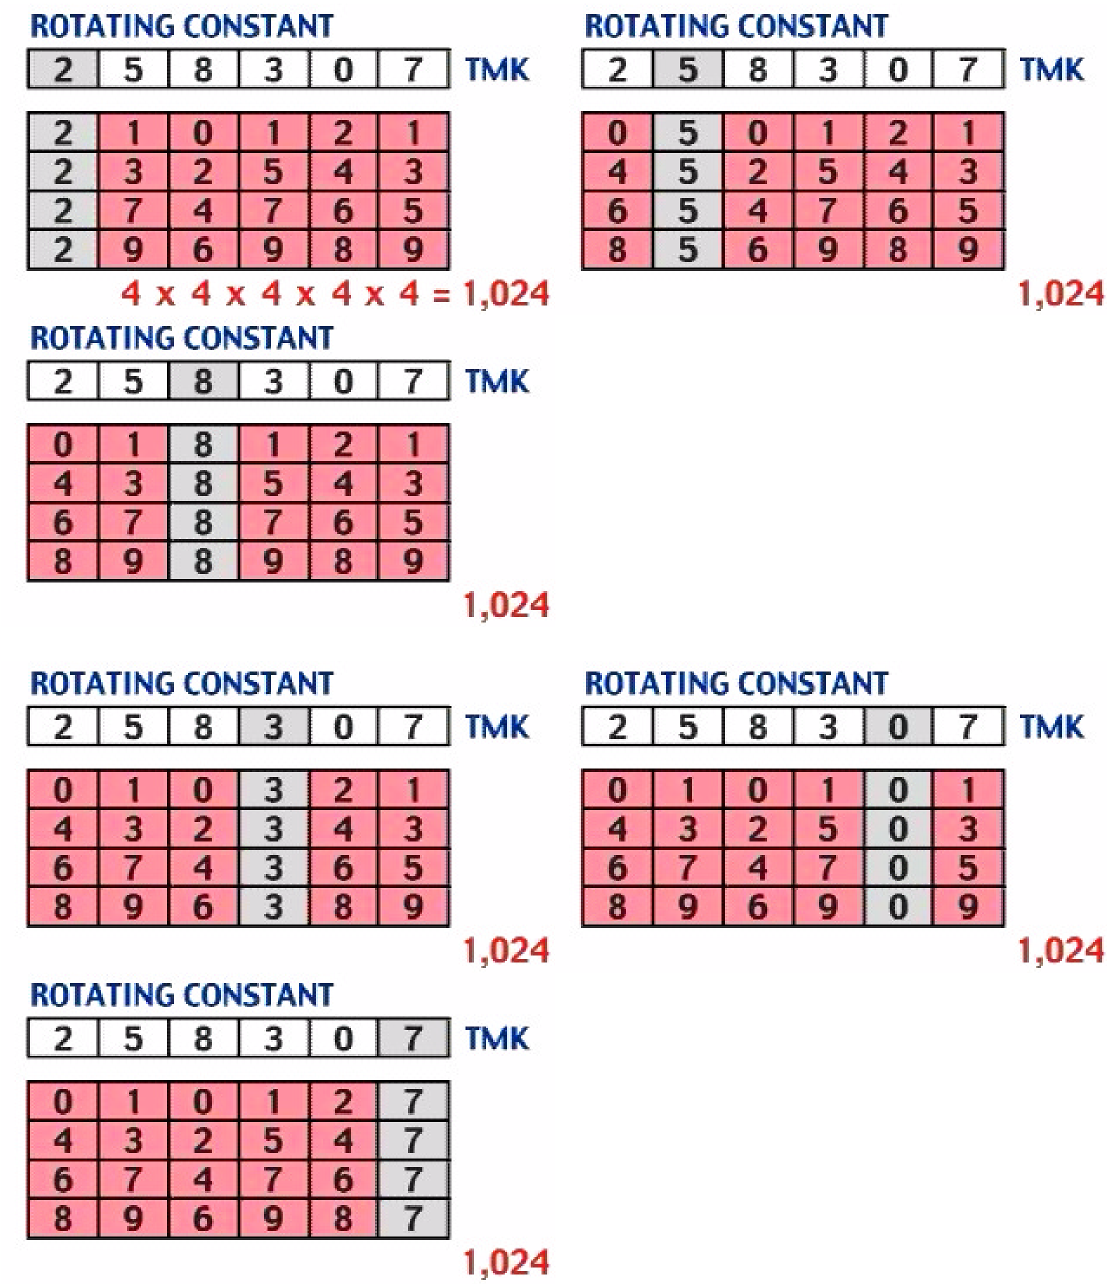

Figure LSS+1126 provides a graphic illustration of the rotating constant system, showing how one chamber is held constant while the others are progressed. A pattern matrix will define which columns are progressed and held. Courtesy of HPC Interactive Learning Series.

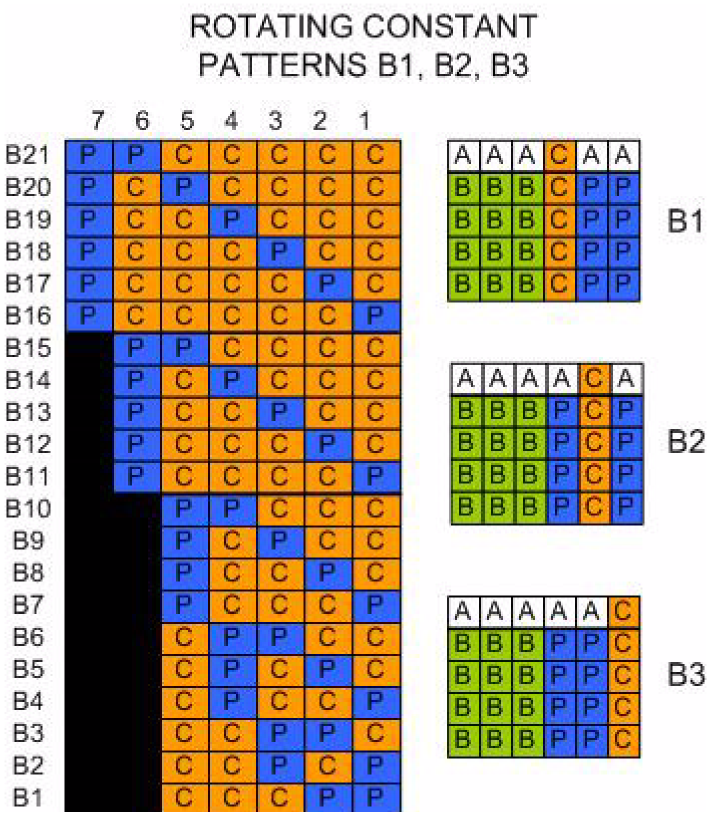
The rotating constant system has certain attributes and advantages over the total position progression method. These include:

- **RC should be used in two level systems because of the ability to add locks in the future. For systems of three levels or higher, the TPP is preferred;**
- **There are fewer incidental master keys in a rotating constant system because there are fewer master pins required;**
- **The system provides more inherent security;**
- **The expansion specification will dictate whether rotating constant or total position progression will provide better system options;**
- **Master pins are only utilized in certain positions;**
- **The change key, master key, and TMK share bitting values in certain positions;**
- **Cylinders are more pick resistant;**
- **There is less likelihood of key manipulation;**
- **There is less key interchange potential;**
- **There are a limited number of combinations available for systems of greater than two keying levels;**
- **The same number of chambers must be progressed (and held constant) for all keying levels, once established;**
- **Positions are subject to rotation based upon a pattern matrix;**
- **Both one and two-step progression may be employed, depending upon manufacturer specifications;**
- **The TMK is part of every change key and master key**

11_5.7.1 Division of the Key for RC

As with the total position progression system, the key must be divided when using rotating constant. In a system of more than two keying levels, the division is fixed and those columns that are to be progressed or held constant must be defined. Unlike TPP, the RC system requires that patterns of sequencing of constant and progressives be selected to write the KBA. These are detailed in section 11_5.7.1.1 below.

11_5.7.1.1 Progression Patterns for Rotating Constant



As described in the introduction to rotating constant theory, the system is based upon the selection of sequence patterns of all combinations of progressed and constant values. The key division

partition position progression table below shows the relationship between the number of chambers within a lock, the number of chambers that are progressed, and the number of patterns that will be produced and which can be utilized to build the KBA. Links from each table heading of progressed chambers provide the matrix for use in defining the KBA.

KEY DIVISION PARTITION POSITION PROGRESSION TABLE					
CHAMBERS	**1 PROGRESSED**	**2 PROGRESSED**	**3 PROGRESSED**	**4 PROGRESSED**	**5 PROGRES**
5	5	10	10	5	
6	6	15	20	15	6
7	7	21	35	35	21

11_5.7.1.1.1 Application of Progression Patterns

The use of patterns that have been generated from two progressed columns (**P**) in three different KBAs is shown below. In this example, patterns B1 (**cPP**), B2 (**PcP**), and B3 (**PPc**) have been applied to the KBA in order to generate combinations for different master keys. Note that two columns are progressed and one is held constant, and that the value of the constant is common to the change key, master key, and TMK. The master chart shows all possible patterns for a five, six, and seven pin lock. Patterns B1-B10 can be used for a five pin lock, B11-B15 for a six pin lock, and B16-B20 for a seven pin lock.

11_5.7.2 Procedure for Defining a Rotating Constant System

The procedure to define a rotating constant system requires the following steps:

- **Determine the expansion specification and the required number of master and change keys and keying levels;**
- **Define the TMK;**
- **Establish the division of the key. If there are only two keying levels, then the division will establish the number of positions for the master and change key. The pattern of progressed and constant chambers is selected, and the positions are progressed accordingly;**
- **For three or more levels, select the master keys that are going to be used;**
- **Select progression patterns to establish KBAs for each master key in order to generate change keys that are required to fulfill the requirements of the expansion specification;**

11_5.8 Documenting Master Key Systems

There are three principal formats for writing and displaying key bittings within a master key system: **list format**, **standard progression format**, and **matrix format**. Any of the three techniques may be utilized to document a system; each has its advantages in specific circumstances. Lock manufacturers typically provide system documentation in list format and will accept expansion specifications from the locksmith in any form that accurately reflects the system and provides precise direction as to how each cylinder is to be keyed. It is important to understand each method, especially if called upon to reconstruct or analyze a system after it has been implemented or for system expansion. The documentation will identify all keying levels, the association between each level of master key and change keys, cross-keys, key interchange, and all incidental master keys.

The format that is chosen to display all theoretical combinations (progressive list) within a system is different than the **bitting list**. The format, whether list, standard progression, or matrix, is able to display all possible combinations that can be used to define each lock within the system, whether they are in fact utilized or not. This would include both useable and unusable combinations.

The **bitting list** denotes the actual association between useable combinations and specific cylinders and documents all combinations used within the system, once key symbols are assigned. The printout that is generated from a specific format can also be used as the bitting list, if desired. It is important that anyone with the responsibility to generate, decode, maintain, or analyze a master key system be thoroughly conversant with each of the documentation techniques. An example and comparison of list, standard, and matrix format is discussed below.

11_5.8.1 List Format

List format is most often used in small systems, generally with two levels of keying, although the format may be utilized in larger systems as well. A **lead sheet** (shown below) will provide the necessary system information for bitting lists used in this format. It shows the expansion specification, identification

information for the specific system, as well as the key division, progression method, MACS, all master keys, and other system data.

A system is written in list or other format after the following tasks have been performed:

- **Determine system expansion specifications;**
- **Method of progression: total position progression or rotating constant;**
- **Type of progression: one-step or two-step;**
- **Define the TMK and write the KBA;**
- **Write the progression list with the sequence of progression (SOP);**
- **Check for MACS violations and eliminate them;**
- **Assign key symbols and document the system.**

An example of a list format is shown in the table below. All of the combinations for a six pin system are presented. Note that

the key has been divided equally: three positions for the master key and three positions for the change key. The KBA is shown for the TMK of **258307.** The list indicates all of the bittings associated with one master key (AA) of 030307. These 64 combinations would be one "page" as described in standard progression format below. Note that key symbols have been assigned for thirteen change keys at random throughout the list of all possible combinations. All of the progressives were derived in odometer style, defined by the standard sequence of progression (SOP) CBA, shown at the bottom of the KBA. That indicates that columns A, then B, then C were progressed, in that order.

TMK	2	5	8	3	0	7
	0	1	0	1	2	1
	4	3	2	5	4	3

11_5.8.2 Standard Progression Format

This format (not utilized by most manufacturers), provides a clear graphical expression of all keying levels, and allows for the display of both symmetrical and asymmetrical systems. It represents a list format in **blocks**. There are 16 blocks per page, and 64 pages for a six pin system in a two-step progression. Each page has 64 combinations. Thus, there are 64 x 64, or 4,096 distinct theoretical combinations.

The chart below shows all 64 change key combinations for the AA master key, page 030307. In this example, AA would be one of 64

available master key combinations, because the KBA (shown in section **11_5.8.3**) provides for a division of the key wherein three positions are reserved for the master key and three for the change key.

In the example, note that the first three progressives **(**F,E,D if the sequence of progression (SOP) is F,E,D,C,B,A**)** are all **030.** That is because master key AA is 030 + the progressives C,B,A. A table can illustrate how F,E,D are progressed against C,B,A. Color coding is consistent with the chart in section **11_5.8.3.** Remember, C and B are always progressed against column A.

0	3	0	C 1	B 1	A 1
			C 2	B 2	A 2
			C 3	B 3	A 3
			C 4	B 4	A 4
F	**E**	**D**	**C**	**B**	**A**

C,B,A represent a total of 64 change keys for each master key (F,E,D). In the example above, the master key AA would be progressed in odometer format. Each group of four change keys represents one block, as shown in the standard progression format chart below. The first two blocks are illustrated and color coded below.

11_5.8.3 Matrix Format

The matrix format is the most sophisticated and efficient means for writing a progression list and can be used for both total position progression and rotating constant systems. It provides a means to cross reference and correlate information in an organized and abbreviated format and relies upon the fact that certain progression data in both rotating constant and total position progression is not repeated. As can be seen in the chart below, matrix can store and display the data for 64 pages (six-pin lock) on one printout page. The listing is ideal for symmetrical expansion specifications but requires a separate keying schedule. The technique was developed by Billy Edwards while employed by Medeco and has become the standard method for manufacturers to document information about a master key system.

In order to fully appreciate how to write a system in matrix format, the reader must understand the following concepts:

- **How theoretical combinations are derived;**
- **Split pin master key theory;**
- **Key division;**
- **Progression techniques;**
- **Relationship between the change key, master key, and top level master key;**
- **Constant values that exist in any master key system. In the progression method, there is certain data that remains the same for each portion of the divided key.**

Certain rules apply to the matrix system. A review of these prior to our discussion should prove helpful.

- **Progression of a KBA follows a predefined format based upon certain columns remaining constant in relation to other columns, in part resulting from the division of the key;**
- **The matrix has two components: the master key portion and the change key portion;**
- **The method of progression once set is constant and does not change;**
- **The key is divided into two segments: MK and CK in order to**

derive combinations for each;

- **Total theoretical combinations within any master key system are derived by adding the two key division segments together;**
- **Each master key is a composite of the MK portion of the KBA and the remaining values of the TMK;**
- **Each change key is a composite of the MK and CK portions of the KBA;**
- **Progression of columns for each portion of the key division is computed from right to left, or the least significant digit to the most significant digit;**
- **Every group of change key permutations is the same for each individual master key progression;**
- **The master key combinations are derived separately from those of the change key, based upon the division of the KBA;**
- **The data in columns I,II,III and in IV,V,VI represent the two divisions of the KBA in a six pin lock with a key division of 3:3;**
- **The data in columns I,II and IV,V represent all of the possible combinations for the progression of two columns of the KBA division;**
- **The data in columns III and VI represent the least significant digit of each division of the KBA, and are progressed against I,II and IV,V respectively;**

In the matrix system, each box correlates to a bitting combination. Think of a highway atlas that displays a list of cities and the mileage that can be calculated between each of these cities. A vertical and horizontal column of city names is provided with the mileages within all of the boxes that are intersected by the names. Mileage is displayed by drawing imaginary vertical and horizontal lines to an intersecting point. The matrix format for determining combinations works in essentially the same fashion.

As can be seen in the matrix below, there are three primary components: the KBA, the master key (MK) matrix, and the change key (CK) matrix. The KBA defines the top level master key, and identifies by Roman numeral each of the chambers. Roman numerals are utilized to avoid confusion with any other numbers. There are two matrix chart templates each providing 64 "addresses" or individual boxes in a 16 x 4 configuration. The matrix that is shown can display a total of 4,096 combinations for a six pin lock, two-step progression, four progressives per position. So, what does all of this mean?

Let us examine each individual component of our matrix to understand how each relates to the others. Note that the KBA reflects that the key is divided 3:3; positions **I, II, III** are for the master key in this example and **IV, V, VI** for the change key. This is the same procedure as for the list or standard progression format. We have simply identified each of the positions with Roman numerals. Now, look at each matrix. The vertical (X-axis) and horizontal (Y-axis) combine and converge to provide 64 separate positions or addresses. Recall that a two-step progression of four depths in three columns is equal to 4 x 4 x 4, or 64 combinations. Now recall that the table in section **11_5.8.2** in standard progression format shows how columns **C,B** are progressed against **A** for the change key. This would also hold true for **F,E** against **D** for the master key. This is further denoted by color coding for ease of understanding. In our matrix, each of the 64 boxes can be said to have a vertical (or X address) and a horizontal (or Y address). **X+Y will constitute each individual combination.**

Consider how the two matrix tables are displayed below. The legend to the upper left of each table identifies the vertical and horizontal column with Roman numerals. The MK matrix shows that the sixteen vertical rows represent **I,II** and the four horizontal columns represent **III**. The corresponding numbers that run vertical are "matrixed" or correlated against the numbers in the horizontal columns. The numbers for all columns have been color coded to show their origin.

In the MK matrix, columns **I,II** are combined with **III** to provide a total of 64 combinations. It can be easily seen that the first two columns of the KBA are progressed against the third column. In our example, MK combination **010** is the first to be generated. In the matrix, **"01"** is the first vertical number for the "X" portion of the address, and "0" is the first number for the "Y" portion of the address. In our example, the master key AA has been associated with X-Y address 010. In like fashion, the change key matrix plots **IV,V** against **VI** to represent the 64 possible change keys by progressing **IV,V,VI**. The table shows that the first change key from the KBA would be 121, or **IV,V** progressed against **VI** (which is exactly what is displayed in the CK matrix). In our example, we have assigned "1" to address 129. Remember that the 64 change key combinations are always repeated for **each** master key combination. So, when we combine the MK matrix with the CK matrix, we have 4,096 combinations ((4 x 4 x 4) x (4 x 4 x 4))that are available and can be easily identified. The

color-coded key diagram graphically displays the origin of each bitting position.

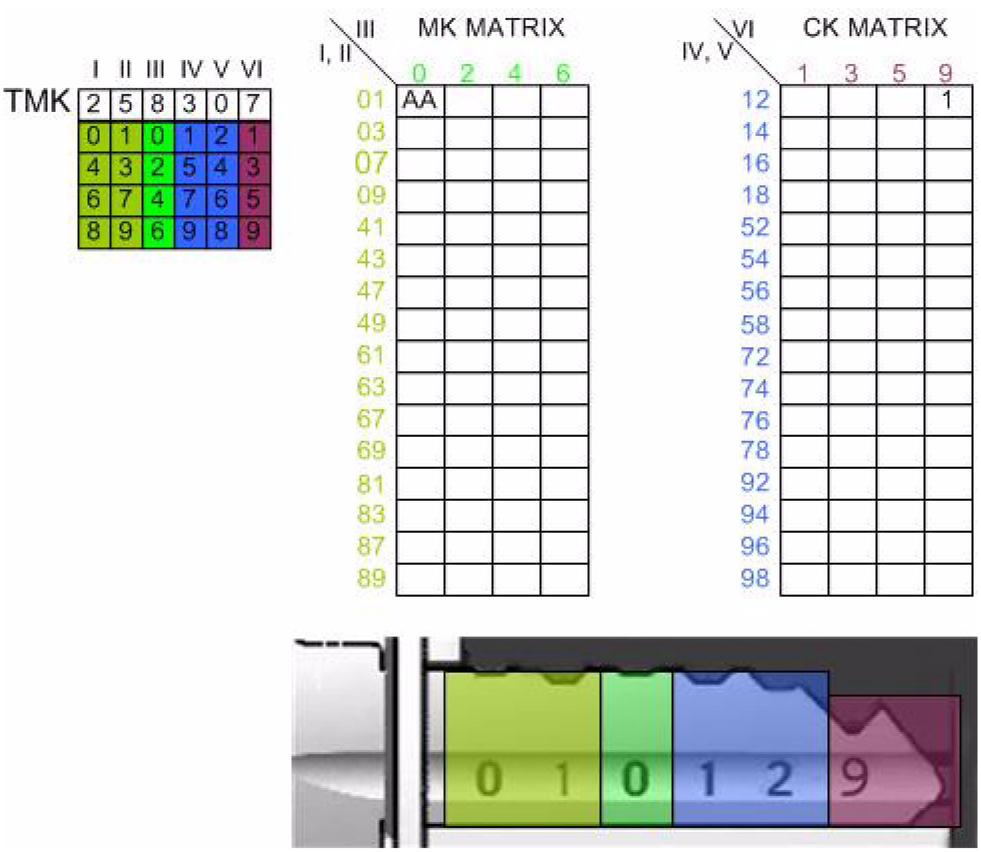

Figure LSS+1133 Division of the key shown in matrix format.

Individual master keys and change keys are selected in random fashion from each matrix, except for cross-keys, which are always chosen first. In the case of cross-keys, if they are not planned and identified initially it may be impossible to do so later. In the matrix format, not all bittings must be defined.

11_5.9 Reverse Engineering a Master Key System

A master key system can be reverse engineered to determine its structure, the relationship between keys, the levels of keying, and to reconstruct the bitting list. This can be done overtly or covertly, depending upon requirements. Reverse engineering may be

required to be accomplished by a locksmith to perform maintenance, especially on a system that has not been documented previously. Covert operations or a crime scene investigation may require the system to be analyzed for a variety of reasons. In either event, sample keys are examined with a decoding instrument such as a key gauge or micrometer. Further initial information may be available from symbol, number, or letter markings on keys to provide insight into how the system was defined.

The following steps should be followed to reverse engineer a master key system:

- **Measure as many keys as possible and list the bittings for each key:** This will allow us to deduce the following information:
    - division of the key
    - number of chamber or positions and how many have been progressed
    - one or two-step progression
    - potential for key interchange in a one-step system where two step should have been used

- **Scan the list for the method of progression, one position at a time:** Define the common cuts for each position. Determine parity, and whether it has been maintained between change keys;

- **Determine the method of progression**

- **Determine the levels of keying:** are all of the levels symmetrical. Are there the same number of change keys under each master key? Are the change keys actually incidental master keys?

- **Determine if each level of keying has the same number of master pins per cylinder.**
Do all change keys differ from the TMK in each position? Regardless of the number of levels of keying, there should never be a TMK depth utilized in any change key position in a TPP system. If, however, an incidental master key has been decoded, then depths will be shared or common to the TMK. Values may also be the same in an RC or PPP system;

- **Reconstruct the KBA:** What are the cut possibilities for each position? Make an educated guess whether the system is a rotating constant or total position progression. If a TPP system, then

cuts for the TMK can be eliminated.

- **Use the KBA to define a matrix.**

Based upon the theories of total position progression and rotating constant systems, it is possible to extrapolate and decode the TMK in these systems with little skill or previous training. A detailed examination of the process is presented in **chapter 31.** A white paper has also been written on this subject by **Matt Blaze**, (AT&T Labs Research). Appreciation is also expressed to Harry Sher, Billy Edwards, and Brian Chan for their assistance.

11_5.10 Master Ring and Interchangeable Core Systems

11_5.10.1 Interchangeable Core Systems and Master Keying

There are different configurations for IC locks, both large and small format, the discussion of which is outside the scope of this text. Differences relate to control lug design, control key interaction with operating shear line, pin stack dimensions and other specifications.

There are two types of interchangeable core locks: those that are not available for conventional hardware configurations, and those that can be integrated with conventional systems. In some situations, it may not be possible to add IC into an existing system. There are limitations within IC systems within the master key environment as well as security implications when using IC. These and certain design rules are outlined below.

- **IC systems have limitations with regard to the number of available combinations and those that may be utilized for master and control keys;**
- **The expansion of IC systems may be limited;**
- **If interchangeable cores are utilized throughout a system exclusively, then severe keying limitations may result;**
- **There may be key interchange and control key issues;**

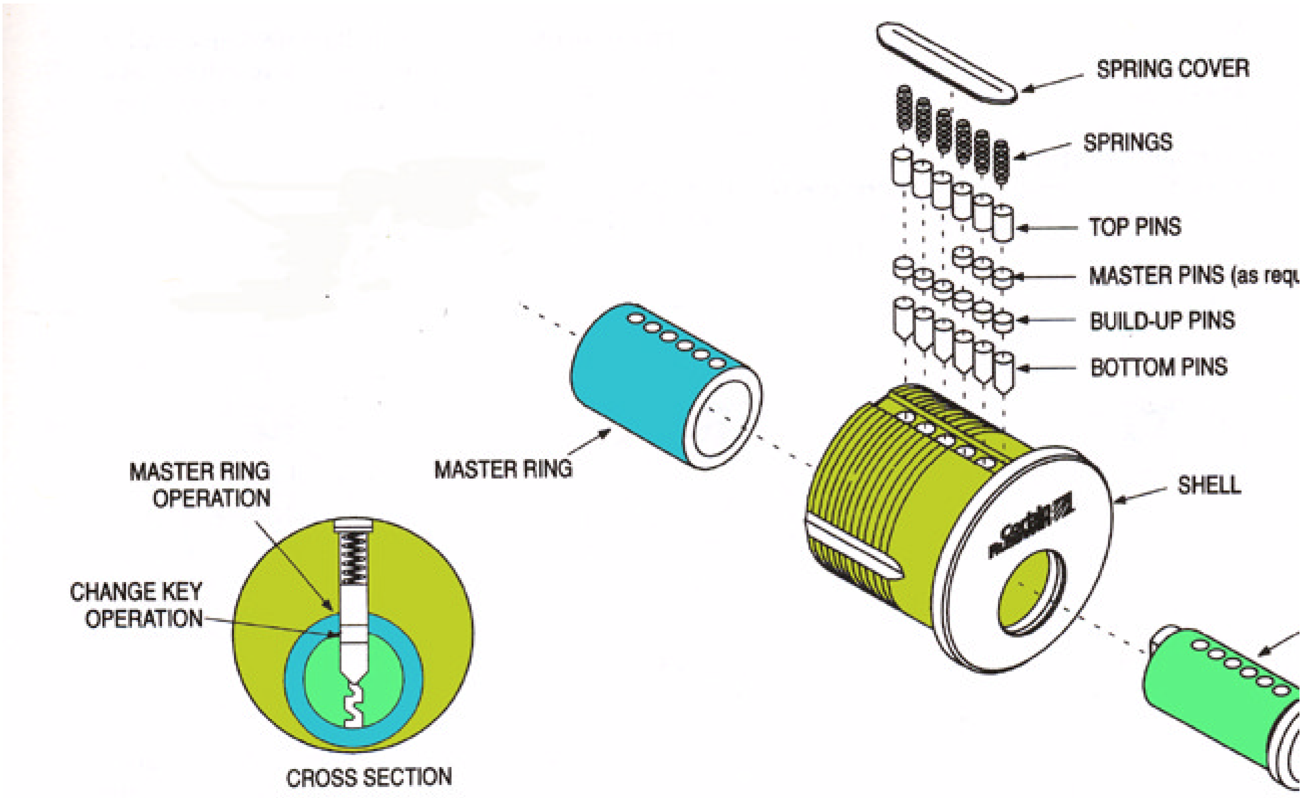
Many years ago, Best utilized the TMK as the control key by withdrawing it one chamber position. This created significant

keying problems;

- **In all IC systems, the control and TMK should be different in all positions;**
- **Parity should be maintained between the TMK and control key; Within the Best A3 and A4 systems, parity does not apply. The Best A2 system requires two-step progression;**
- **If parity is not maintained, then there is no assurance that the change key will not inadvertently act as a control key. The lack of parity can also lead to difficult keying situations because the build-up pin may not exist. The control key in such an event becomes a change key. In addition, the core may be removed with a change key by pulling it out of the lock slightly;**
- **If parity is maintained, then a problem may also occur that can allow the TMK for one system to be used as the control key for another. A detailed discussion is beyond the scope of this work.**

11_5.10.2 Master Rings (MR)

Corbin is still producing locks with master ring technology, although the demand is almost exclusively limited to maintenance of installed systems. The master ring offers significant advantages over conventional single shear line systems of up to four keying levels, but somehow has been forgotten as other designs became popular for master keying. There are a number of security advantages that this hundred-year-old technology offers that have become relevant since recent disclosures regarding the compromise of master key systems through the extrapolation of top level master keys from change keys. Detailed information has therefore been included in **LSS+**.



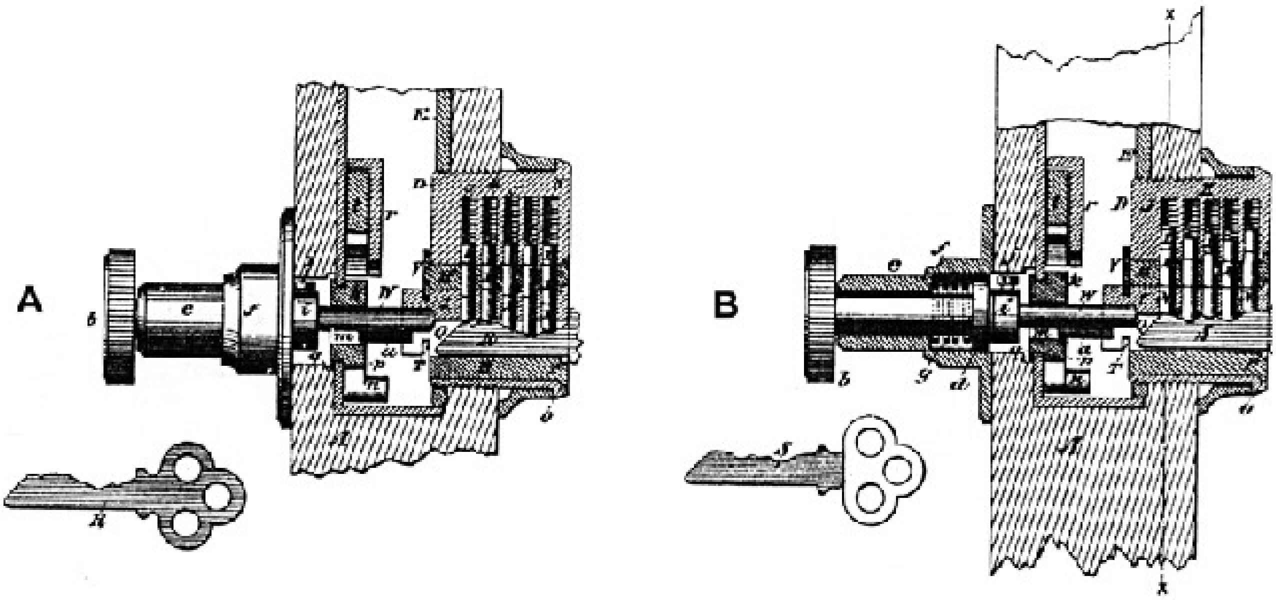


Figure LSS+1134 Diagram of a master ring cylinder, courtesy of Corbin Russwin.

The concept of the master ring was invented by Edward O'Keefe, a New York City locksmith, and disclosed in his patent, granted in 1889 (**414720(139)**). The patent rights were subsequently transferred to P&F Corbin. Corbin and other manufacturers have introduced the concept of a **master ring** or **sleeve**, as an effective means to eliminate cross-keying while maintaining high pick resistance. A round metal sleeve or jacket fits over the plug, creating a second shear line. Physically, the plug is inserted into the sleeve; then the plug-sleeve assembly is inserted into the shell of the lock. Cross-keys and incidental master keys cannot occur in the master ring locks unless an extra master pin is inserted in the pin stack below the ring shear line. Two distinct physical shear lines are created, thus preventing a composite of lower pins and master pins from splitting at **one** physical shear line.

It may be helpful to compare the master ring to the interchangeable core lock, first patented by Best (**3206958(140), 3206959(141), 3603123(142), 4386510(143), 4444034(144)**). Both have two shear lines. In the ICores, the plug shear line is also called the **operating shear line**. Change keys and master keys always work at the plug shear line in these locks. The control key works at the **control shear line** to permit core exchange. It can be master keyed at the plug shear line and also at the control shear line (for control master keys).

In the **MR**, there is no control key. All change keys operate at the **plug shear line** level; all **master keys** operate at the **ring shear line**. In operation, the change key will lift its corresponding set of tumblers to the level of the plug. The master key will lift the tumblers and master pins to the level of the master sleeve that rotates around the plug. When the change key is used, the master ring remains fixed with the shell. When the master key is used, **both the plug and master sleeve rotate** because the plug shear line is blocked. The only theoretical difference in shear lines between ICore locks and **MR** locks is the build-up dimension between plug and the second shear line, and the function of the second shear line. In the IC, it is to remove the core; in the master ring locks, it is to prevent the creation of incidental master keys or composite pin combinations.

The tumblers cannot be split as in a conventional keying

arrangement **between** the plug shear line and the master sleeve shear line. In other words, the plug **and** the master sleeve can never rotate simultaneously; thus, the possibility of creating incidental master keys is eliminated.

11_5.10.3 Differences Between Conventional and Split Ring Master Keying

There are significant differences between setting up a conventional cylinder and one with a master ring within a master key system. These distinctions are summarized below.

- **Incidental master keys, as a composite combination between change and master key, do not exist in the master ring environment;**
- **Progression of bittings is entirely different for a dual shear line system;**
- **Master ring cylinders are more flexible for keying;**
- **The equivalent of approximately one added chamber is achieved with master ring in generating theoretical combinations. Thus, a six pin master ring lock is roughly equivalent to a seven pin conventional cylinder;**
- **Every chamber in the master ring lock has two shear lines;**
- **The plug shear line is usually reserved exclusively for the change key;**
- **The ring shear line is utilized for all master keying levels;**
- **There are few constraints in the traditional relationship between master key and change key;**
- **After the introduction of System 70 (in 1970), fewer new master ring keying systems have been installed;**
- **Master ring locks are particularly well suited for construction and selective master keying;**
- **Master ring reduces the problem of cross-keying;**
- **The number of levels of keying does not pose any significant restrictions for the master ring lock;**
- **There are generally a far greater number of change keys available in the master ring system than with conventional systems;**
- **Not all Corbin Russwin hardware can support master ring locks, due to the larger diameter cylinder;**
- **Additional planning is required to integrate single shear line**

cylinders into a master ring system, and it is rarely possible to do so after the fact;

- **Master ring cylinders are generally keyed for up to four levels (GGMK);**
- **Depending upon keying level, double pinning may be employed at the ring shear line if the bitting values between MK, GMK, or GGMK are different from each other;**
- **TMK values can be safely shared with change keys;**
- **Change key combinations can be randomly assigned to any master key with none of the restrictions imposed in a conventional system;**
- **Parity rotation can be used to increase system security and the number of useable combinations;**
- **The top pin is always .171";**
There are never any master pins at the plug shear line;
- **Bottom pins will always be equal to the change key bitting values;**
- **A master ring lock can be more complex to pin for three or more levels of keying because of the requirement to introduce added master pins;**
- **A ring lock that is keyed to three more levels can be easier to pick than a conventional cylinder;**
- **Key interchange and cross-keying can occur if added master pins are inserted at the ring shear line;**

11_5.10.4 Differences in the KBA for Master Ring Locks

There are significant differences in the logic employed in deriving combinations for the master ring lock in comparison to the conventional single shear line cylinder. Essentially, traditional progression techniques utilizing a KBA are employed to generate master key and change key combinations, but there is no required linkage through the division of the key between the two sets of combinations. Virtually any change key combination can be associated with any master key. Additionally, almost all of the available depths within a cylinder can be utilized in the derivation of change keys. This includes the depths that are reserved to the TMK; a vast departure from the progression methodology employed in conventional master keying.

The key bitting array for the master ring lock contains two separate progression matrices: master key for generating combinations at the ring shear line, and change key for producing combinations as the plug shear line. These two areas must be mutually exclusive to prevent key interchange. This can be accomplished by changing one bitting in one position.

In practice, master key combinations are derived by progressing the master key portion of the KBA. The key bitting array shown in the first illustration (section **11_5.10.4.1**) maintains parity during progression. We shall compare this KBA with a conventional cylinder to highlight the differences in logic.

The TMK combination is shown at the top of the array. Note that the first position (2) is held constant for all master keys. In the TPP method, we derive a total of 4 x 4 x 4 x 4 x 4 = 1,024 theoretical MK combinations. The change key is derived from the bottom portion of the KBA, and can produce 5 x 5 x 5 x 5 x 5 x 4 = 12,500 change key combinations, in contrast with a maximum of 4,096 change keys from a conventional lock with one shear line. Note that all of the progressives with the **exception** of (2) from the TMK are utilized for generating change keys. This will prevent key interchange and any master key from operating at the plug shear line, and any change key operating at the ring shear line. A true master ring system can produce an expansion specification of 1-1,024-12,500.

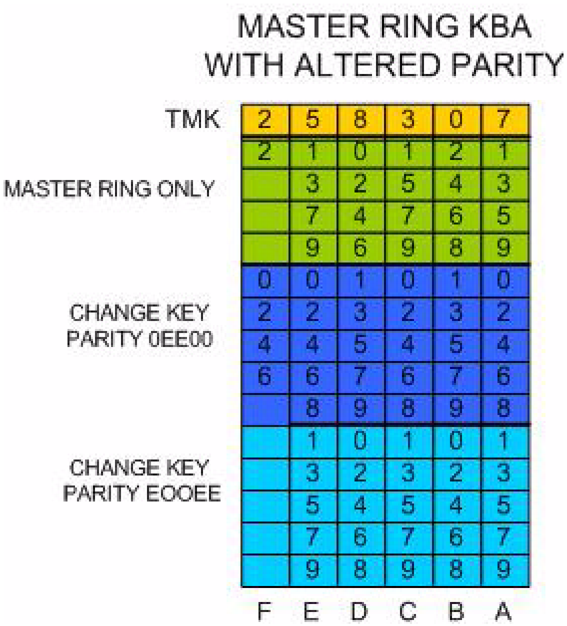
11_5.10.4.1 KBA with Parity Maintained

MASTER RING KEY BITTING ARRAY
CONSTANT POLARITY

TMK	2	5	8	3	0	7
MASTER KEYS ONLY	2	1	0	1	2	1
		3	2	5	4	3
		7	4	7	6	5
		9	6	9	8	7
CHANGE KEYS ONLY	0	1	0	1	0	1
	4	3	2	3	2	3
	6	5	4	5	4	5
	8	7	6	7	6	7
		9	8	9	8	9

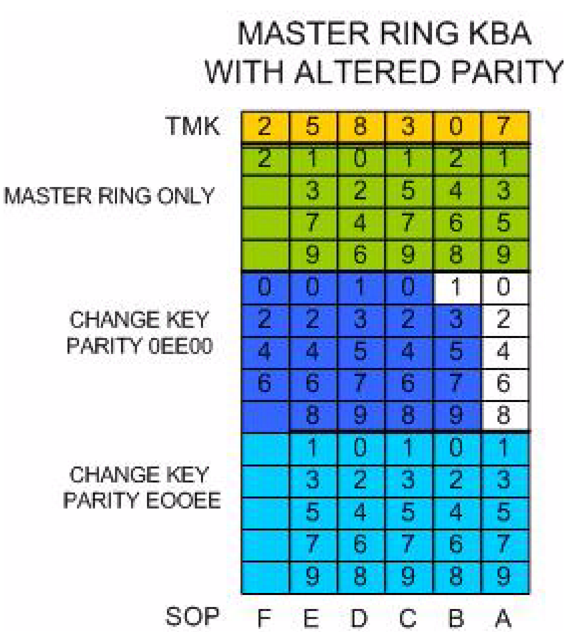
The first group of eight master keys using the portion of the KBA dedicated to their progression would produce the following combinations:

210121	**210141**
210123	**210143**
210125	**210145**
210127	**210147**

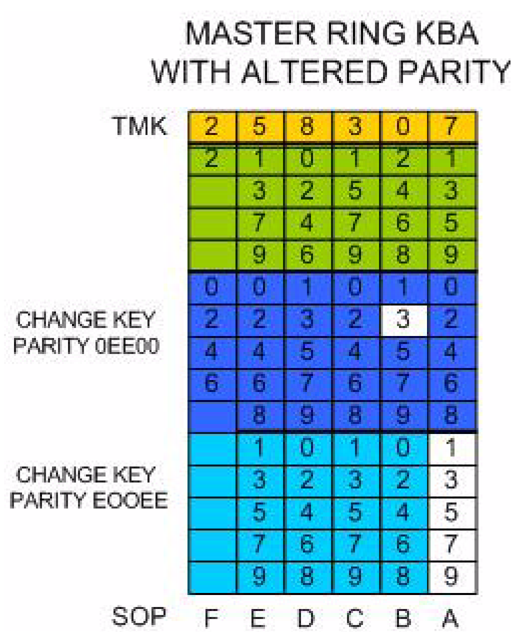


Likewise, the first ten change keys in sequence could be:

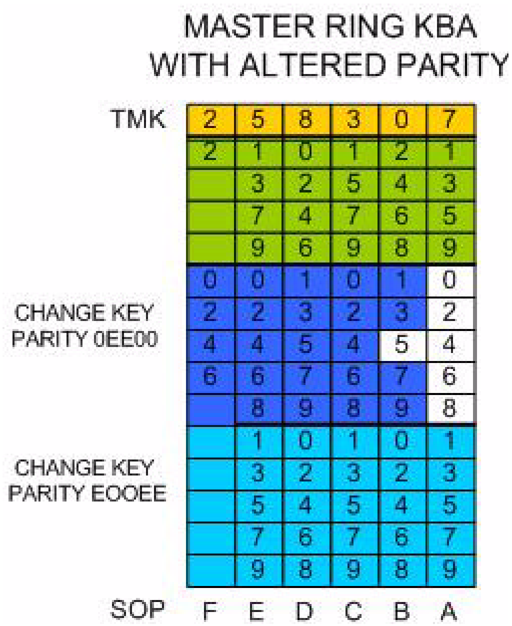
010101	**010121**
010103	**010123**
010105	**010125**
010107	**010127**
010109	**010129**



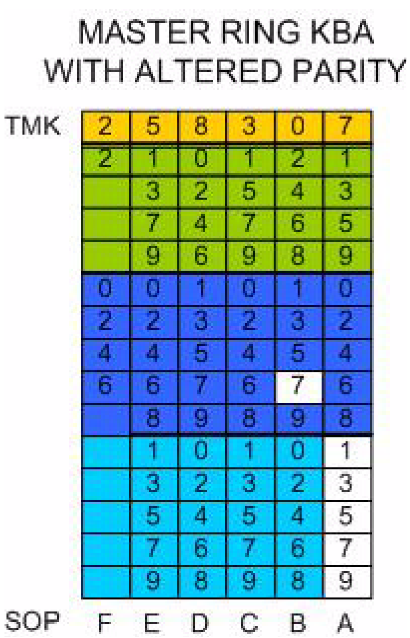
Unlike a conventional system where master keys are, by definition, associated with change keys, any of the master key combinations can be associated with any of the change keys in the master ring system.

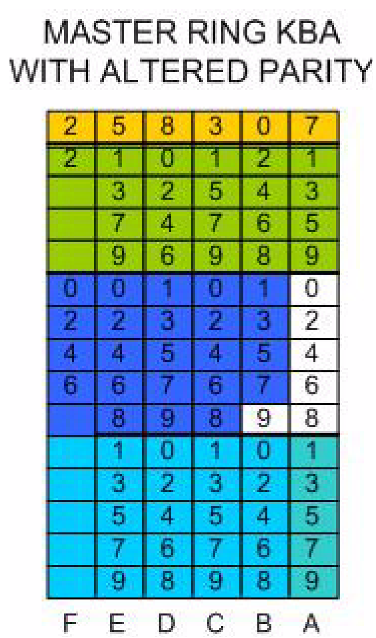


11_5.10.4.2 KBA with Altered Parity



A second method for deriving change key combinations involves the periodic alteration of parity in all but one column during the progression sequence. The technique may be considered as a corollary to rotating constant, but relating to parity. In effect, a **rotating parity** system has been created. In the KBA shown below, the master key portion is identical with that shown in the constant parity model, above. However, there are now two parts to the change key matrix. In order to use parity to employ all progressives, the parity of all previously progressed columns must be changed simultaneously as each new column changes. Although it may appear that key interchange will ultimately occur, the first column (F) keeps this from happening. Remember, one cut can prevent interchange.





Graphic illustrations of how the KBA is progressed are shown below. In the color-coded tables, each vertical group of progressives is highlighted (white) to show the sequence of progression.

11_5.10.5 Pinning and Decoding Master Ring and Interchangeable Core Locks

LSS204: Brian Chan discussing the pinning of a Best IC lock

Master ring mechanisms have two physical shear lines; they are keyed slightly differently than conventional locks. In contrast, within the ICore there may be several distinct keying levels at the plug shear line, in addition to the control key at the control shear line. The diagrams show the difference in construction between master ring and interchangeable core.

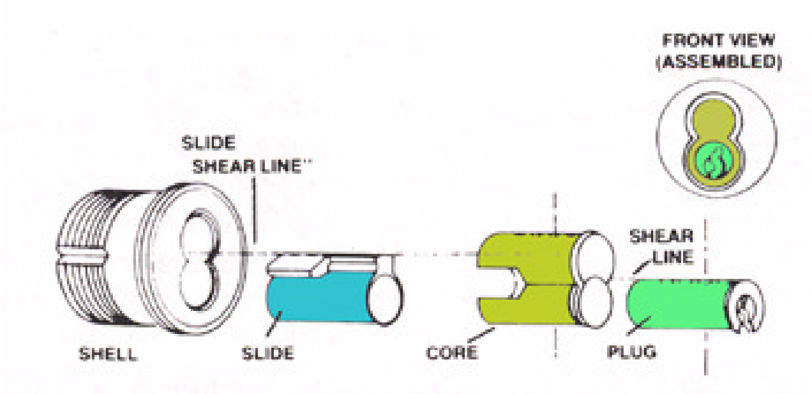

Figure LSS+1136 Both master ring and interchangeable core locks have two distinct shear lines. However, their use is for very different purposes. Courtesy of Corbin Russwin.

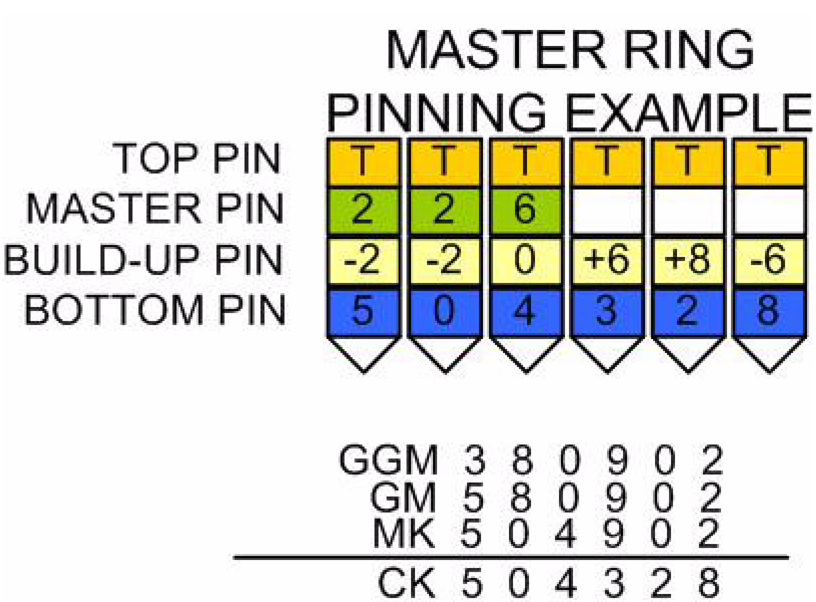
11_5.10.5.1 Master Ring Locks

Corbin master ring locks have up to four sets of tumblers in each chamber: top, master pin, build-up, and bottom. All but the top pins will be utilized for master keying. The same length top pin is used in each chamber (.171").



Individual change keys will have corresponding bottom tumblers that are raised to the conventional plug shear line. In order to program the master key, however, the overall length of at least two and sometimes three pins must be considered. The purpose of the build-up pin is to make up the difference in the pin-stack between the bottom pin and master ring. The length will be computed from the change key bitting to the **shallowest** master key bitting in each chamber, assuming the system has three or more keying levels. When more than one master keying level is utilized, master pins are also used to compensate for the

difference in master keying levels.

The Corbin master ring has a thickness of .142" for a .552" plug diameter. Therefore, the effective diameter at the master ring shear line would be .694". Thus, the length of the lower, build-up and master pin for any master key bitting depth must equal the combined diameter of the plug and master ring. The diameter of the ring shear line is equal to ten depths in the pre-System 70 system, and five depths in System 70. It can be seen that the depth increments that are utilized for bottom and master pins are equivalent. If, for example, the first chamber has a bottom pin value of 4, and the value of the master key cut is also four, then (4-4 = 0) the build-up pin length would be 0 (ten depth increments).

Depending upon the change key and master key(s) bitting, the build-up pin will be assigned differing values. The thickness of the master ring is equivalent to a "0" value build-up pin. If the change key bitting depth is **less** (shallower) than the master key, then the build-up pin will have a **positive** value. Conversely, if the change key cut is lower than the master key, then the build-up pin will have a **negative** value.

The following chart illustrates:

In the three examples below, the change key bitting has a value of 3, but the master key depth is 3, 5, and 1. Note how zero,

negative, or positive values are inserted for build-up pins to bring the master key to the ring shear line.

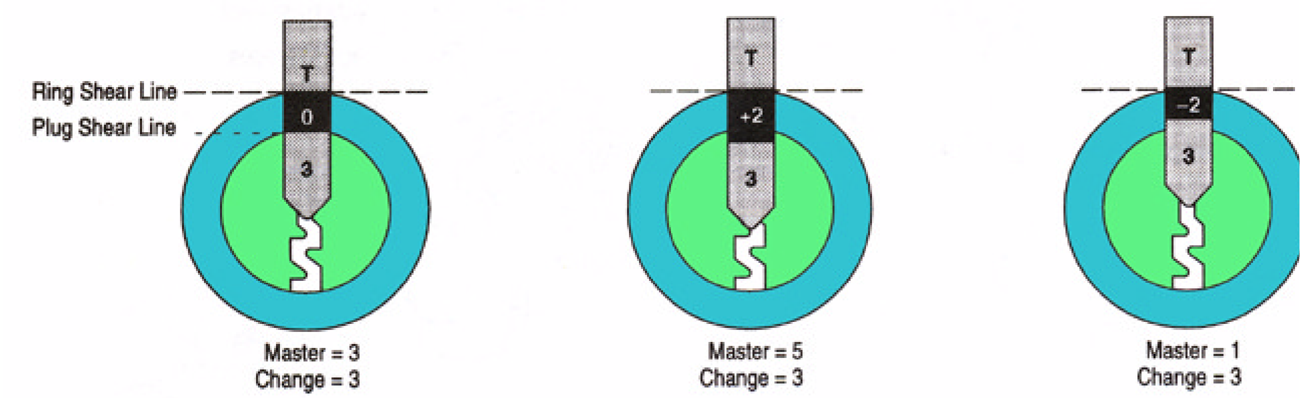


Figure LSS+1137, Build-up pins are required in order to add or subtract values in order to raise pins to the ring shear line. Courtesy of Corbin Russwin.

11_5.10.5.2 Decoding ICore Locks

This section deals with the decoding of ICore locks relating to three issues: extrapolation of the TMK within a master key system, extrapolation of the control master key, and decoding the bitting value of the pins that are operating at the control shear line. As previously noted, the ICore and master ring locks are similar in that they both have a second physical shear line. The function of the second shear line is, however, quite different for each lock. The master ring lock utilizes its equivalent of the control shear line for all master keying levels, thereby eliminating the link between keying levels and the ability to decode the pin stack in the context of our current discussion. In the ICore lock, the control shear line allows the removal of the assembly that contains all locking components that are directly controlled by the operating and control key.

11_5.10.5.2.1 Decoding the TMK

Within the interchangeable core environment, all keying levels will be pinned at the operating shear line. In this respect, the lock is no different to decode than a conventional cylinder. Once a change key is obtained, the TMK can be derived by sampling each position with each bitting value that can be utilized within the keying system. The presence of the control shear line is irrelevant to the process and it cannot be decoded, either intentionally or by error. It should be noted that there is no

correlation between the top master key and the control key. In fact, knowing the code for the control key will not yield any information regarding any master key. Nor can the control key be utilized to extrapolate the TMK, intermediate master keys, or change key.

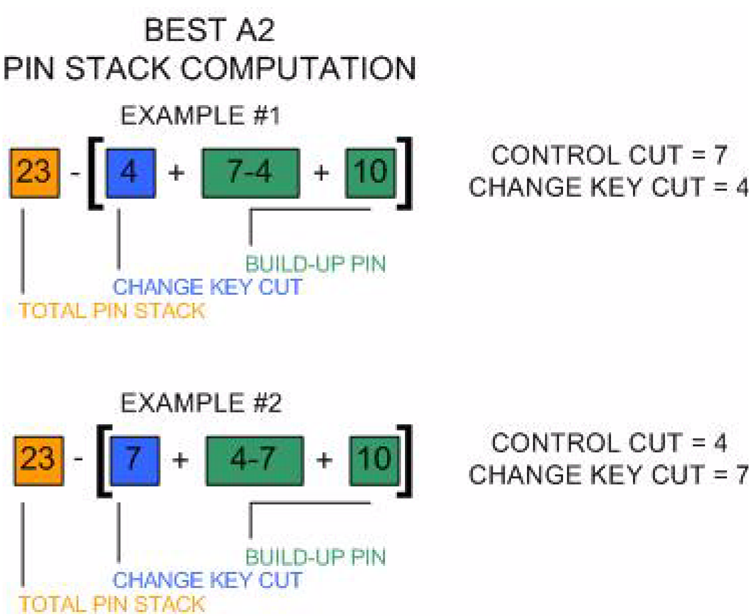
11_5.10.5.2.2 Decoding the Control Shear Line

The control key bitting values can be determined easily but require that the lock be disassembled so that the top pin for each chamber can be measured. We shall utilize a Best A2 system for our examples. The decoding process for the control key will work in any interchangeable core lock if the following conditions are met:

- **The combined pin stack height must be constant for all chambers. In the case of the A2, it is 23; for the A3 it is 16, and for the A4 it is 14;**
- **The overall pin stack length within each chamber in the target lock must not deviate from the factory standard;**
- **The number of depth increments between the operating and control shear line must be known;**

The formula to compute the pin lengths in the A2 is shown below. Formulas for the A3 and A4 would vary according to the overall pin stack height requirements for each core. There is a fixed relationship between the control and operating key, based upon physical spacing between the operating and control shear lines. For Best locks, it is possible to decode the control key by knowing the overall pin stack height and the length of the top pin.

As with the Corbin master ring, there are a total of four pin types: **top, control build-up, master, and bottom pin**. All master key levels will have their shear lines at the plug level (operating shear line) because the lock is keyed as a conventional cylinder. In determining the pinning for the control key, the total pin stack height must be known.



In the Best A2 removeable core lock, the total pin stack height (denoted by red to blue lines) is 23 increments. The number of increments between the operating and control shear line is 10. In order to compute the length of the control pin, the top pin is removed and measured. Its length plus 10 more increments (the distance between the operating and control shear lines), is subtracted from 23. The remainder is the value of the control pin. Two hypothetical examples show how the values of each pin are computed when pinning a lock. Note: master pins have not been shown in the examples, for clarity. However, their value would be added to the change key cut in determining the length of the control pin.

In example 1, we desire the change key to have a value of (4) and the control key to have a value of (7). In this case, there will be three pins within the chamber: the bottom pin, build up pin, and top pin. We know that the total pin stack length must be 23 for the A2. The values of each pin are denoted by colored blocks. The bottom pin, shown in blue, is equal to 4. The build up pin is the difference between the control cut value (7) and the bottom pin value of (4). This number, (3) comprises the number of depth increments that would have to be added to reach the operating shear line. In other words, if the control key is inserted with only the bottom pin, there would be a difference of (3) to reach the operating shear line. But, we are not opening the lock at the operating shear line with the control key. We need to be at the **control shear line**, so we must add another ten depth increments in order to utilize the control key at the proper shear line.

Thus, the formula is the total of the green blocks, or (13) for the build up pin.

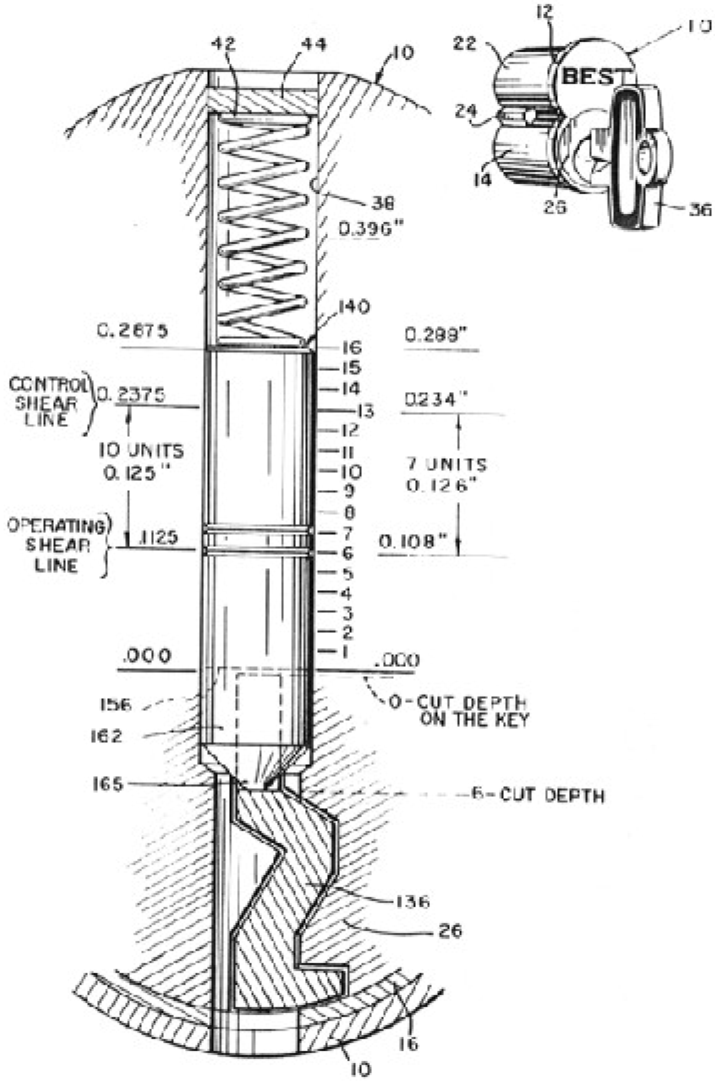
In example 2, it is the same formula, but note that because the change key is deeper than the control key, we have to deal with a negative number. In this case, the bottom pin is (7). The build up pin is also (7) because 4-7 = -3. Add -3 to +10 = 7. Remember, we are computing the length of bottom and build up pins, which are cumulative, toward the control shear line. With only a bottom pin in the plug, the control key (4) would cause the bottom pin to protrude into the shell by three depth increments. The difference between the operating and control shear line is ten. Therefore, we can only have a build up pin with a value of (7) to make up the difference to the control shear line (3+7). In both examples, the total value of bottom and build up pins are subtracted from 23 to determine the top pin.

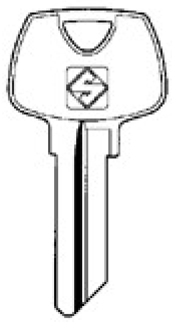
There are three versions of the Best ICore: A2, A3, and A4. The chart shows the number of depth increments, depth coding, number of pins, and total pin stack height for each lock.

BEST IC LOCKS			
MODEL	**DEPTHS**	**INCREMENT**	**PIN STACKCODE**
A2	10	.0125"	230-9
A3	7	.018"	160-6
A4	6	.021"	140-5

11_5.10.5.2.3 Decoding the Control Shear Line Master key

In certain applications, a series of removeable core locks may be master keyed at the control key level. For example a chain of restaurants in Chicago may require that one regional manager be able to remove the core from any restaurant in the city, and also allow the local manager to change the lock for his particular restaurant. In such an instance, an extra master pin would be placed between the operating and control shear line. The master control key can be extrapolated in the same manner as the TMK by using the local control key (equivalent to the change key in a conventional cylinder) to probe each pin stack. The only difference is that the control shear line is utilized rather than the operating shear line to derive the master control key code.





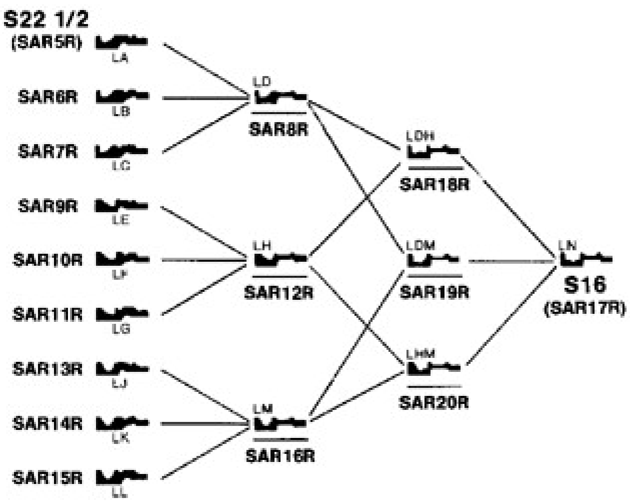


Figure LSS+1138 Best lock, model A2 and A3. This diagram shows the relationship between the operating and control shear line. In the A2, there are ten depth increments between the two shear lines; in the A3 there are seven increments between operating and control shear lines.

11_6.0 Sectional Keyways and Multiplex Keying Systems

Many manufacturers offer the capability for complex keying, through the use of sectional keyways. By definition, a **multiplex key system** is comprised of a series of different keyway subsections that may be used to expand a master key system. This is to allow the repetition of individual key combinations within

different keyway sections. Shown below and in the linked graphic is a Sargent **LN** family of keyways. The graphic representation shows each individual keyway as a grid of different keyway wards, indicated by individual color patterns.

Keyways are designed so that change keys for one subsection may not enter other sectional keyways. The effect of these systems is to greatly increase the number of possible differs without added key interchange.

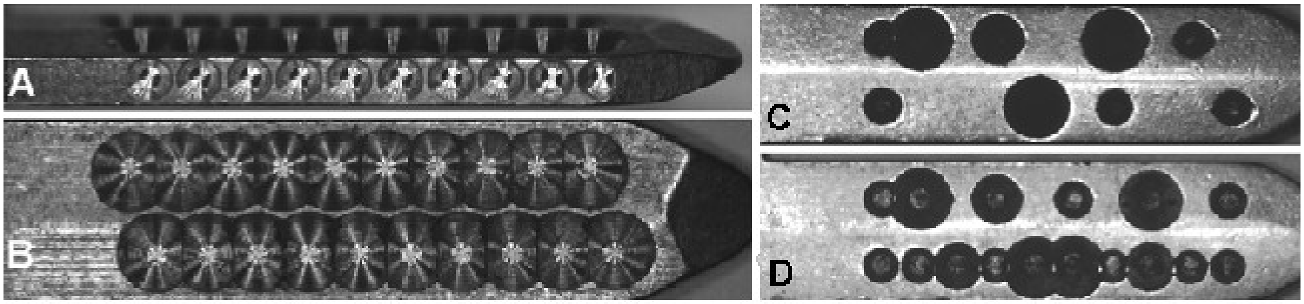
Multiplex key systems may be configured in many ways. In the accompanying illustration, the milling for keyways **LA, LB, LC, LE, LF, LG, LJ, LK, LL** are all different. Key **LA,** for example, cannot enter keyway **LB, LC,** or any other keyway within the system. In like fashion, **LB** cannot enter **LA, LC, LE; LC** cannot enter **LA, LB, or LE;** and **LE** cannot enter **LA, LB, LC.** Thus, individual key code 75126 could be repeated in separate locks located in different areas of a building using keyways **LA, LB, LC.** In this scheme, the key for keyway **LA** would only open a lock with the **LA** keyway. Although keys **LB, LC,** and **LF,** for example, had the same tumbler bitting as **LA,** they would not open the lock with keyway **LA** because the keys would be prevented from entering the plug.

Key **LD** can be milled to fit keyways **LA, LB, or LC.** Likewise, key **LH** can be milled to enter keyways **LE, LF,** or **LG.** At the next level, **LDH** can access all keyways for **LD** and **LH; LDM** can access **LD** and **LM,** and **LMM** can enter all **LM** and **LH** subsets. The top section, **LN** can access all keyways within this grouping. Note that as the hierarchy of keyways is built, the letter

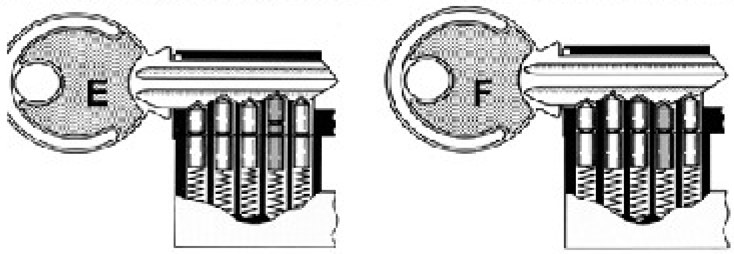
designations become a composite of lower sections.

Many lock manufacturers offer **families** of sectional keyways that can restrict entrance of all but the proper keys into subsections. Three or more levels of control may be available in certain keyway families. A potential problem with such systems is compromise using multi-sectional key blanks rather than sectional blanks. The difficulty occurs during key duplicating, especially at the retail level. Use of the wrong blank can result in unauthorized access to keyways.

If a multiplex keying system is encountered during a burglary or theft investigation, it may be prudent to determine which sectional key blanks are available locally in order to identify possible system compromise. Multiplex keying systems are ideally suited to large office complexes that are comprised of many buildings in different locations. Security and organizational control can be maintained with such systems.



11_6.1 Special Keyway and other Configurations



Some high-security lock manufactures incorporate special designs within their cylinders to accommodate very large master key system installations, without compromise in security. EVVA is such a company. They produce a cylinder, described in detail in **Chapter 19**, that utilizes pin tumblers in combination with eight rotating magnetic discs. In addition, their unique keyway design allows for 32,000 different theoretical keyways.

The combination of magnets, pins, and keyways allows extremely large keying systems to be implemented. Thus, a major hospital complex in Vienna, Austria required 40,000 lock cylinders with 257 master key subgroups. Using the magnetic cylinder, EVVA was able to meet these requirements without difficulty. Few other lock manufacturers could claim to do so.

11_6.2 Dimple Locks

Cylinders utilizing multi-surface keys, such as the Keso, Kaba, and DOM pin tumbler locks, can offer complex keying through the placement of tumblers within different pin chambers. This is called **positional master keying**. See **Chapter 17** for a more detailed discussion of these locks.

Within most dimple locks, there are actually many more pin chambers than are actually used **for any one key.** Thus, a cylinder may have twenty pin chambers but only seven pins in actual use. The number and location of the pins are staggered, depending upon keying plan.

There may always be, for example, thirteen "empty" chambers in any given lock. An empty chamber will generally have a shallow pin that requires no cut in the bitting surface of the key. Different keying combinations are obtained by staggering the combination of tumblers. Although different length of pins may be placed in any chamber position, every lock in the same master key series must have that same pin length for a specified chamber position in order for the master key to work. **The master key simply reflects a composite of every possible chamber position and pin length that is used in any individual lock within the system.**

High-security dimple lock manufacturers employ a number of safeguards to reduce possible compromise, including the maintenance of close tolerances, patent and copyright protected blanks, complex bitting configurations, and special key machines. It may be argued that the positional system offers a higher level of security than the conventional split pin system, due to the large number of pins, complex design, and lack of multiple shear lines. Perhaps most significantly, the system cannot be compromised through the disassembly of only one cylinder, as with conventional systems.

11_6.3 Magnetic Locks

Locks that use magnetic cards to control locking mechanisms are of two basic designs: those that employ a stripe that contains flux reversal information (such as a credit card) that is passed across a read head to sense the pattern of reversals, and those that utilize a material to store magnetized spots that mate with corresponding pins within a matrix inside of the lock.

Within certain magnetic card locks that use barium ferrite vinyl (BFV) or similar materials, positional master keying is utilized and can pose a serious threat to the security of a master key system. In one magnetic card lock for example, twenty magnetic pin positions are available for use. The design requires that pins in each location be raised above shear line through the action of repulsion by like magnetic fields.

Typically, an individual magnetic keycard will have up to eleven magnetic "spots" or domains that correspond to magnetic pin positions. Each lock within a system will always have eleven magnetic pins, but the combination (location) of pins will be different for each lock. Thus, magnetic pins will be placed in different chambers throughout the system, according to a predetermined plan. Additionally, the polarity of each magnetic pin for each chamber will be varied: some north polarity, some south.

The security of this lock relies upon the **position** and **polarity** of each pin. It can be seen, then, that the master key will be a composite of all pin locations and their polarity. For the master key to operate all locks, the polarity for each pin position must remain constant. Thus, with a sufficient sample of different locks within any positional master key system, the master key can be derived.

The author conducted an investigation involving a very popular magnetic lock at a major hotel in the United States. Within ninety minutes, the keys to eighteen rooms and the hotel master key was derived without ever taking any lock apart. The time required to derive the magnetic "signature" of each room was under ten seconds. The procedure developed by the author was impossible to detect, was essentially without noise, and left no trace within the lock. Other magnetic locks suffer the same security problem.

11_6.4 Axial Pin Tumbler Locks

Methods have been devised to master key axial pin tumbler locks. Such a technique was described by Falk in 1973 (**3738136(145)**) and utilized by Fort Lock Corporation. The system involved the use of different-shaped pins and edge cuts on the key. Multiple levels of keying can be achieved with this scheme and with more traditional techniques.

11_6.5 Sidebar Locks

There are many methods to increase the number of theoretical combinations within a sidebar lock. Multiple sidebars, multiple gates and sidebars, different sidebar profiles, and the design of the geometry of the pins and their relationship to the bitting surface of the key can affect the way in which master keying is executed. A unique design has been implemented by Medeco in their M3 locks. See **chapter 17**.

11_7.0 Servicing and Examination of Master Keyed Locks

Examination and servicing of one or more locks within a master key system may be necessary during the course of an investigation in order to determine if they have been previously disassembled or tampered with. The addition or removal of locks in a complex keying system may also be required.

11_7.1 Taking Apart the Master Keyed Cylinder

Disassembly of any master keyed cylinder requires extreme caution in order to insure that the tumbler combination and pin stack for each chamber is not disturbed. It is mandatory that a setup tray be used for this purpose. Although data regarding disassembly of pin tumbler locks was presented elsewhere in this text, added information pertaining to the master keyed cylinder is required to avoid irreversible errors.

Working with a cylinder that is suspected of containing more than a lower and upper set of tumblers requires special precaution, especially if pins are not taken from each chamber through the spring-retaining clip. Locks with one or more master pins in each chamber must be disassembled correctly, or the pin stack order may be altered. The controlled removal of the follower tool

from the lock is imperative if pins are to be withdrawn through the interior of the shell.

It may not be necessary to disassemble certain cylinders in order to derive all pin stack combinations and pin lengths. Methods of shimming of a cylinder and the use of systems keys are discussed elsewhere in this text.

11_7.1.1 Detailed Procedure

Starting at one end of the lock, very gradually withdraw the follower, barely exposing the pin stack within the first pin chamber. The author prefers to have the lock positioned so that the pin chambers are oriented in such a way that the pins release in an upward direction. Thus, the lock is held in an upside down position in the left hand which is also used to control movement of the follower tool. The tweezers are controlled by the right hand.

Using a special pair of tweezers (HPC-TPT-5 or equivalent) apply downward pressure on each tumbler with the center pin of the tweezers. As the follower tool is slowly withdrawn, the pin will begin to eject from the chamber due to the forward bias created by each spring. The follower is controlled to maintain a constant pressure on the side of each tumbler, thereby preventing the pin from flying out of the bore. This pressure, in conjunction with the use of the center pin of the tweezers, can be used to control release of each tumbler.

Very slowly allow each pin segment to move out of a chamber, then move the follower back in position over the chamber hole, inhibiting further release of pins. As each tumbler is released, remove it from the shell and place it in the setup tray **in the order removed.**

Start at the bottom of the tray for the proper chamber number. When all of the pin segments have been removed for chamber number one, the precise pin stack order should have been reproduced. After the first chamber is empty, move the follower to the next chamber and repeat the above procedure until all pins have been removed from the lock. When the pins have been withdrawn from all chambers, the setup tray will exactly replicate the horizontal and vertical positioning of all pins within the plug.

11_7.2 Changing the Keying Level of a

Cylinder

Whether a lock is to be set to a higher or lower level of master keying within a system will determine the difficulty of such change. Although it is a simple matter to remove one or more master pins in order that the master key will not open a particular lock, the cylinder must be keyed according to the KBA and predefined levels.

The proper method to downgrade a lock so that only a change key will open a previously master keyed lock, for example, would be to completely re-pin the cylinder. Thus, all master pins would be removed and a new set of lower pins installed that correspond to the combination of **only** the change key. Combinations for the change key, master key, and TMK must be known prior to working on the cylinder.

11_8.0 Construction Master Keying

11_8.1 Introduction

Several techniques have been developed over the last fifty years to protect new locks and keys from compromise at building sites and to regulate and change access to locks in other specialized environments. In the case of new buildings, the problem is caused by the need for workers to have keys while construction is in progress.

Control, duplication, and return of keys at the conclusion of a job is often difficult to enforce, resulting in the circumvention of all key control and the defeating of inherent security features of any lock. Construction master key systems have also found application in schools, dormitories, institutions, and for use during labor disputes and temporary emergencies where access must be instantly controlled, allowed, or denied.

There have been several approaches to construction mastering, including special pockets to hold extra bearings, the insertion of special key sections into the keyway, the use of locks with a second set of bores, and creation of temporary master pins. In addition, lockout devices have also been developed which block the entrance of any key into the cylinder until the special blocking device is removed.

11_8.1.1 Cylinders Containing a Second Set of Bores

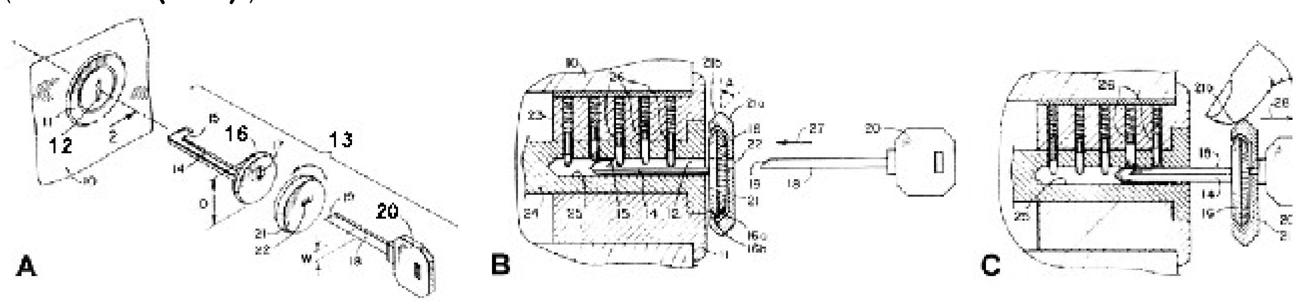
Cylinders have been developed with a second set of bores drilled in the shell. Once the option is enabled (by rotating the plug with a control key) they can facilitate:

- **Access control;**
- **Allow the use of a regular key;**
- **Block all regular keys and master keys and only allow the use of a special key.**

The Russwin cylinder will be used as an example of this type of keying. A similar principle has been applied within the hotel industry by TrioVing of Norway, and is described in **Chapter 17.**

The Corbin and Russwin cylinder consists of a shell containing two sets of bores, one set in the standard vertical plane at 12 O'clock and the other, offset by several degrees, at 11 O'clock. The **plug** will contain **one** set of bores.

There are usually six cooperating bores in the plug and shell, oriented in the normal 12 O'clock position. However, there will only be five offset chambers in the shell at the 11 O'clock position; the sixth bore position will be solid. There are driver tumblers and springs in both the standard and offset bores. There are bottom tumblers and one or more master pins in the plug.



In normal operation, the change key will work the lock by raising the tumblers in the 12 O'clock bore position to shear line, allowing rotation of the plug. The absence of a bore in the sixth position of the offset chambers will prevent the change key from being withdrawn in the 11 O'clock position, because there is no place for the last pin in the plug to go. Therefore, the key cannot be withdrawn.

To lock out the normal change key, the special block-out key is inserted, the plug rotated to the 11 O'clock position, and the special key is withdrawn. It is possible to withdraw the block-out key from the plug in the 11 O'clock position. This is because the last tumbler position on that key has been filed, so that there is no steeple or rising angle encountered by the sixth tumbler within the plug. Thus, this pin is not raised above shear line as the key is removed. To return the cylinder to normal operation, the block-out key is inserted at the 11 O'clock position, the plug then rotated back to the 12 O'clock home position, and the key withdrawn.

Cylinders utilizing this scheme can be master keyed in the normal manner. However, the master key cannot be used as a block-out key. In addition, there is the possibility of system sabotage, in that a change key can be altered by filing the last tumbler, in effect creating the block-out key. If the plug is then rotated to the 11 O'clock position and the key withdrawn, the lock cannot be operated without use of the special key. Furthermore, it may be possible that a **cross-key** could be created to work as a block-out key. In this case, a completely different and unanticipated tumbler combination could be created and parked in the offset position. In that instance, a key with that combination would have to be used to return the lock to normal operation.

11_8.1.2 Special Keyway Insert

Many years ago, Schlage introduced a form of construction keying that required the placement of a special insert into the keyway to block all but the lock-out key. The special key would open all of the locks, just as the regular master key would. Upon completion of construction, the insert would be removed, disabling the lock-out key and returning the system to normal operation. Other companies have offered similar schemes. Many patents have been granted for these mechanisms, notably to Schlage and Yale. See the patent issued to Check in 1962 (**3059462(146)**).

11_8.1.2.1 Principle of Operation

The insert is a specially cut key with some of the keyway and bitting material removed. In the Schlage system, these inserts will usually be made to raise the last one, two, or three tumblers to shear line. When the special construction key is inserted, it merely picks up the remaining tumblers to the proper level, allowing the plug to rotate.

Placing the insert into the keyway effectively blocks any but

specially cut keys from entering the lock. The inserts can also be back-cut, making them difficult to withdraw without the proper removal key. Schlage has offered construction mastering, utilizing the insert principle, for their old series wafer locks as well as their pin tumbler cylinders.

When construction is completed, a plastic removal key is inserted, causing the construction piece to lock onto the end of the removal key. Both are then withdrawn from the plug, returning it to normal operation. DOM utilizes a similar scheme with their dimple locks.

11_8.1.3 Corbin: Temporary CMK Master Pin Using Side Pockets in the Plug

Corbin produces a cylinder that features a special construction master key (CMK) arrangement that allows the pin stack to be altered irreversibly upon the completion of the project. During construction, the CMK is utilized for access. The operation of the special master key is cancelled when it is no longer needed. This is accomplished through the use of a specially designed plug that has two small pockets or bores, drilled forty degrees from the center of one chamber (usually the last chamber). The diameter of these bores is too small to accommodate master pins or top pins; only the bearings will fit into the holes. Three .045" ball bearings are utilized as a master pin, as shown in the diagrams below, during the construction process. The bearings are permanently "parked" in the plug after construction when the lock is returned to its normal operation. Once the bearings drop into one of the pockets, they cannot be removed unless the lock is disassembled. Note that the steeple of the last cut (tip) on the CMK is removed to prevent key picking or jiggling.

The system utilizes a bearing equal to a master pin having three depth increments (pre-System 70 lock) or 1.5 increments (System 70). The theory of operation is quite simple. The bearings are placed directly above the bottom pin, or the master pin. So long as the construction master key or change key does not raise the bearings above shear line, the lock continues to function in the construction mode. However, if at any time the plug is turned with the bearings **above** shear line, then they will fall into one of the pockets upon rotation. At that moment, the pin stack will be returned to its normal configuration, and the CMK will never work again. The ball bearings can be placed above the bottom pin, or above the master pin with the same effect. Depending upon

their position, the change key or TMK is used to reset the system.

The combination of the CMK is usually set so that one progressive is different by three depth increments (pre-System 70) from that of the TMK, as shown in the KBA for this lock. The CMK corresponding bitting position is always set for a depth of 5 1/2 for a System 70 lock, or a 7 in the pre-System 70 configuration.

The lock can be configured in one of two ways, both with the same result. In the diagrams, the bores for the bearings are color-coded blue, the bottom tumbler is green, the ball bearing is red, the master pin is yellow, and the top pin is brown. Cylinder **A** is shown in an idle state. In **B**, the CMK allows the plug to rotate freely because the ball bearings are placed above the bottom pin, and are below the shear line. They can never make contact with the side bores because they are encapsulated in the pin stack. In **C**, the **change key** is turned in either direction to cancel the CMK. Note that the CK only raises the bottom pin thereby placing the ball bearings at shear line. As the plug turns, they drop into one of the bores and disappear. In **D**, the CMK is reinserted, but cannot work.

In the diagrams of cylinders **D**,**E**,**F**, the master key is used to reset the system. In cylinder **E**, the lock is in the idle state. In **F**, the CMK is able to operate the cylinder. In **G**, the master key is turned so as to bring the bearings to shear line, and park them into one of the corresponding bores upon rotation. In **H**, the CMK is inserted but is blocked from operating because the master pin does not split at the shear line.

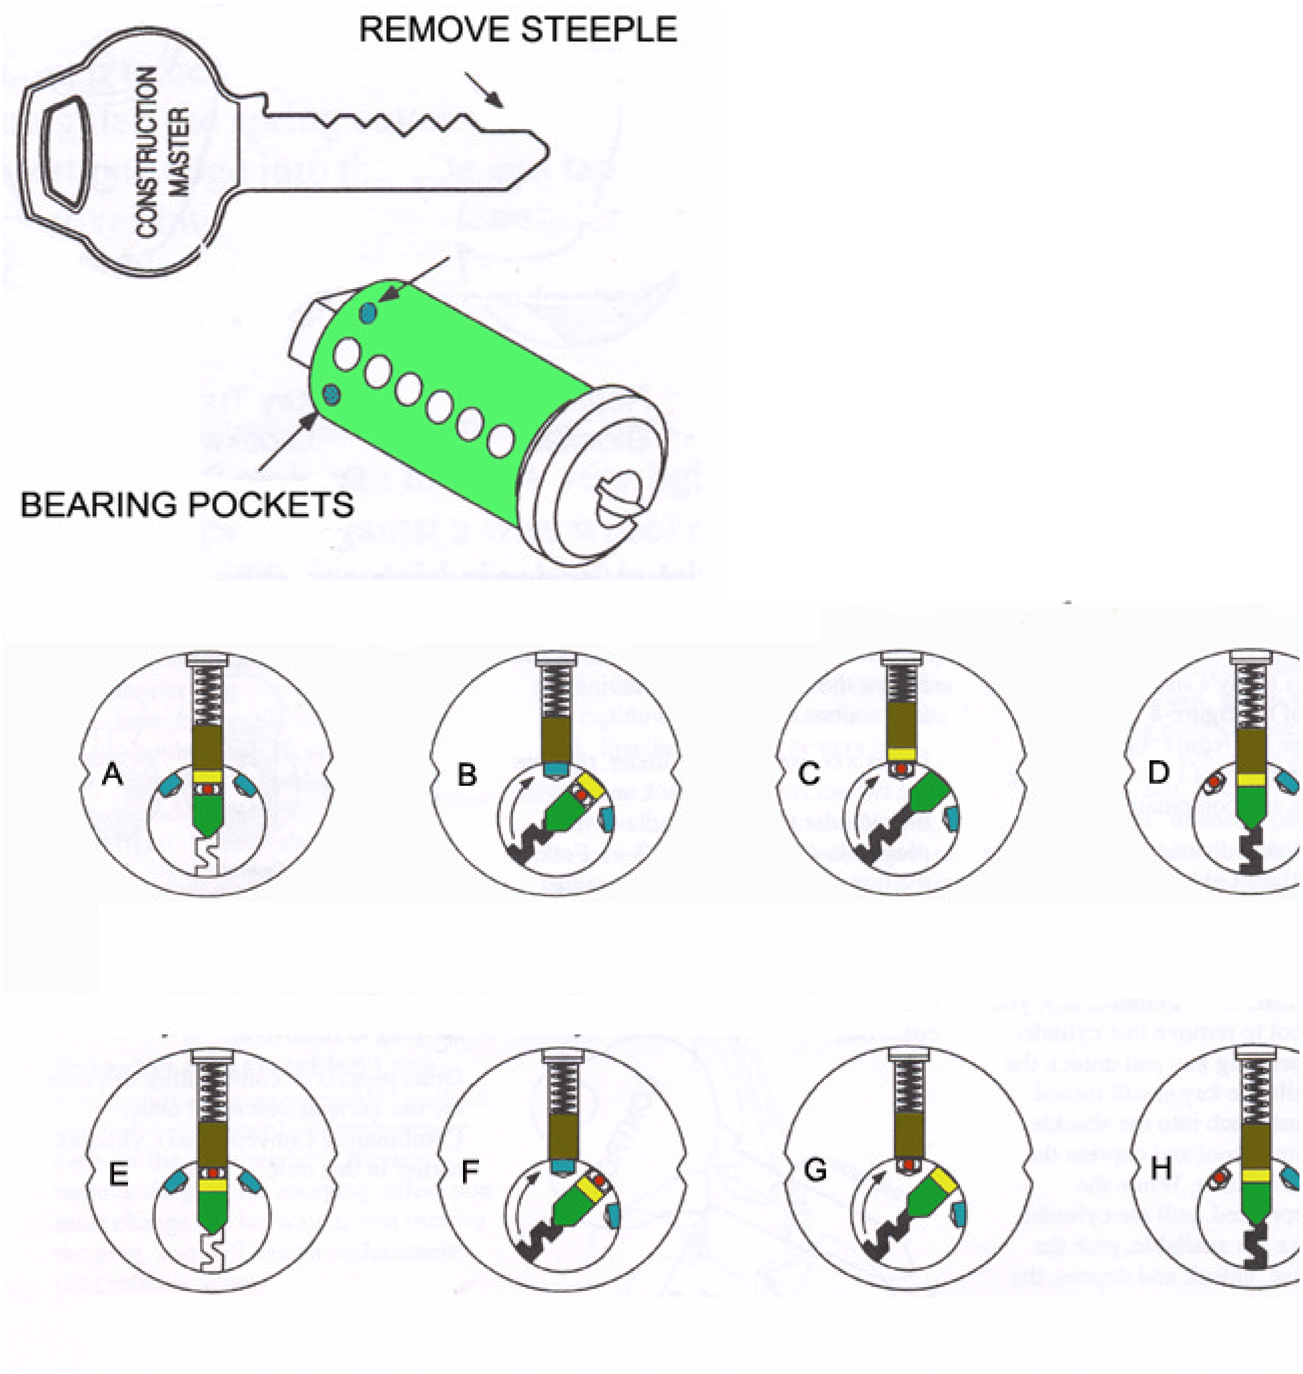


Figure LSS+1139 shows a Corbin construction master key system that relies upon ball bearings to be parked in small bores drilled off center from one chamber. In A,B,C,D, the bearings are placed below the master pin, and are controlled by the operation of the change key. In E,F,G,H, the master key performs the reset function. Courtesy of Corbin Russwin.

The KBA for the construction master is slightly different than for a conventional cylinder. In a two-step progression for a pre-System 70 lock, one of the progressives in the sixth column is lost because of the use of that value for the CMK. In this instance, the sixth position of the CMK is set at 9, which is three depth increments deeper than the TMK position.

KBA FOR CONSTRUCTION MASTER

CMK	1	4	9	7	2	9
TMK	1	4	9	7	2	6
	3	6	1	9	4	0
	5	8	3	1	6	2
	7	0	5	3	8	4
	9	2	7	5	0	

Figure LSS+1140 KBA for the construction master key system. This example is for a pre-System 70, and provides for a total of 3,072 combinations (4 x 4 x 4 x 4 x 4 x 3). The value of the CMK cut is 9. A depth of 8 cannot be utilized because it only varies by one depth increment from the CMK value.

CHAPTER TWELVE: HARDWARE SURVEY

Basic Lock Configurations: Hardware

12_1.0 Introduction

This chapter provides information about and identification of the hardware components that comprise every locking system. These include locks and lock covers, latches, bolts, and related locking mechanisms. For an excellent description of early locking hardware, the reader is directed to **Chapter Nineteen** of the Price book, contained within the Infobase. Doors, frames, and other hardware are discussed in **Chapters 38-39**. In those chapters, detailed information is presented about each locking component in the context of burglary and robbery prevention.

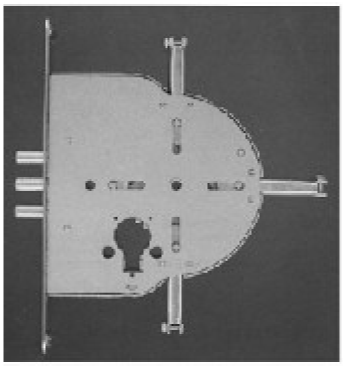
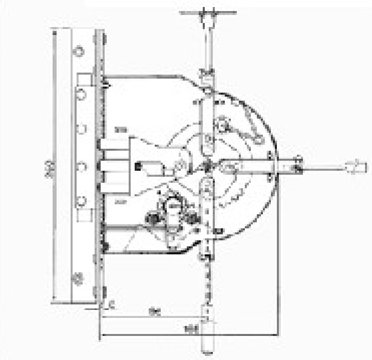
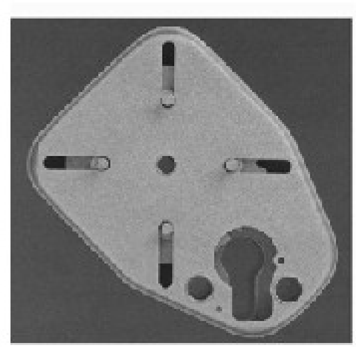
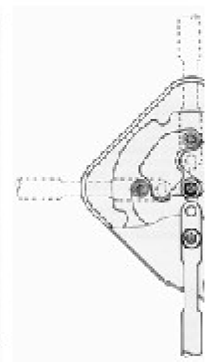
There are many types of locks and lock configurations. The diversity of products result from different requirements related to security, convenience, mechanical configurations, and the purpose for which the lock is used. Additionally, each area of the world has developed different methods and approaches to security, reflected in the unique use of materials and designs. Within each country or region there is standardization of locks and related hardware with respect to mechanical configuration. Information regarding European and American testing standards for door locks is presented in **Chapter 37.** Certain classifications of locks are defined by ANSI, based upon a specific use. Thus, there are entrance, store, classroom, communicating, dormitory, and hotel locks. Specialty locks, such as cam, padlocks, tubular, mailbox, telephone, and combination are discussed in **Chapters 17-23.**





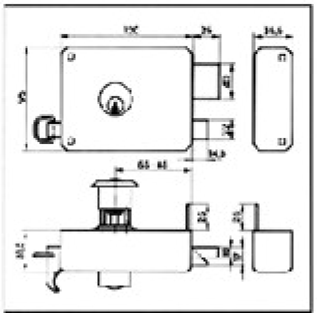


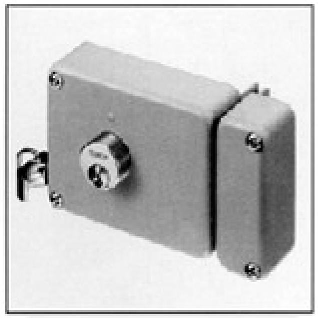


12_1.1 Bolts and Strikes

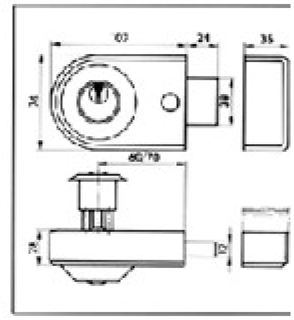
There are a number of different types of bolts, depending upon the lock, jamb, and strike design. These are defined below.

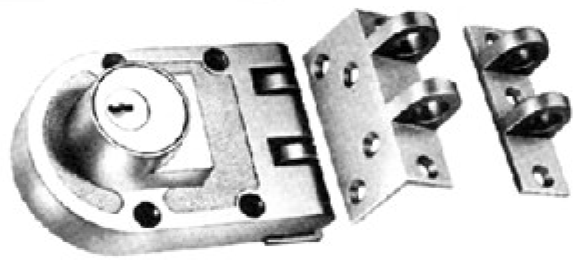
12_1.1.1 Bolts





A **bolt** is a metal bar that when actuated is either projected horizontally or vertically, or swings into a solid mass to prevent any door, window, or other object from moving or opening. Bolts may take a rectangular or hook form or may be comprised of several interconnected pieces operating together. The term can be found in the literature as early as 1753, although in 1400 it was described as part of a lock.





Extra strong bolts can be employed to lock a door at the top, bottom and sides. For example, **cross-bolt** or **double-bolt** locks are fitted on the inside surface of the door to increase security. Features such as solid steel bolts on both sides, bolt projection of 80-100 mm controlled by a gear wheel, and lock mechanisms with multipin cross profile or profile cylinder are examples of complex bolt arrangements.

12_1.1.2 Latches

A **latch** is a type of bolt that can take several forms. It is a device for retaining a door or other moveable surface to which a lock is attached. The use of the term can be found as early as 1382. **Lache** was used in 1420 and **latche** in 1575. In 1611, Shakespeare spelled it **latches**. A **latchbolt**, unlike a dead bolt, is a standard, angled or beveled projection.

The **night latch**, a form of **deadlatch** lock, is a spring loaded bolt that may be withdrawn by knob from the inside and by key from the outside. The latch can be set to the unlocked position or it can be locked in place against end pressure. It is usually associated with a rim lock.

LSS+1201 A Yale nightlatch, circa 1909. This is perhaps the most popular locking device even introduced. Its companion rim lock is shown below.

12_1.1.3 Actions of Bolts and Latches

There are a number of ways of describing the actions of bolts and latches relating to whether they are spring loaded, how they are thrown and retracted, and how they lock. There are deadlocking bolts and latches, night latches, secondary bolts, and various combinations of night latches and dead bolts.

12_1.1.3.1 Deadlatch

A **deadlatch** is a specific type of latch that has a beveled edge. It can be automatically or manually locked against end pressure when in the thrown position. The term may have several meanings:

- **Night latch that may be deadlocked;**
- **Night latch with a secondary locking bolt to prevent use of celluloid to bypass it;**
- **Arrangement with a night latch secondary bolt that may be locked from the inside.**

12_1.1.3.2 Deadlocking

Deadlocking generally refers to a special added locking action that may be initiated to prevent the bolt from being withdrawn because of external pressure or the use of the handle. Generally, deadlocking is activated by an extra turn of the key that throws the bolt an added length into the strike.

12_1.1.3.3 Dead bolt

A **dead bolt** is a lock bolt having no spring action. The bolt is usually rectangular or square and is moved into the locked and unlocked position by a key from either side of the door. This is contrasted to a **spring-loaded bolt** that may extend automatically. The dead bolt, when projected, is locked against end pressure; the bolt thus deadlocks when thrown. To complicate the definition, there are single, double, one-way, classrooms, and standard door lock bolts.

Figure LSS+1208 Examples of dead bolts in different configurations. Courtesy of Illinois State Police, Bill Sherlock.

12_1.1.3.4 Auxiliary Deadlock Latchbolt

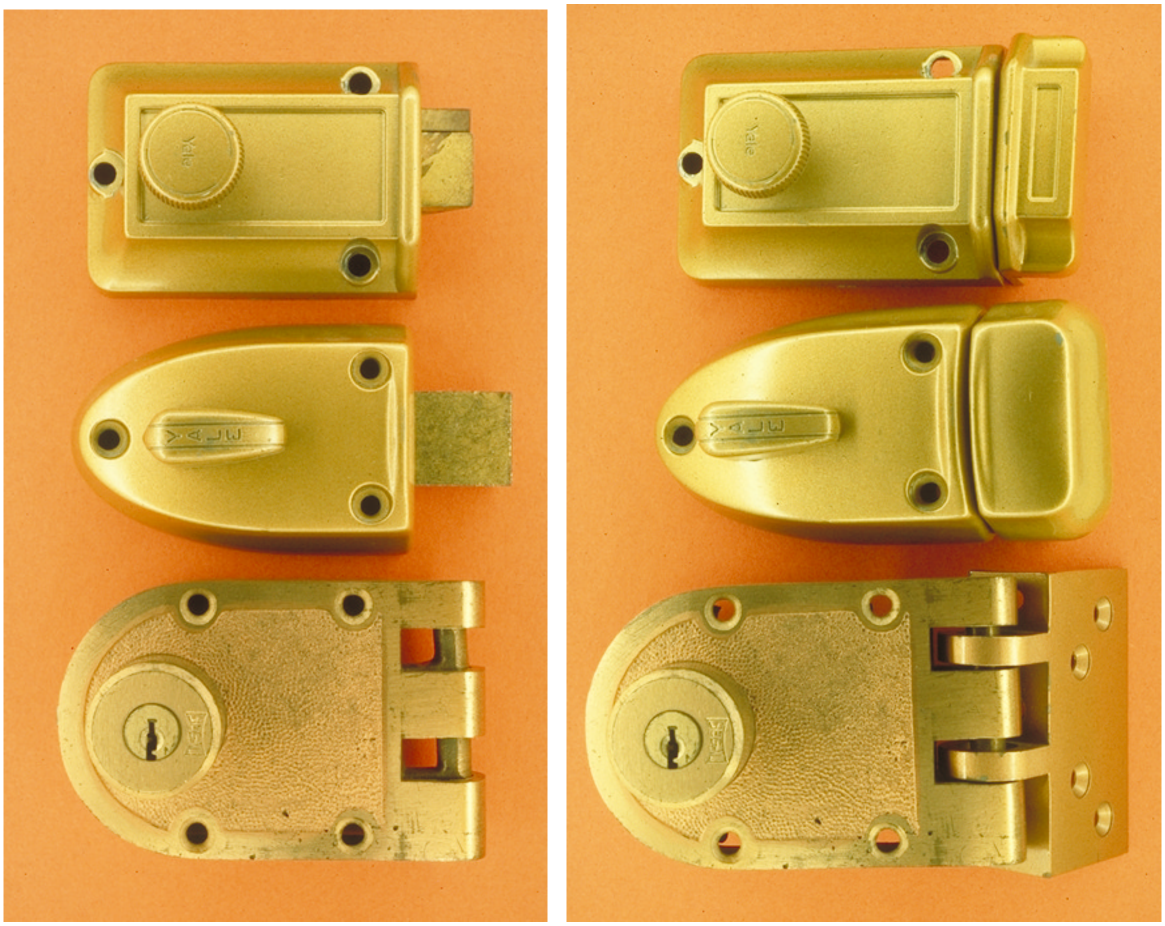
An **auxiliary deadlock latchbolt** comprises an additional bolt that is depressed by the strike when the door is closed, to automatically deadlock the bolt against end pressure.

12_1.1.3.5 Secondary Bolt

A **secondary Bolt**, also referred to as an **anti-thrust bolt or anti-pick latch**, is a spring-loaded auxiliary slide attached to the main bolt that cannot be retracted when the primary bolt has been extended into the locked position. Its purpose is to frustrate attempts to withdraw the main bolt by thin plastic or metal shims, wedges, or the application of end pressure. A secondary bolt is not the same as an **auxiliary deadlock latchbolt.**

12_1.1.3.6 Deadlocking Night Latch

In a **deadlocking night latch**, sequential actions are required to double lock or unlock. Thus, the first action throws the bolt; the second either throws it further or physically blocks it from being withdrawn.



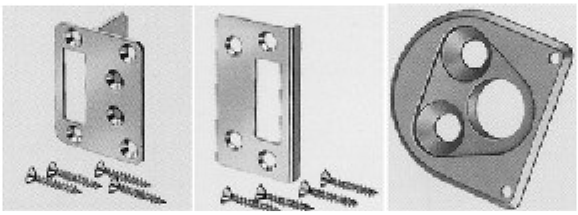


Figure LSS+1209, examples of single and double-locking night latches. Courtesy of Illinois State Police, Bill Sherlock.

12_1.1.3.7 Double-Cylinder Deadlatch

A **double-cylinder deadlatch** is a deadlocking latchbolt, retracted by a key from either side of the door.

12_1.1.4 Strike

A **strike** is a metal plate that is mortised into, around, or on the doorjamb to accept and restrain the bolt. The strike may be as simple as an opening in the jamb or of a more sophisticated design, even incorporating high-security features. A **jamb** is the inside vertical face of a door or window frame. Like all parts of the **escutcheon**, the strike plate must be made for the type of door. Strikes are designed to withstand forces from kicks, pushing pressure, pry bars, or wedges.

12_1.1.4.1 Breakaway Strike

A **breakaway strike** is a remote controlled electric door lock in which the strike is electromagnetically retracted to operate. A security strike plate is used with additional anchors in the wall to provide resistance to forced-entry.

12_1.1.5 Handing

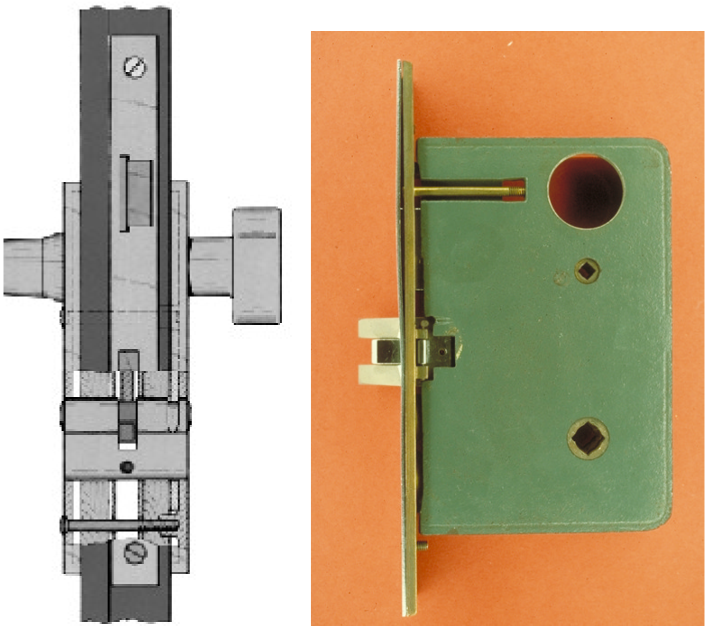
The **hand of a lock** defines on which side of the door the bolt is located and extends. It is referenced to the keyway of the lock. For example, when the keyway is oriented right side up and facing the viewer and the bolt is to the left, then the lock is said to be left-handed. From the back of the door, the hand of the lock is determined from the way the door swings. The definition is equally applicable to safes and vaults with respect to the orientation of the combination lock.

12_2.0 Locks and Associated Hardware

There are two types of door locks: primary (main) and secondary. In the United States, the main lock is generally a key-in-knob or mortised cylinder. Secondary locks provide added security and can take many forms. In Europe, profile locks and mortise locks are predominant.

12_2.1 Mortise

A mortise is the opening in a door that is made to receive a lock or other hardware. The term does not find use prior to the middle to the end of the eighteenth century. A mortise lock is designed to be cut into the edge of the door or other frame. Locks are **mortised** or **surface** mounted. A **rim cylinder** is mounted **on** the surface of a door, rather than being inset. Cylinder mortise locks are simply mortise assemblies into which a locking cylinder has been inserted.



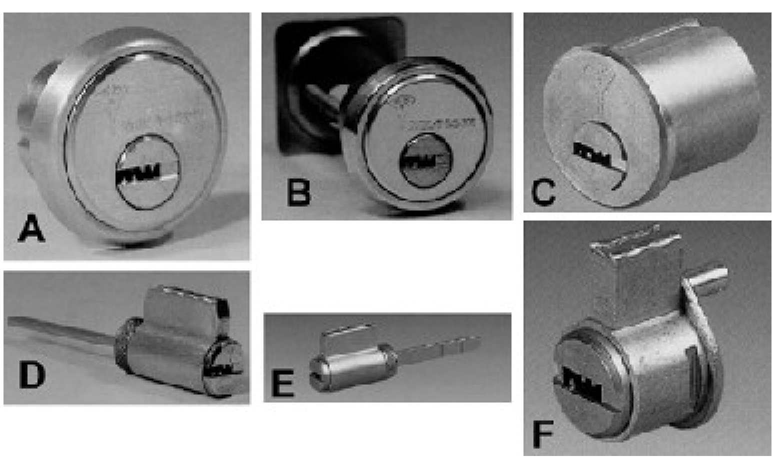


Figure LSS+1204 (ISP 46-2963) Example of a mortised lock, and the mechanism for holding the cylinder.

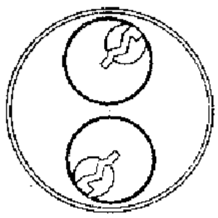
12_2.2 Cylinder and Security Locks



Mechanisms are often referred to as cylinder or security locks. Like keyhole locks (European), they are not complete lock sets, but rather lock **inserts** for simple mortise configurations.

12_2.2.1 Cylinders

A **cylinder** is a round lock that is designed to screw into standard fittings that are mortised or inset into the door.

Cylinder locks are generally pin tumbler, although other locking mechanisms may be used. A **bicentric** lock has two plugs and sets of pins or wafers within one cylinder, such as manufactured by Winfield.

Most cylinder locks are similar and interchangeable. Their diameter, threads, and length are all of standard design so they will fit most door frames. A longer cylinder can always be made to fit doors requiring shorter length by utilizing an expansion ring. The converse is not true: too short a cylinder cannot be made to work properly.

Cylinder connecting bars have also been standardized: they are either square or rectangular and can generally be cut to the required length.

LSS+1202 A Yale rim lock, introduced in 1909.

12_2.2.1.1 Mogul Cylinder

The **mogul** cylinder is a special variety of the standard pin tumbler configuration; it is typically used in prisons. These locks have very large pins, springs, and plug for increased security and physical strength. See **Chapter 17.**

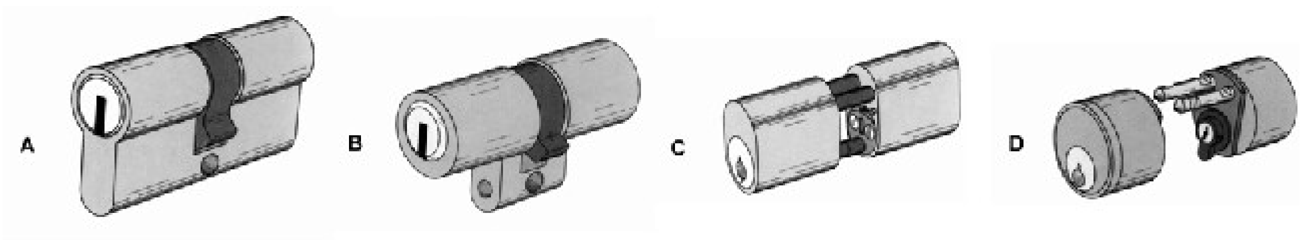
12_2.2.1.2 Interchangeable Core and Removable Core

Interchangeable Core (IC) locks, key changeable locks, and removable core locks are quite popular in commercial environments.

12_2.2.1.2.1 Interchangeable Core

The interchangeable core lock allows removal of the entire core from the cylinder with a control key. The core thus removed can be interchanged with many of the IC lock manufacturers.

12_2.2.1.2.2 Key Changeable



The **key changeable** lock is a cylinder that can be recombinated through the use of a special change key, and without disassembly. Winfield makes such a product for the hotel industry. See **Chapter 22.**

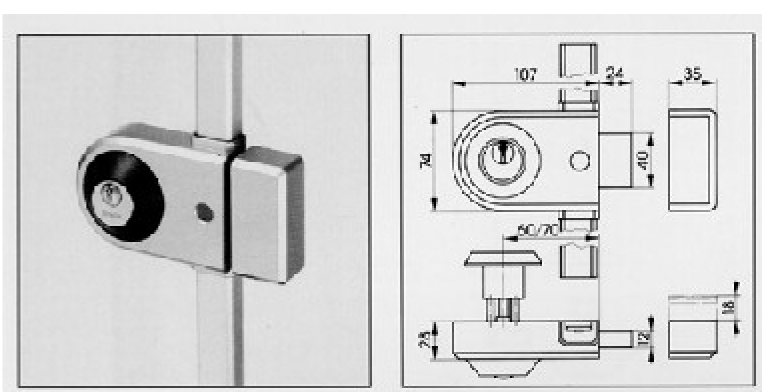
12_2.2.1.2.3 Removable Core

The removable core is a lock assembly that contains all pins and springs and which can only be installed in a specific type of lock housing such as a mortise cylinder or key-in-knob lock.

12_2.3 Profile Locks

Profile locks, found in Europe and other parts of the world, perform the same function as the U.S. cylinder lock. All of the door-mounting surfaces and hardware are designed to accept one of four recognized European configurations. These locks are identified as **profile cylinders**, **Swiss profile**, **oval cylinder**, and **round cylinder**.

12_2.3.1 Escutcheon



The **escutcheon** is a surface-mounted metal or plastic trim that can add to appearance, security, support, and protection of the lock. Generally, cylinders will not protrude from the escutcheon by more than 2 mm. The **rosettes** or shields will not be screwed onto the door from the front, if they are to prevent forced removal in burglary attempts. Rosettes are necessary to protect cylinders mounted in doors with slender metal profiles.

12_2.4 Rollstud Lock

A **rollstud lock** provides multipoint locking in conjunction with a central locking mechanism. They are typically installed into the door frame for greater security.

12_2.5 Tubular Frame Mortise Lock

Tubular frame mortise locks are used in thin metal frame doors. They are generally equipped with one of three kinds of bolts: **dead bolts**, **swing bolts**, or **hook bolts**. A dead bolt in the tubular frame door can only be locked once with a bolt penetration into the jamb of 10-12 mm. In some special locks, the throw can be increased to 20 mm. This limited throw is often not sufficient to offer any significant security.

12_2.6 Swing Bolt Locks

A **swing bolt lock** can achieve higher security through the design of the bolt. When idle, the bolt rests in the vertical position. The advantage is that the shape of the housing does not limit the length of the bolt. Upon locking, the bolt swings to a horizontal position, with up to one half its length extending into the strike for approximately 30 mm. The other half remains in the lock housing. These bolts are also found in swinging doors. Finally, swing bolt locks with **hook bolts** are utilized primarily on sliding doors. The bolt actually hooks into the strike plate, preventing movement.

12_2.7 Lock and Bolt Guards

Many manufacturers, including HPC, produce door and bolt guards to protect cylinders, latch bolts, and jambs from forced attack.

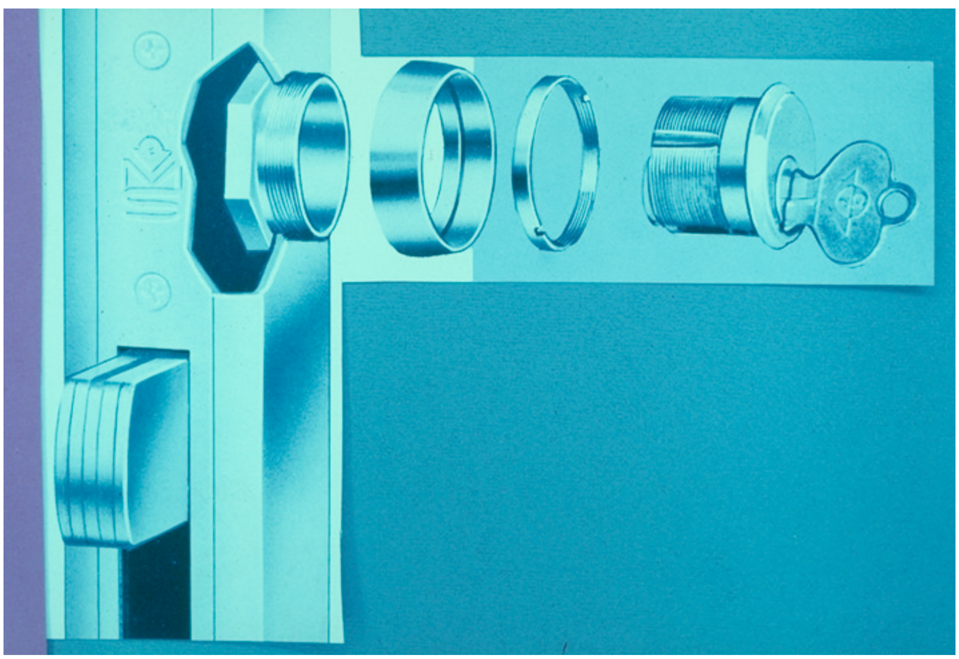


Figure LSS+1210, a guard ring assembly protects the cylinder from attack.

The cylinder is one of the most vulnerable components, especially when mounted on a narrow aluminum door. If left unprotected, the cylinder can be easily removed by pulling, wrenching, or twisting. See **Chapter 32** for specific techniques. The various lock guards protect against lock and plug pulling and drilling.

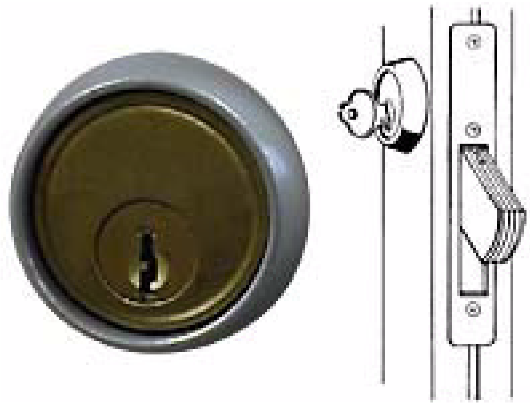

Figure LSS+1203 An HPC cylinder guard.

Door guards provide barriers to prevent door opening by a knife, saw, celluloid strip, or shove knife. They protect latches and bolts. Narrow aluminum doors are also vulnerable to pry bar and jamb spreading, described in **Chapter 32.** Interlocking door guards can solve the problem.

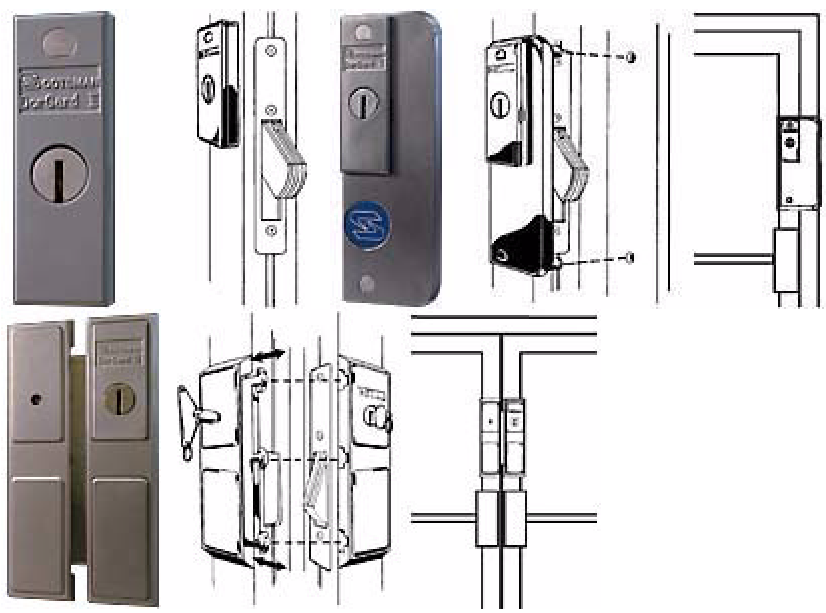

Figure LSS+1205 Various HPC door guards produced to protect narrow aluminum doors.

Figure LSS+1214 (ISP 38-3529 left, 40 center, 42 right). In 38, the cutout required for the locking hardware shows the weakening of materials. The

result is the requirement of little force to fracture the mounting material and gain entrance.

Figure LSS+1215 (ISP 43-3529 left, 44 right). Little effort is required to compromise a jimmy-resistant bolt.

12_3.0 High-Security Locks

High-security locks are discussed in detail in **Chapters 10,** and **25-26-27.** They are utilized increasingly in commercial facilities to provide added resistance to both forced-entry and surreptitious bypass. High-security locks are classified because of a number of common characteristics, including:

- **Patent protection;**
- **Proprietary key sections;**
- **Keyways and blanks;**
- **High differing potential;**
- **Double independent locking systems (such as pin tumbler and sidebar);**
- **Special physical protection against forced-entry;**

- **Pick resistance;**
- **Key control;**
- **Resistance to penetrating tools, including impressioning, forcing, drilling, sawing, prying, pulling, and driving.**

Locks must be available in standard configurations for rim, mortise, key-in-knob, and padlocks. UL 437 Standard defines tests for high-security locks and is discussed in **Chapter 37**.

12_4.0 Knockoff and Inferior Quality Locks

In high-quality cylinders, brass or bar stock is used for the body and plug. Both may be drilled and reamed at one time to maintain closer tolerances. There is a vast difference in quality and materials between properly machined and produced parts and the knockoff. Inferior copies or **knockoffs** and poorly produced OEM locks and keys have flooded the U.S. and European markets. Although they look to be secure and well made, such appearance is often deceiving. In fact, inexpensive locks may offer little protection against forced or surreptitious entry.

Generally, inexpensive locks mean less quality control relating to tolerances. Simply stated: the maintenance of tolerances costs money. In locks, as with any other manufactured part, the consumer gets what he pays for. Predominantly manufactured in Asia, inferior locks can be readily identified by a number of traits. Poor quality, composition, tensile strength, thickness of metals utilized in production, and poor maintenance of tolerances is typical. In addition, the lack of adequate temperature control during the manufacturing process can affect metal crystalline formation and hardness, ductility, and strength.

Many production and design problems directly relate to the ability of a lock to withstand forced and surreptitious attack. Lock plugs and bodies, especially those that are die cast, can exhibit characteristics that will make them especially susceptible to picking. Typical defects include:

- **Poor hole alignment;**
- **Oversized pin chamber holes;**
- **Surplus chamfer on the top of the bottom**

pin and chamber;
- **Excessive clearance between the plug and the body.**

These locks provide less resistance to forced-entry. It is axiomatic that inexpensive cylinders, keys, strikes, and other hardware will fail under the stress that is encountered during an attack. Many factors contribute to such deficiencies, including:

- **Absence of drillpins or other protection;**
- **Heat treatment of the components;**
- **Quality and purity of metals;**
- **Strength and hardness of metals.**

PART C: General Locking Systems

Specific Principles of Operation

Part C deals with the most basic lock designs that are commonly found throughout the world. Each fundamental variance is described, from the simplest warded lock to the most complex electronic system. We begin with a discussion of the warded lock, followed by detailed information in subsequent chapters regarding the logical and necessary technical refinements to this simplest of mechanisms.

The Simplest Lock

Our discussion of the primary locking mechanisms must of necessity begin with two fundamental and interrelated questions: **what is a lock?** and **what is a key?** In order to grasp the following material and the information presented in the chapters detailing techniques of bypassing the various locking mechanisms, the reader must always be mindful of and ask these questions. Whenever working with a lock, these two fundamental questions have to be considered and understood before success can be achieved. This is regardless of whether a key is being produced, the combination changed, the lock is being rekeyed, or it is to be bypassed through picking, decoding, or impressioning.

Additional questions will generally explore related issues that are pertinent: **how does this particular locking mechanism work?** and **how does the correct key perform its function in this mechanism?** A thorough understanding and conceptualization of the

inner workings of each type of lock, and what precisely occurs as the key performs its function, is essential if one is to be successful in performing any operation involving locks and keys. Such an understanding is especially critical for success in picking or bypassing locking mechanisms.

So, what is the answer to our initial questions: **What is a lock** and **what is a key**? In its simples of forms, a **lock** is a mechanism contained within a physically secure enclosure of any size or configuration. It is fastened or secured to a door or other moveable piece. Its primary element is a **bolt** of varying size and length that can be shot into a staple or recess and rigidly held there until it is required to be withdrawn. Whenever the bolt is thrown, the door will be prevented from moving. A **key**, in whatever shape it takes, is simply a device for operating the mechanism within the lock in order to actuate or move the bolt to the locked or unlocked position.

The concept of a bolt being thrown through the control of a key is an idea that took many centuries to develop and implement. In the modern lock, many designs are utilized to add security to the bolt. These take the form of levers, wafers, discs, pin tumblers, sidebars, rotating wheels, or other sophisticated mechanical or electronic mechanisms. The **security** of any lock has two primary components: the capability to resist physical attack and its ability to reject all but the proper key, combination, or access code. As the number of permutations of keys, combinations, or codes increase, the lock can offer higher security, assuming other basic manufacturing criteria are met.

Each of the chapters in Part Two details a primary locking mechanism. The reader should keep in mind that in every design, regardless of the kind of lock, the goal is to make more difficult or complex the task of simulating the actions of the correct key to throw the bolt. **Picking** a lock is the correct and precise simulation of such action and will result in its being opened.

Four thousand years of evolving lock design, from the most elementary mechanisms to those incorporating the most sophisticated electronics, can be reduced to one relevant issue: **the difficulty in simulating the actions of the correct key to throw the bolt.**

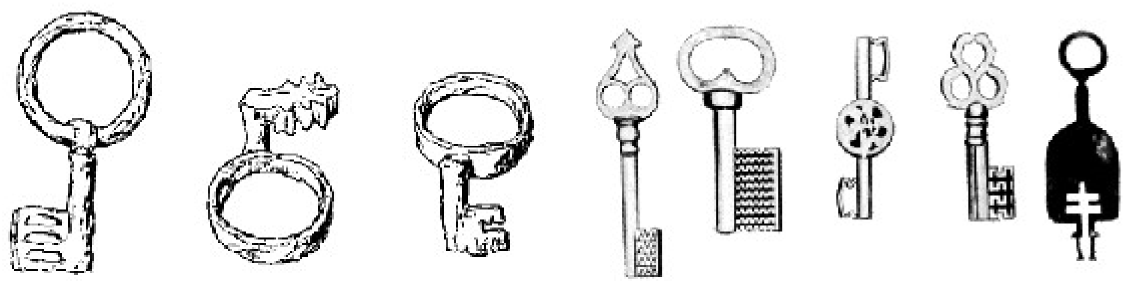
Our discussion of the **warded** lock will begin to focus on the methods employed by lock makers to make "throwing the bolt" more

difficult without the correct key.

CHAPTER THIRTEEN: THE WARD

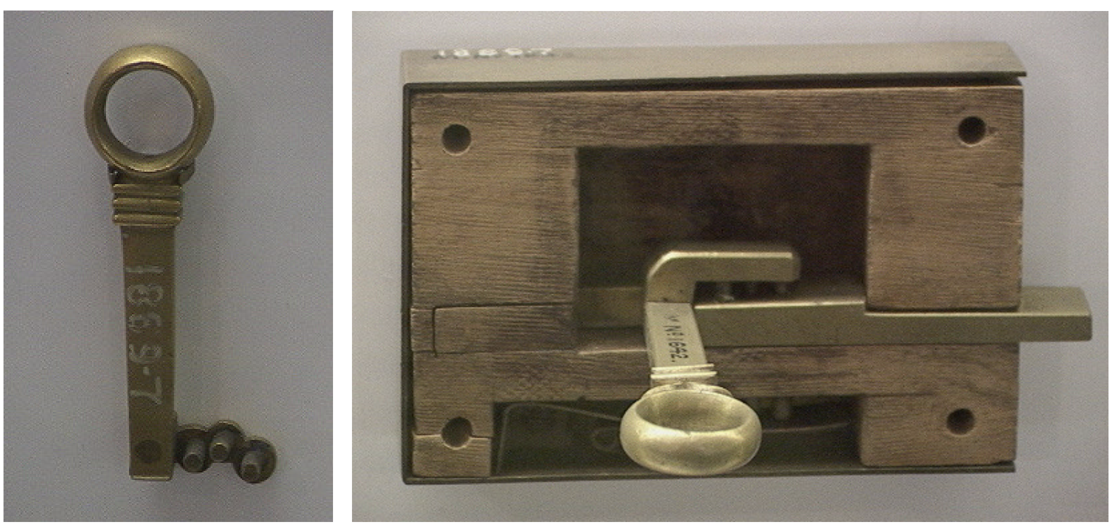
Warded Locks

Master Exhibit Summary



13_1.0 Introduction

The warded lock is the most basic mechanism and is used in applications where security is not the prime concern. As we shall learn, this lock has been in existence for thousands of years, and was the first facet in the lengthy development of modern locking devices. Inherent limitations in the original concept set the stage for future refinements and innovation in locking mechanisms. From simple wards, craftsmen and inventors over hundreds of years would conceive of levers, wafers, pin tumblers, discs, and other locking technologies to improve upon the wards limited security. The result: sophisticated mechanical and electronic locking devices that offered previously unimagined security and technology.



13_1.1 History and Development of the Warded

Lock

It is unclear where the warded lock was first designed and produced. Warded-type **keys** were found in the volcanic lava that buried Pompeii, Italy, in 64 AD. It is likely that the Romans were first to develop and employ wards as a means of making a lock more secure. Perhaps the Etruscans in Northern Italy conceived the warded design, although it is known that the Greeks and Egyptians also knew of the mechanism.

Romans were skilled in their work with metals. They realized that large keys and bolts were impractical. It was a relatively simple matter to bypass such large components to open early locks. Thus, mechanisms with smaller openings and throw bolts were fashioned.

LSS+1301 Example of Roman key and lock, from the ruins at Pompeii, 79 A.D.

Figure LSS+1302 Examples of early Roman keys.

The logic appears to have been that the complexity in the design of a key made for more security. As the ward developed, keys became extremely complicated and intricate, creating a maze of angles in the bitting.

We know from remnants of Pompeii that keys rotated less than 360°, once inserted into door locks. Thus, it would appear that the Romans also invented the spring-loaded bolt. These door fastenings were different than employed by the Greeks or Egyptians. Like a padlock hasp, the latches joined short lengths of chain to effect fastening. The combination of complex keys and bolts made for much more secure locks.

The ward, comprising one or more hidden devices, would block entry and frustrate the movement of any except the correct key. During the Middle Ages, locksmithing flourished and ward designs became increasingly complex as well as works of art.

The need for more and more security grew as robber barons pillaged the countryside. For the landowners and men of wealth, possession of handsome locks guarding castles and their valuables was a status symbol; the locks were things of pride and prestige.

As society generated and accumulated more wealth and riches, lock development and refinement continued. The craftsmen responsible for security hardware were the locksmith guilds, originally formed during the Middle Ages. These powerful groups regulated terms of apprenticeships, rules and conduct for journeymen, and all manner of production from prices of locks to the number of rivets. Such strictness helped to maintain the integrity of the trade. Locksmithing would remain a father-to-son enterprise until the nineteenth century.

Figure LSS+1303 A key from a French lock, fourteenth or fifteenth century.

Figure LSS+1304 An Australian door lock, eighteenth century.

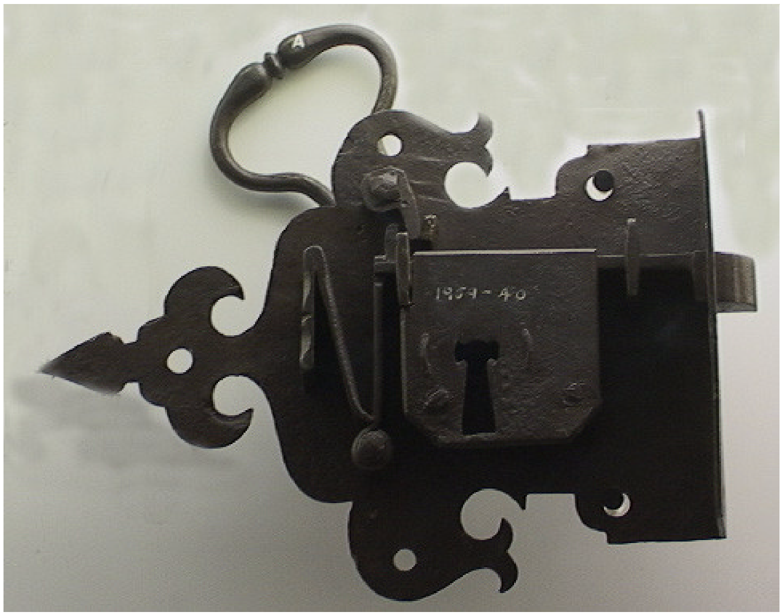


Figure LSS+1305 A Flemish door lock, seventeenth century.

The warded lock was the only reliable security device for several centuries until the development of the lever and then the pin tumbler lock. It was an extremely popular locking device and remains so to this day and in many applications. The lock provided a powerful tool to the guilds, allowing them to offer security to their clients.

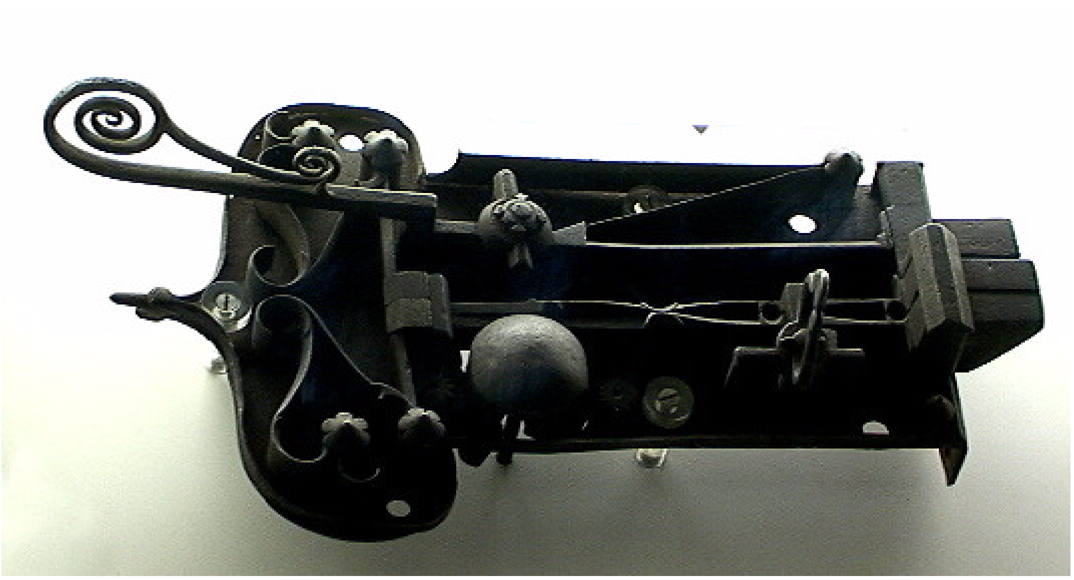

Figure LSS+1306 German door lock, seventeenth century.

The science of locksmithing did not progress much after the

nineteenth century beyond more intricate designs to confuse the thieves. False keyholes, false wards, and lots of "gingerbread" were the order of the day. Chests that cut off fingertips, fired pistol shots, had secret panels, or ejected murderous knives were produced. However, the basic design of the warded lock remained the same from the Roman period until the Renaissance, when the lever lock was invented.

The problem with the warded lock was that it left very little opportunity for truly improving the security of the device, past the many gimmicks noted above. One of the locksmithing development centers of the world was in Willenhall, England, and later, Wolverhampton. The Willenhall locksmiths understood that any warded lock could be picked. This realization would ultimately lead to the conception of the lever.

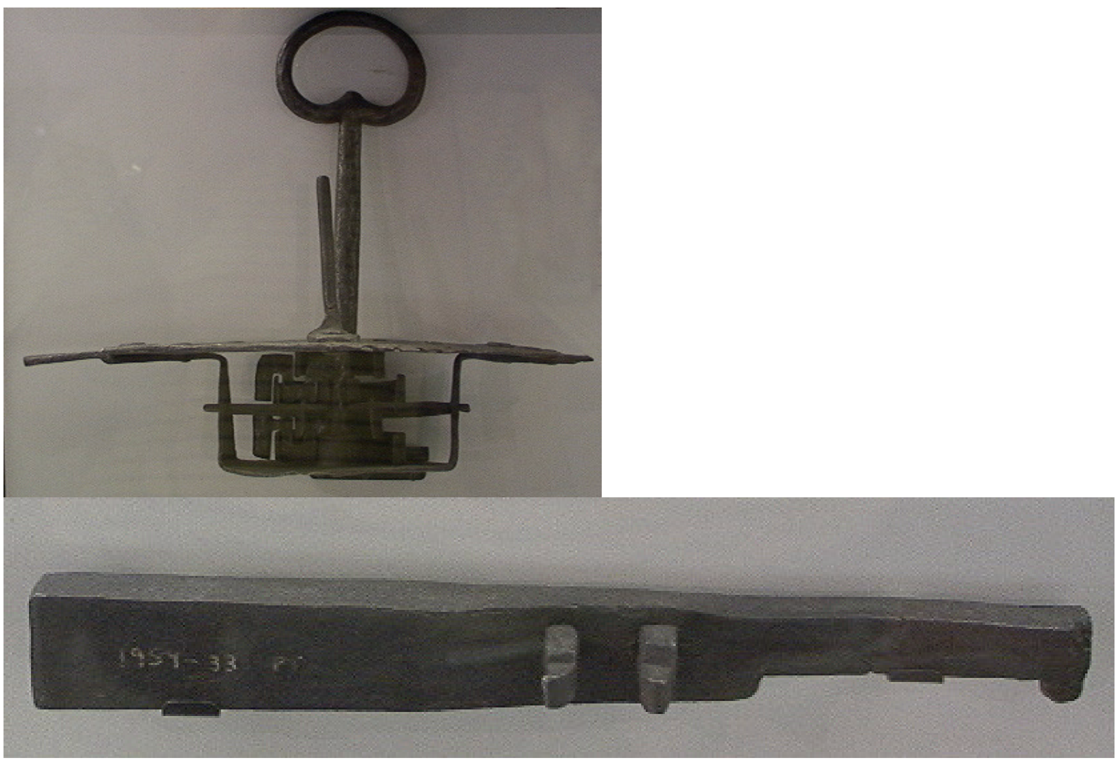

Figure LSS+1307 An English door lock and key, eighteenth century.

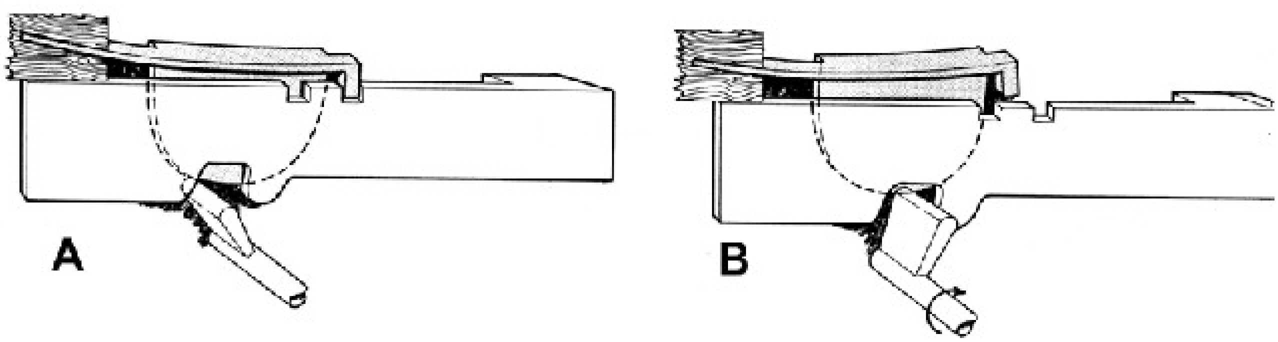
What the warded lock design provided was the first essential component in the modern, secure locking device: the concept of a **keyway**. Wards are an obstruction to prevent the key from entering or turning within the lock. Although wards are placed in various "hidden" positions, in some ways the same effect is obtained by a combination of wards forming a keyway. Their

purpose is to block all but the properly grooved blank from entering. In modern locks, keyways have replaced other forms of fixed wards.

Figure LSS+1308 An English lock and its key, sixteenth century.

Figure LSS+1309 Another example of an early English lock and its key,

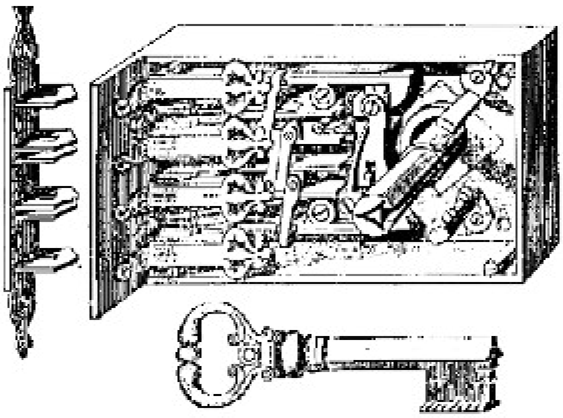
13_1.2 Applications of the Warded Lock



Warded locks are found in applications requiring minimal security. They are primarily employed in padlocks and in older homes and hotels using a mortise configuration. Luggage, cabinet, handcuff, and some jail and prison locks all utilize the warded principle. The Master laminated padlock is perhaps the best known application of the principle. Every schoolboy has at one time used such a lock to secure his locker or bicycle. Specially designed higher-security warded locks have been used in

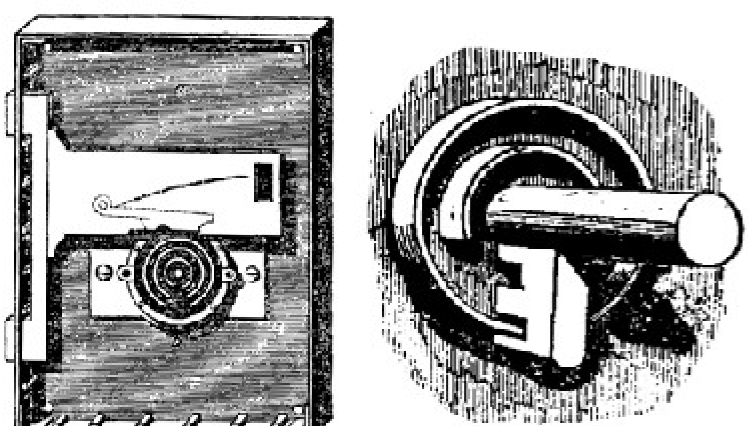
some jails and prisons. Today however, lever or pin tumbler devices have mainly replaced them.

Simple master keying systems have been developed for warded locks. A limited number of different key combinations are available, and thus, keyways may often be varied where many change keys are required. Master (skeleton) keys are designed to pass all different keyways and wards within a particular system.



13_2.0 The Warded Lock: General Operating Principles

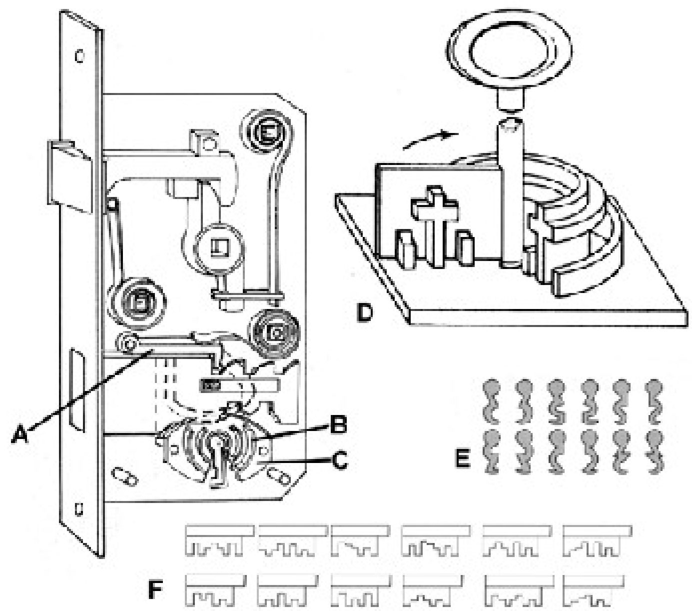
The concept of security in a locking mechanism took root in the development of the warded lock. The ward was thus an extremely important development. Prior to its introduction, security in locks and containers took many forms, relating to exterior devices to block the entry of keys. The ward was the first attempt to internally control which specific key would properly function, after entry into the lock.



All warded lock configurations are based upon the same principle; they have existed with little modification since being invented by the Romans. Wards offer limited security because skeleton keys can be produced for them.

A lock, in its most elementary form, consists of a bolt and a method of throwing it. The warded lock introduced the first refinement to this basic principle. Its designers placed barriers or wards in secret locations within the lock to block the movement of the bolt until the correct key was inserted. Wards may take many forms; however, they all perform the same function.

Within the mortise lock, for example, wards are generally circular raised metal strips and placed concentrically around the keyhole post. They will prevent the insertion of all but the correct key, and until all wards are passed, the key cannot make contact with the bolt. Thus, for the correct key to operate a warded lock, it must have corresponding ward cuts to allow its entry and rotation. This will permit contact with and actuation of the bolt.



The security of the lock lies in the placement and number of the wards. Depending upon the design, there may be few or many of them. Producing locks with different keyways may further enhance security. This will prevent keys with the same ward pattern, but different keyway configuration, from entering the lock.

A B

The much-heralded security of the warded lock was rather short lived, for it did not take long for thieves to learn how to bypass these mechanisms. It was found that they were simple to

pick, impression, and produce skeleton keys that would circumvent all wards.

Exploded view of different keyways.

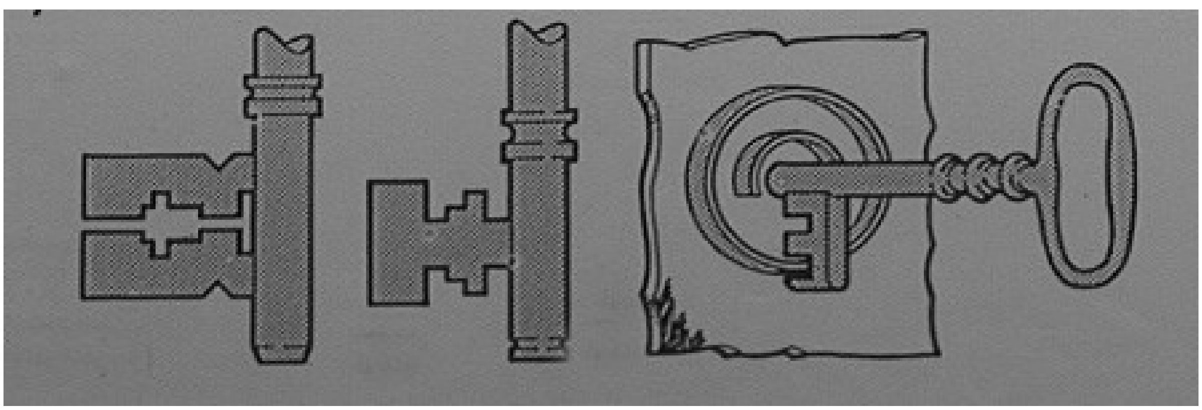


Figure LSS+1310 A detailed view of the typical warded key, and its interaction with fixed wards within the mechanism. For every obstruction within the body of the lock, there must be a corresponding absence of material on the bitting of the key.

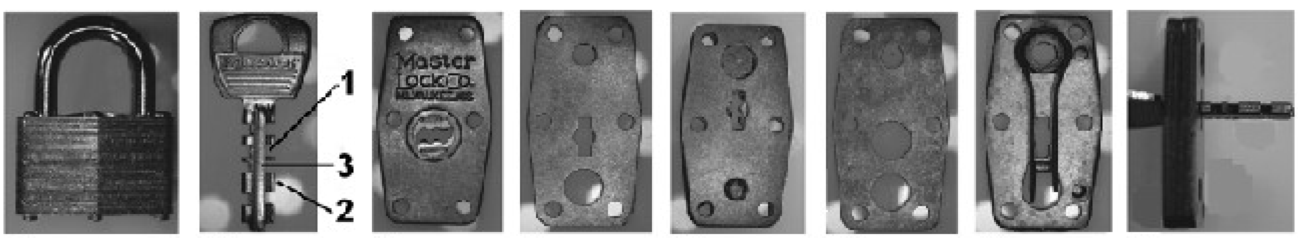
The design of wards within cabinet locks closely resembles the basic design of the mortise lock, although with a less complex key design. The ward configuration for the padlock differs in the relationship between the key and the bolt/shackle-release mechanism. The basic principle, however, is still the same: metal barriers are utilized to keep the key from rotating until



corresponding sections of metal in the key are removed.

13_3.0 The Warded Lock: Basic Design Configurations Operation

Warded locks come in three basic configurations: **padlocks**, **cabinet locks**, and **mortise locks.** Although each design applies the warded locking principle, construction and operation is slightly different for each.

13_3.1 Warded Padlocks

Padlocks probably comprise the largest single use of the warded principle, at least in the United States. Master Lock Company manufactures the most popular warded padlock. It is constructed of laminated steel sheets, which determine the location of wards.

A B C D E F G H

13_3.1.1 Definition of Terms

The principle components of the warded padlock are defined below.

Key: The critical portions of the key are the **bow, blade, ward cuts, and tip.** The bow provides a handle; the blade is the bitting surface; ward cuts are made on the blade; and the tip provides an anchor and reference seating for the key.

Keyway Plate: This round insert actually forms the keyway. It is a stamped piece of metal creating grooves that block entry of all but the correct blank.

Pass Plate: This lamination allows an uncut key to rotate without obstruction. The plate simply has a hole cut in the center, in contrast to the **ward plate** which actually blocks rotation of all but the correct key.

Ward Plate: This piece will block rotation of a blank key. In order to rotate around the ward plate, the key must have a corresponding cut.

Tip Stop and Guide Plate: This component is located at the far end of the keyway and is the last plate to make contact with the fully inserted key. Its purpose is to center and stop the key.

13_3.1.2 Specific Principles of Operation

Several wards or obstacles form part of the body of the lock and act as a blocking device to the key's rotation. When the proper cuts are made, the key is allowed to turn and release the shackle. The compression of one or more spring steel bands retains the shackle in a locked position. The bands are spread when the key rotates, thus allowing the release of the shackle. There can be any number of wards placed in the padlock, enabling the manufacturer to offer many different key combinations. The keyways can also be varied, thus adding to the number of differs.

Wards are formed using ward plates stacked between pass plates. The ward plates conform to the dimension of a blank key in terms of the overall width of the blade. An uncut key is prevented from rotation until an equivalent thickness of metal is removed from the bitting, at the precise location corresponding to the position of the ward. The key will turn and release the shackle if:

- **A cut corresponding to the position of each ward is made on the blade;**
- **The key makes contact with each locking band and is free to spread them to a greater diameter than the shackle. There may be up to three spring wires or bands that hold the shackle in place.**

13_3.1.3 Keys for Warded Padlocks

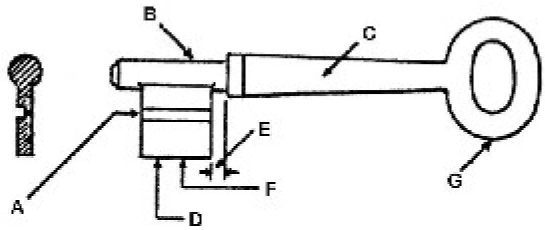
The design of the padlock allows the use of skeleton keys to bypass all wards and open every mechanism. Keys for warded padlocks are either single or double sided. Double-sided patterns are normally symmetrical, so the key may be inserted and rotated in either direction to open. The keys usually appear in the form shown. Note the square cuts match the size and position of each ward.

Warded padlocks are often used outdoors and may be subjected to environmental changes without adverse impact. The simplicity of the mechanism makes them quite reliable in difficult conditions. Although warded padlocks have strong shells or casings, these have no effect upon their resistance to picking and impressioning. Their heavy protective coverings may shield them in the case of brute force attack, however.

13_3.2 Cabinet Locks

Warded mechanisms are used in cabinet and drawer locks. These operate on the same basic principle as those found in mortise locks. They offer little security and are really a convenience lock. A long post, having a hollow or pointed end with a rectangular piece of metal secured to it, characterizes the key. The pin, which projects from the center of the lock, acts as an anchor for the key and for an axis upon which the key rotates. In this type of mechanism, the wards take the form of spring steel wire set around the central pin. To allow rotation, the key must have slots cut to fit over and pass these wards.

13_3.3 Mortise Locks for Residence and Hotel



In many parts of the United States and throughout Europe, warded locks were widely used in hotels and residences. The basic design is that of the cabinet lock, except that the mechanism usually has a greater number of wards to pass, which are physically larger. There were actually two varieties of warded locks for this application. The simpler design featured different keyways as the only block to actuation of the bolt; any key having the proper keyway could move the bolt. In the more secure designs of the mortise lock, keyways could be varied as well as the position of wards.

The mortise **lever** lock would replace the warded mechanism in many parts of the world, dating back a hundred years or more. Keys for warded and lever locks can appear in exactly the same configuration. Without an examination of the internal components, if may be impossible to tell the difference from the exterior. Attempts at picking and impressioning will indicate the tumbler design.

13_3.3.1 Definition of Terms

The following terms describe the actions and components of the

warded mortise lock.

Barrel Key: A barrel key or pipe key is constructed with a long hollow shaft to the tip, where the bitting is attached to the barrel. The barrel rotates around a pin, protruding from the center of the keyway. The pin anchors the key and maintains its position once inserted.

Bit Key: This describes a key with a bit projecting from its shank, in contrast to the barrel key that has a hole in the end of the post.

Bow: The portion of the key that forms a handle.

Bullet or Bulleted: The longitudinal grooves on the bitting of a warded key that match grooves in the keyway. A key that does not have such correspondingly shaped grooves will be prevented from entering the lock.

Collar: The flange or projecting rings on the shank that prevents the key from being pushed through the lock.

Collar Ward: The ward that surrounds the circular portion of the keyway, and provides for a bearing surface for the tip of the key.

Drill Pin: A fixed stump or pin within the lock on which a pipe key fits in order to allow rotation.

Key Bit: That part of the key that enters the lock and meets the wards.

Key Blank: A key, having the correct keyway, which has not been cut and which may be shaped to fit a particular lock.

Mortise Warded Lock: A warded lock inset into a door.

Nib Ward: The simplest type of ward and which is formed by making

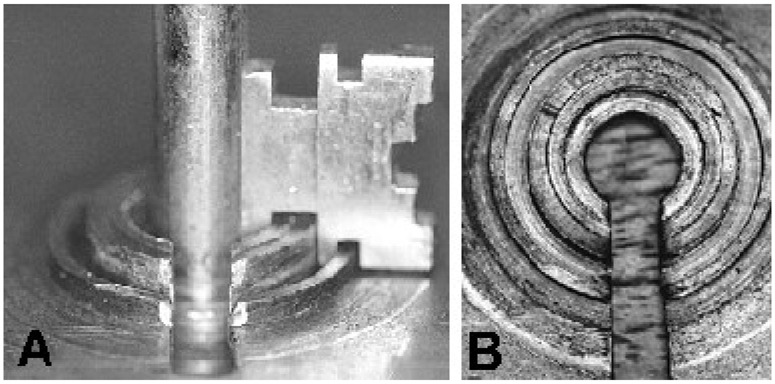
a depression on a metal plate. A plain slot in the bit of the key will pass the ward.

Pin of Key: A key with a solid circular shank and projecting bit. When inserted into a warded lock, it rotates around the shank.

Pipe Key: Same as **Barrel Key**.

Rotating Wards: These are made of steel wire and are placed in a circle around the keyway. The correctly-cut key moves over these wards.

Shank or Stem: The long stem connecting the bow with the bitting of the key.



Skeleton Key: A key with much of its bitting removed in order to pass all of the wards and thereby allowing actuation of the bolt.

Ward Gauge: A device to measure ward depths for a particular key. This can take the form of a strip of metal that is cut with the different ward depths in ascending order. The ward gauge is utilized to reproduce keys.

Warded Key: A key having notches or cuts to correspond with ward locations within a lock.

13_3.3.2 Theory of Operation

The warded mortise lock operates on the same general principle as the padlock. Wards are placed internally, to form an obstacle to insertion and rotation of the key, until they are passed. These wards generally take the form of raised metal strips, which are concentrically placed around the keyhole post. To clear these obstructions, the bitting must be cut so the wards can pass through the square-shaped slots in the key. Until all wards are passed, the key cannot make contact with the bolt.

13_3.4 Handcuff Locks

Many handcuffs use a very simple form of warded lock, employing a keyway with a post. The key rotates in order to release a ratchet mechanism. These locks may be easily bypassed. Ball-point pen cartridges, paper clips, pieces of wire, and anything that can simulate the shape of the key will work if the mechanism has not been double-locked. The more inexpensive handcuffs can also be pried apart, by applying pressure at the pivot point where the halves are joined together. In addition, a fine metal shim may be utilized to bypass the ratchet mechanism. See **Chapter 23**.

13_3.5 Jail and Prison Locks

Many prisons and jails throughout the world are still using the warded lock. They are massively constructed but operate on the same principles as other warded designs. The keys are very large and difficult to duplicate. Attempts to pick these locks usually include the use of large objects such as spoons, ice-cream sticks, tooth brushes, etc.

13_4.0 Producing Keys for Warded Locks

It is never necessary to take a warded lock apart to produce a key for it. There are a number of techniques for learning the location of the wards. These methods are described in **Chapter 30**, "Impressioning." Regardless of design, all keys must perform the same function: pass all wards to allow entry and rotation, to actuate the bolt.

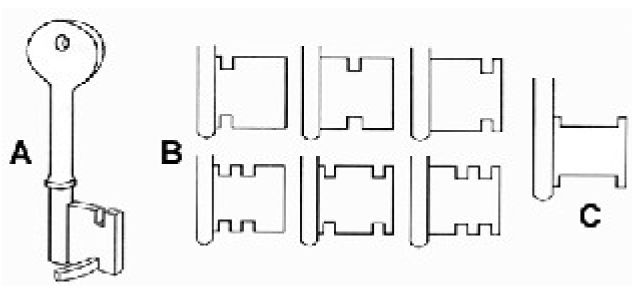
13_4.1 Pipe Key

In the **Pipe Key**, the stem is the hollow part connecting the bow with the bitting portion. The pipe will fit over a corresponding post in the lock. If the stem is solid, it will seat in a corresponding hole in the center of the lock. The bitting or bit is the "working" portion of the key. All bits are essentially rectangular and cut in steps, corresponding with the ward positions. Square slots are made on various surfaces of the key to pass the wards. A Warding file is used for this purpose.

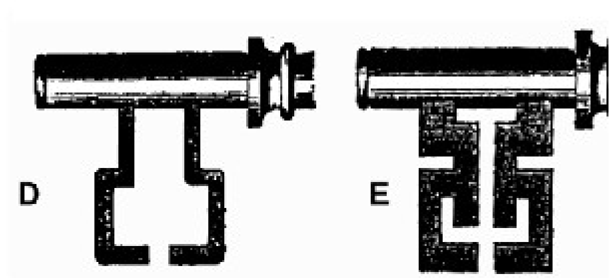
Little precision is required when cutting warded keys, if the goal is simply to allow the key to open the lock. This is because wards are affixed to the shell or casing. Therefore, as long as the cuts on the key are wide and deep enough to pass the wards, the key will be able to turn and operate the bolt. So it doesn't matter if the key is cut too deep or too wide; the mechanism will still operate. The poor tolerance required of the keys contributes to the locks rating as a low- security device. Skeleton keys can be created which will open all warded locks by simply cutting away **all** of the bitting, except for that area required to come into contact with the bolt.

13_4.2 Padlock Keys

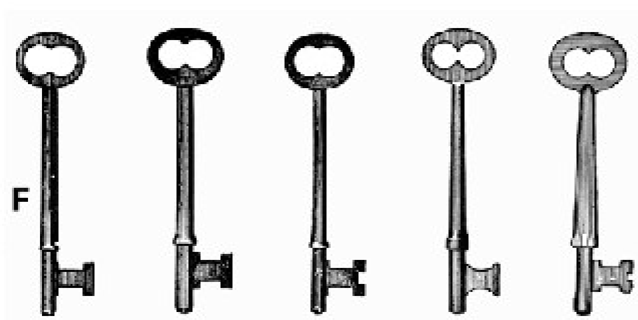
Warded padlock keys are all similar in appearance. They are cut on both sides in symmetrical form. The Master padlock is typical of such mechanisms. A set of five skeleton keys will open virtually every one of these padlocks.



13_4.3 Specialty Warded Keys



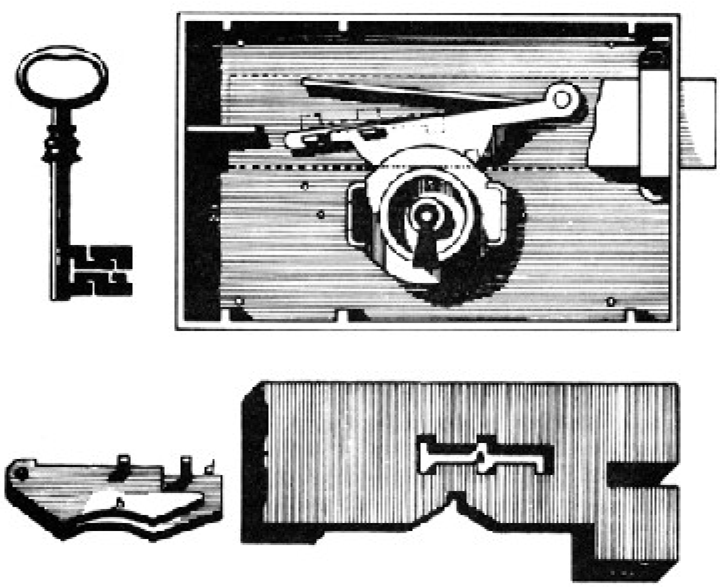
There are thousands of variations of warded keys for luggage locks. There are a number of catalogs available to locksmiths that offer precut luggage, cash box, mailbox, and other keys. For certain types of trunk keys, there is a master book that was originally printed by Bernard Zion in the 1930s, by Majestic Lock Company. This catalog has become the sourcebook for these types of keys. Locksmiths simply traced the design from the drawings.



13_5.0 Security of the Warded Lock

Warded locks do not provide any level of security due to the ease in determining the location and number of wards, as well as the simplicity in picking and impressioning. Their entire security is based upon the hidden location of the wards and variations in the keyway. A maximum of approximately one thousand different change keys may be available for any particular keyway series. Key combinations cannot be changed. This means that if a lock has been compromised, as in the case where a key has been lost or an unauthorized key has been obtained, the lock simply must be taken out of service. A patent was granted to Soref in 1927 for a modified design of a skeleton key (**1645407(147)**) which the inventor called a master key. See also Pankratz for his 1921 patent of a skeleton key and method of removal of a warded key from one side of the lock (**1370552(148)**).

CHAPTER FOURTEEN: THE LEVER



The Lever Tumbler Lock

Master Exhibit Summary

14_1.0 Introduction

This chapter examines the development of the lever lock, initially introduced during the Renaissance. It traces its subsequent evolution and refinement over the next two hundred years. The fundamental lever principle marked the first real innovation in secure mechanical locking design; it vastly improved upon the warded lock described in the previous chapter.

Usually constructed of brass, aluminum alloy, zamak, or steel, the lever tumbler lock can be found in many different applications, meeting varying security requirements. These locks are popular in padlocks, post boxes, coin telephones, safe-deposit boxes, lockers, safes, cabinets, cash boxes, jails and prisons, and other uses. The lever signaled the introduction of the first locking mechanism that offered a basic design change from the warded lock. It provided the conceptual framework for many improvements and variations during the next two centuries. The lever mechanism, by its inherent design, made possible the development of truly secure locks that would have been impossible using wards.

The lock's history and significant technical advances are chronicled here because of their impact upon the field of locksmithing. Their cumulative impact upon the lever, wafer, and pin tumbler mechanisms cannot be underestimated. A careful analysis of many of today's locks and locking concepts will show they are but variations of the original lever principles. An examination of the lever lock, from the perspective of picking and impressioning, is presented in **Chapters 29-30-31.**

14_1.1 Development of the Lever Lock

Many engineers, scientists, metal workers, and craftsmen played vital roles in the evolution of the lever lock. Barron, Chubb, Bramah, Hobbs, Newell, Andrews, Petit, Parsons, and many others will always be remembered for their ingenious contributions, culminating in the high-security lever devices available today. These men challenged each other and the world to continually develop more security. Their rivalry led to the most important design developments in 3000 years. Perhaps the greatest catalyst was A. C. Hobbs, the American locksmith who galvanized the London Exhibition of 1851, by picking the impenetrable Bramah lock. The race to design a better lock was now at a feverish pitch; the lever was one product of that impetus.

14_1.2 The Lever Lock: Initial Concept and Design

With the exception of the Egyptian pin tumbler, most locks prior to the eighteenth century relied upon a system of wards as described previously. Around the middle of the nineteenth century, the Willenhall locksmiths recognized that warded locks could be easily picked or otherwise bypassed. An alternative was required. They were searching for a mechanism that could not easily be opened, even if the burglar knew the internal design of the lock. The lever provided the concept that offered security against picking and other forms of compromise. Actually, the true benefits of the design were not completely recognized during the Renaissance.

Although we do not know who first developed the lever concept, it is clear that it was produced in response to the ease with which the warded lock could be compromised. There is a reference to the lever in an 1819 British patent, although its precise origin is unknown. Whatever the source, the introduction of the lever caused a revolution in lock design.

14_1.2.1 Banbury Lock

It appears that Banbury introduced the actual forerunner to the lever lock about 1700. In his design, the key raised the lever from a notch in the bolt, allowing it to slide and permitting a catch to fall into a second position. The bolt was then forced forward. The height of the lift was immaterial so long as the

notch was cleared. These locks were made of wood, with metal parts inserted in slots cut into the housing. The first designs had few parts. They consisted of the case, bolt, and lath, which was a piece of metal that formed a continuation of the bolt. The bolt head and the talon, or angled cut in the bottom of the lath, completed the mechanism.

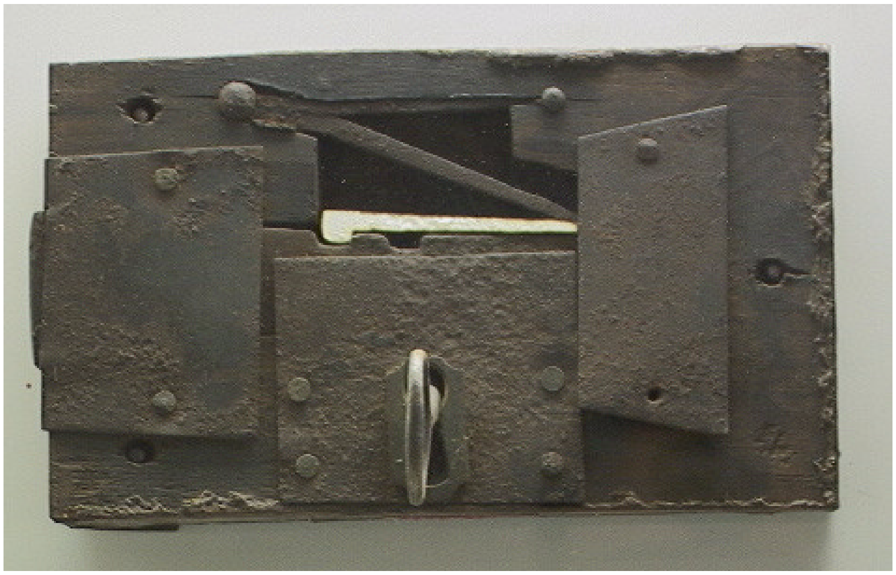


Figure LSS+1401 The original Banbury lock.

14_1.2.2 Barron Lock

In 1778, Robert Barron, an Englishman, conceived, patented and produced the **double-action** lever lock and is credited with its invention. The lock was the first mechanism to offer any significant security against picking, resulting from its design and high manufacturing tolerance. As will be noted in **Chapter 29**, the Barron lock did suffer from certain design defects with respect to picking.

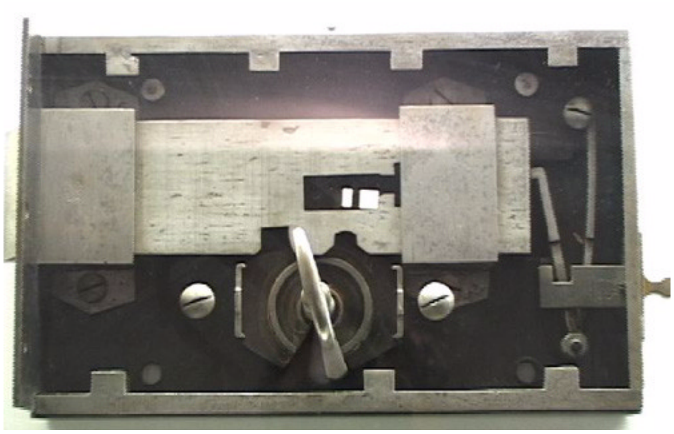

Figure LSS+1402 The original Baron lock.

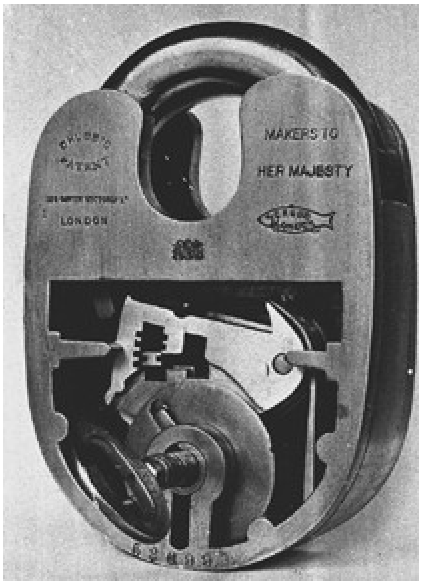
Levers were not only used to secure the bolt but to surround, hold, and block its movement until the correct key was inserted. This feature distinguished the lock from its predecessors; originally, the purpose of the lever was to hold the bolt in one position. Ultimately, several levers would be added; this eliminated the use of tricks and false patterns that were common with warded locks.

The Barron lever lock is important for several reasons. Although there were earlier designs that used a bolt containing a stump to block movement, Barron actually conceived the double-action technique. This, combined with the use of two or more levers, (each of which had stumps on their end), provided the beginning of real security and fundamental changes in design. The stumps were required to pass through a slot on the bolt latch when in their correct positions.

The bolt of the Barron lock was cut with a gate or squarenotch behind which were two or more levers. Each lever end had a square corresponding projecting stump that would stop the bolt from moving. When the correct key was inserted, it would lift all of the levers until their stumps cleared the notches. The key could then be rotated further, to slide the bolt. If any of the stumps were positioned either too low or too high with respect to the levers, the bolt was held fast and the lock could not be opened.

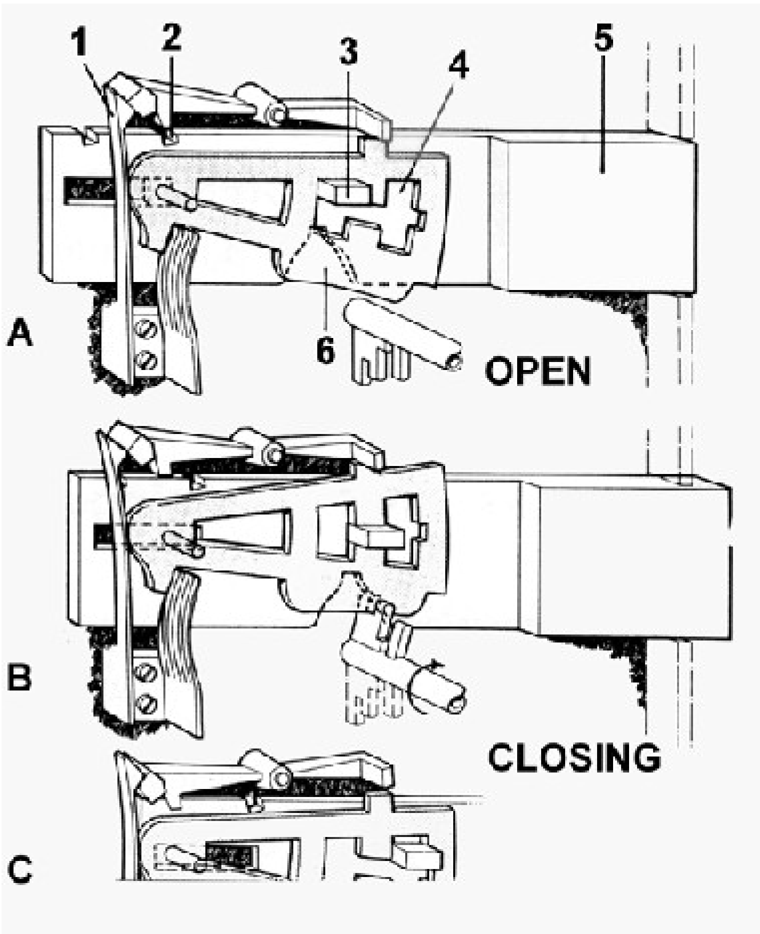
The double-action concept is readily understood when it is realized that if the tumbler either was under or over-lifted the stump could not pass. There were two claims in the Barron patent: one dealt with the location of the lever with regard to the stump; and the other, the projection of the bolt through the



lever. Refinement of the Barron patent is evident in every lever lock in use today.

14_1.2.3 Chubb Detector Lock

The Chubb family of Wolverhampton made many vital contributions to the development of the lever lock. Charles and his brother Jeremiah eventually opened a lock factory in 1818, after patenting their immediately successful Detector lock. This facility is still in existence and is a world leader in the development and production of locks and safes. Even by the end of the nineteenth century, their products were known and respected throughout the world.



Prior to their entry into the lock-manufacturing business, the brothers, in 1804, had opened an iron-mongering enterprise in Portsea, England. There, they gained valuable experience in metalworking that would prove decisive in their later development of locks. Jeremiah analyzed the revolutionary Barron lever lock and found deficiencies in its design. As a result, the lock that Chubb first offered was quite different in practice from that patented by Barron, although the locking method was essentially the same.

In the Barron lock, the gate was incorporated within the bolt, allowing multiple stumps that were part of each lever to pass through it. In other words, stumps or projections were located at the end of each individual lever, at different vertical positions. They were aligned to one horizontal plane by lifting each lever to a different height through the action of the key and its varying depths.

Chubb decided that the locking process should be, in effect, reversed from that conceived by Barron. Chubb placed the gates on each lever with one corresponding stump on the bolt, rather than placing stumps at the end of each lever with one large gate in the stump. The locking action of Chubb and Barron are functionally the same. In the Chubb design, the gates form part of each lever. All levers must be individually raised to clear the stump, which is affixed to the bolt. It can be seen that the bolt can only slide if the stump is clear to enter all of the gates within the levers.

Chubb is best remembered for the introduction of the **detector**, around 1827. This was a special device fitted on certain locks to increase security. It provided notice of attempted entry caused by the use of the wrong key or by picking. Chubb determined that to open the lock in either case, the thief would be required to sequentially lift each lever to its proper level. In doing so, over-lifting usually would occur. There have been a number of modern improvements in lever lock design that were based upon the original detector theory. Chubb was granted a patent in 1993 for example, for a similar mechanism (GB **2264531A(149)**).

The purpose of the Detector would be to react to and record this over-lifting. It did so by locking an added lever into a special position within the bolt, which would block movement of all other levers and prevent the bolt from moving. Over-lifting of any lever above the drop-in point of the stump into a gate would trigger the Detector.

The Detector would warn a lock owner of any attempt to open and made picking virtually impossible. A special key was required to reset the Detector once triggered in order to allow the lock to be opened. In 1878, Chubb also introduced a double-sided detector latch that incorporated notched or serrated levers. This further frustrated picking attempts. Saw teeth placed in the ends of the levers that would mesh if raised improperly were also employed. Serrated levers are in wide use today in high-security applications.

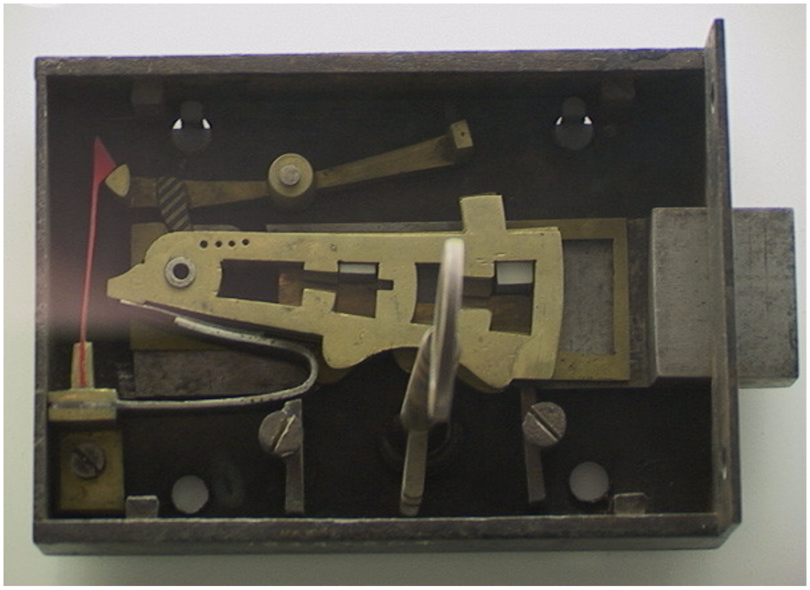


Figure LSS+1403 Chubb Detector lock, 1827 design.

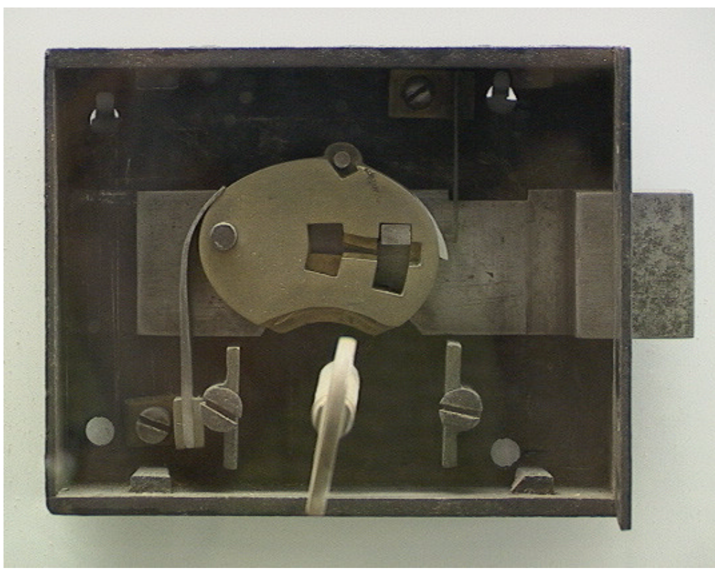

Figure LSS+1404 Chubb Detector lock, 1837 design.

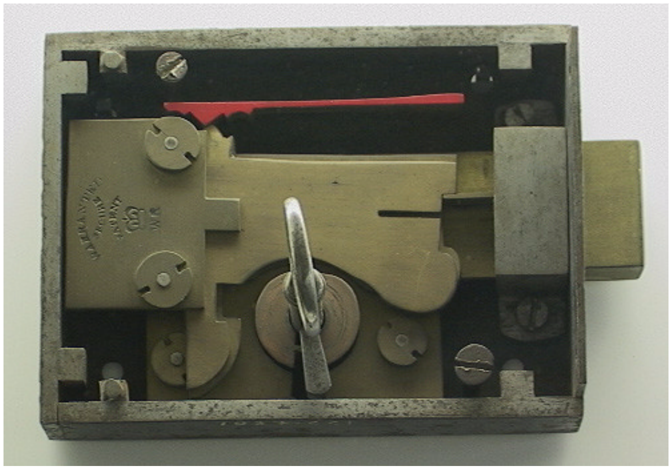

Figure LSS+1405 Chubb Detector lock, 1837 design. Note the detector arm that locks into place upon overlifting (in red).

14_1.2.3.1 Picking the Chubb Detector Lock

Chubb developed an anti-picking curtain after his lock was compromised with a lighted taper that was employed to smoke the levers. The technique is discussed in **Chapter 30.** Chubb realized that once the levers were covered with carbon, a blank could be inserted and rotated until contact was made with each lever. The points of contact could then be read by inserting a small mirror on the end of a wire with a finely focused light. It was easy to see where the bitting had contacted the bellies of each of the levers.

Through smoking, the lock picker now had vital information. He knew where the key would make contact and where the key would begin lifting each lever. With practice and patience, the levers could be lifted to the correct level without tripping the Detector. In 1883, Chubb provided the solution: the rotating barrel and curtain. This simple invention closed the keyhole when the key was turned, preventing both the insertion of a picking tool and the feeling of the interior of the lock. Security against picking and impressioning was greatly enhanced.

14_1.2.4 Tucker and Reeves Shifting Bolt Lock

Patents were issued to Tucker and Reeves, first in 1851, for a shifting bolt lock. This device was specifically designed to frustrate picking attempts that relied upon a technique of placing back pressure on the bolt. In their lock, they made the bolt so that it floated to allow one end to rise and fall. If

pressure were applied, the bolt would shift up and down, making it difficult to determine when each lever was raised to the correct level.

A second patent was granted to these inventors in 1853 for their Safeguard Lock. Four wheel-shaped levers were mounted and rotated around a central pin that was enclosed in a moveable barrel that formed the keyhole. The key actually entered the lock through a second keyway that was offset from the operating keyhole. The design of this lock made it impossible to insert picking tools to reach the levers, because the stump on the bolt could not enter the gate until the key turned the moveable barrel. Any picking attempts utilizing pressure would be frustrated.

14_1.2.5 Subsequent Refinements

Three inventors developed further refinements to the original detector lock. In 1852, a patent was issued to **Hobbs** for his six-lever protector lock. It had five traditional levers, with the stump mounted on another lever on the rear of the bolt that could not be seen. Picking would cause pressure to be applied to the bolt, triggering the sixth lever horizontal-arm to jam the action of the bolt.

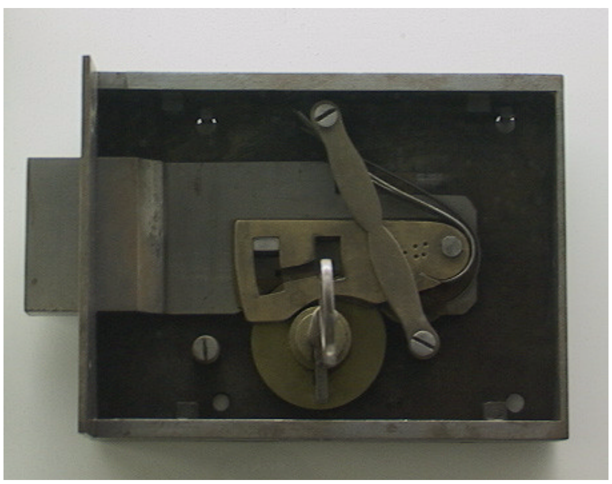

Figure LSS+1406 Hobbs six lever protector lock.

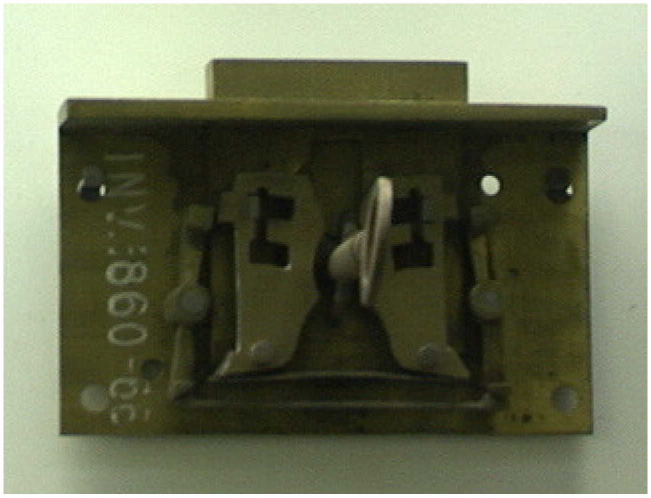
Then in 1859, the **Hamps** double-action lever Detector was introduced to improve upon the Chubb invention. The lock had two sets of four levers operating in tandem. The Detector worked on both sets of levers, thereby increasing security.



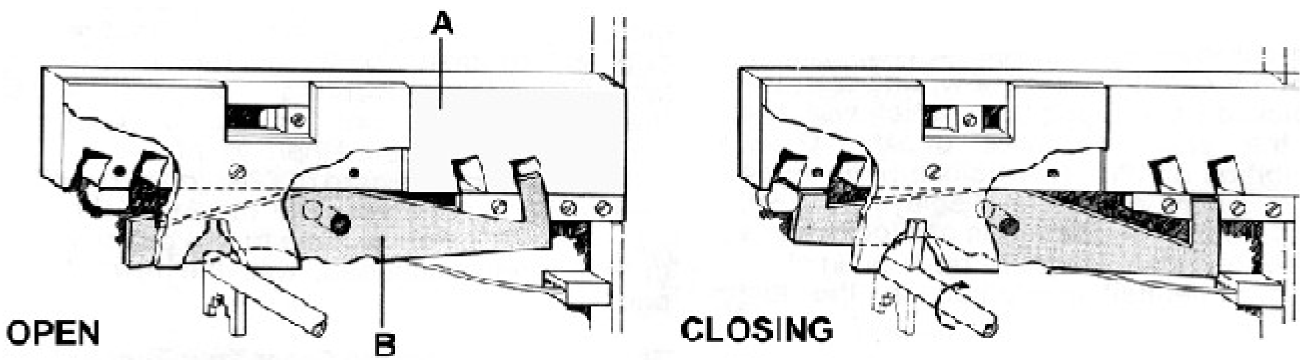


Figure LSS+1407 Hamps double-action detector lock, circa 1859.

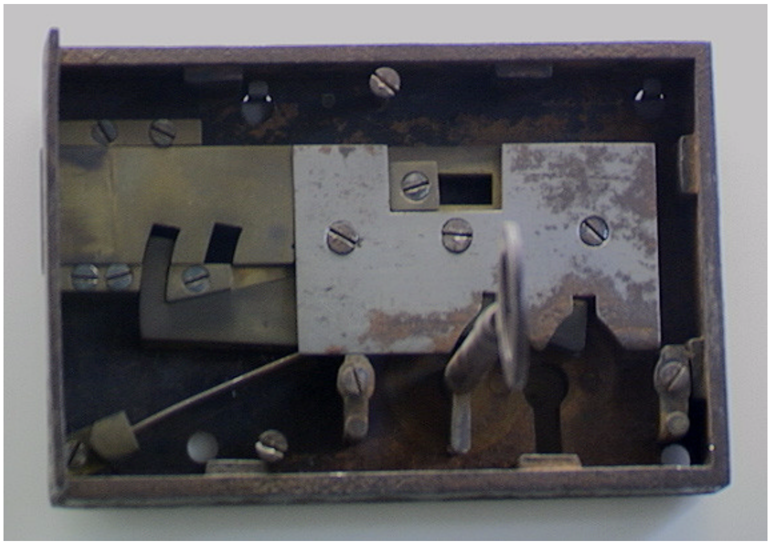
Parsons produced his balanced lever lock in 1832, adding several innovative security features. In this device, the levers pivoted at their midpoint. The talon, with which the key engaged in order to slide the bolt, would hide the right arms of the levers.

When the key was turned, the lever arms were lowered, thereby disengaging the bolt. If any of the levers were raised too much by use of a false key or pick, the arm would be hooked into the bolt to immobilize it. This lock had seven levers. There was also a second keyhole, used when a key was inserted from the other side. The key would actually meet a second set of bellies.



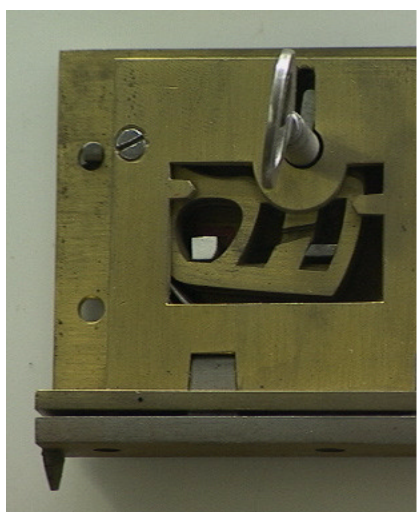


Figure LSS+1408 Parsons balanced lever lock, circa 1832.

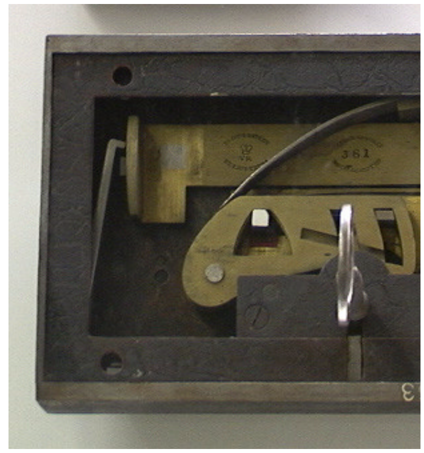

George Price was a master locksmith, inventor, and manufacturer who lived near Wolverhampton. In 1859, he introduced and patented the **ne plus ultra** Lever Lock. This design incorporated a special plate that would tilt slightly when picking was attempted, thereby inhibiting movement of the bolt.

LSS+1409 Examples of the Ne Plus Plus lock designs by George Price. Price was one of the most famous locksmiths and inventors of his era. These mechanisms were developed around 1859.

Price is also remembered for his treatise, ***Fire and Thief Proof Depositories***, written in 1856. This classic work has been revised by the author and is contained within this Infobase. Price also developed a **lock** to resist attack through the use of gunpowder blown into the lock case.

The lever mechanism, through almost two hundred years of development and refinement, can meet today's varied needs. Its design is simple, yet it can provide very high-security. The original lever concept has fostered the creation of locks based upon the gate and fence theory. The S&G combination lock, the Briggs and Stratton sidebar lock, and the Abloy wafer lock are but three examples of the clever utilization of the lever principle.

14_2.0 The Modern Lever Lock

This section details principles of operation, keying, and key systems of the modern lever lock.

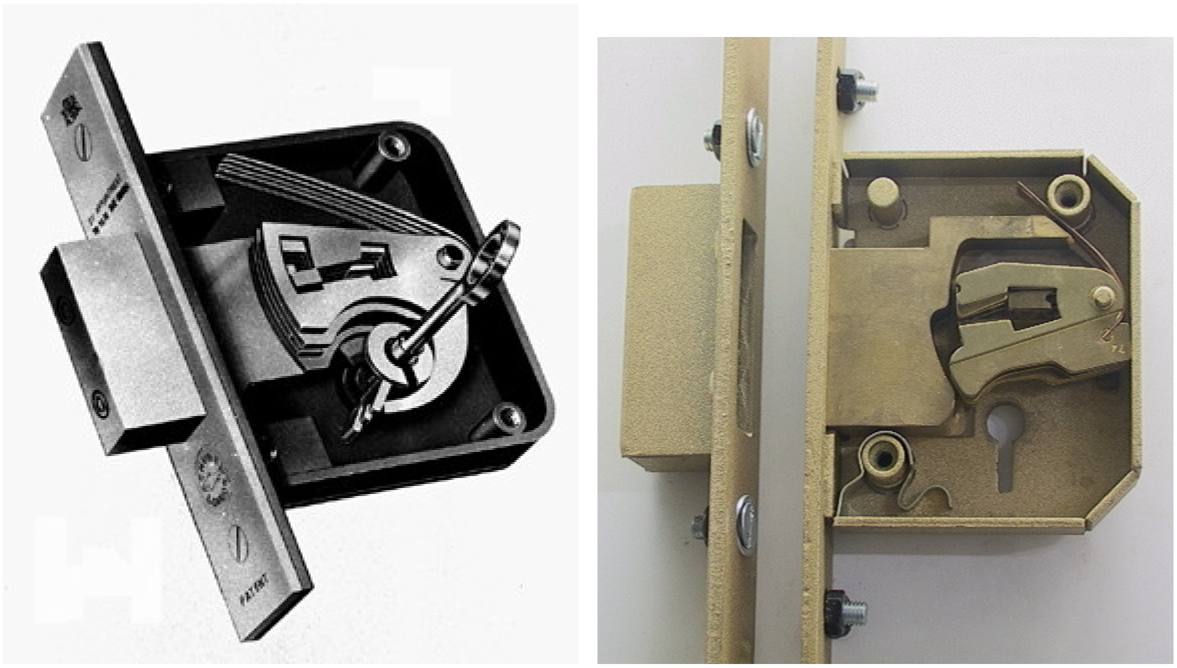

Figure LSS+1410 Chubb seven lever mortise lock, circa 1995.

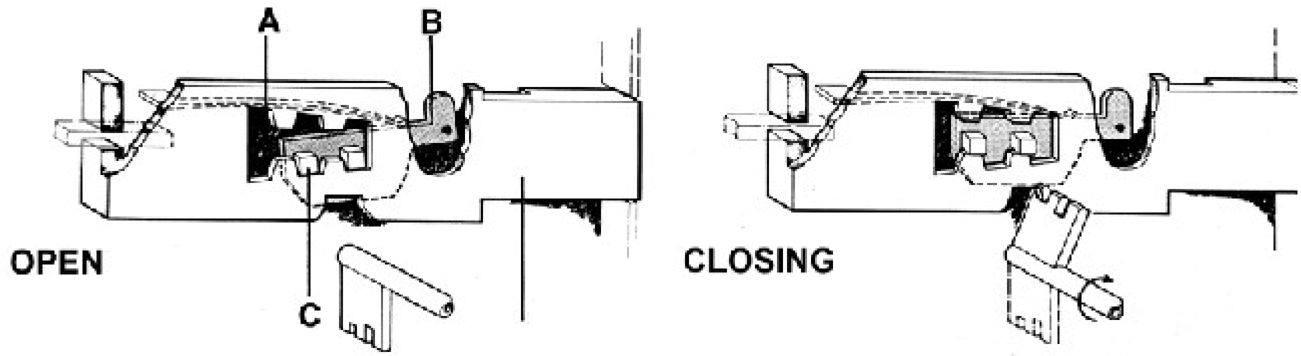
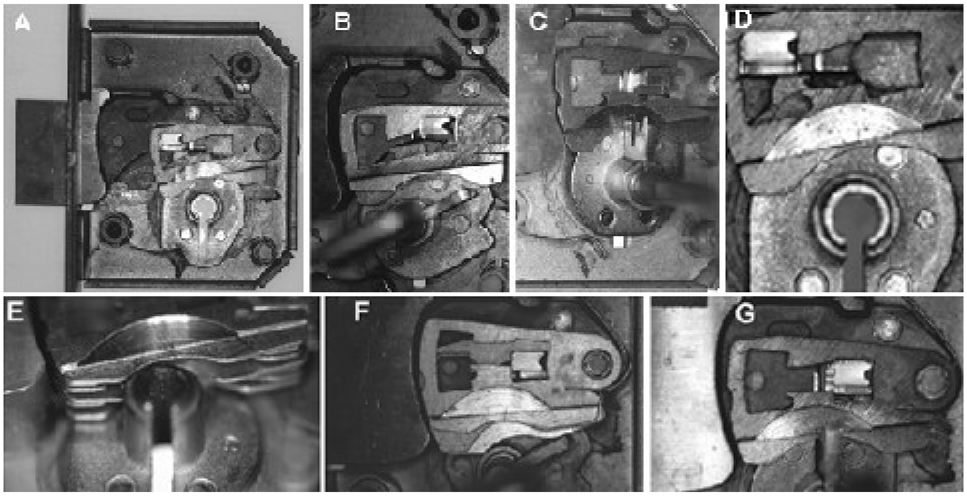


14_2.1 Principles of Operation

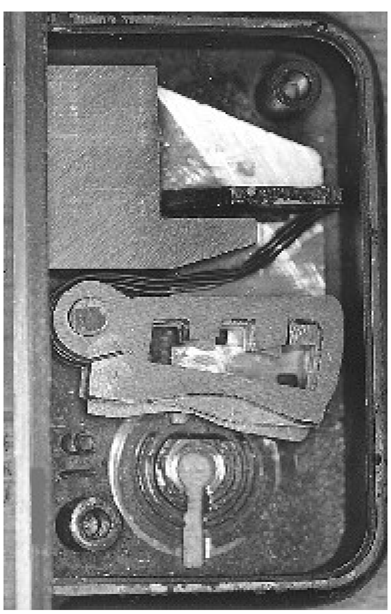
The basic principle of operation relies upon the movement of one or more levers in conjunction with a stump attached to the bolt. As will be demonstrated in later chapters, the lever lock operates upon the same theory as the combination lock used in safes and vaults. The only difference is that the levers do not **rotate** but **pivot** about a fixed point. Essentially, **any** mechanism employing a moving fence and gate scheme is operating in similar fashion to the original lever lock. The purpose of the lever is to block movement of the bolt until it is lifted to a precise position. A lock having one or many levers operates in identical fashion; only the security is affected.

Generally, an inset pin to one side of the lock anchors the lever tumblers. It allows the tumblers to move or swing in a vertical direction and acts as an axis point. In order to keep the levers in a "locked" position, pressure is applied to each by means of a spring steel wire projecting from the tumbler and working against the shell or housing.

The bolt mechanism contains a vertical metal bar, called a fence or stump. It is set so that when the levers are in a locked position, horizontal movement is blocked by the lead edge of each



of the tumblers. In order for the bolt to be retracted to the unlocked position, it is necessary for each of the lever tumblers to be simultaneously raised to a point where all of their gates are in precise vertical alignment. This will allow the fence or stump to pass **through** the gates.



The security of the lock is based upon the "double-action" locking principle: each lever must be lifted to the precise point where the stump "fits" into its corresponding gate within each lever. If one or more levers are out of alignment with the stump, the bolt cannot move and the lock cannot be opened. This double-action design distinguished the lever mechanism from the warded lock, and signaled a fundamental change in the thought processes involved in designing locking mechanisms and in the concept of locking.

Double-action means that a lever cannot be over or under-lifted, if the lock is to be opened. Rather, each lever must be lifted to the precise point for the gate to accept the fence. Security in this lock is thus a function of the number of levers, the dimensions and designs of the gates, the size of the fence or stump, and corresponding tolerance between gate and fence.

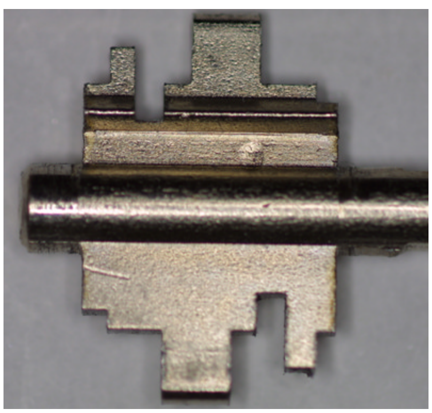
The **key** performs two critical tasks. It lifts each lever to the correct position, and it forms the mechanical link to slide the bolt once the fence or stump is able to enter the gates. The bitting of the correct key is cut to correspond to each lever. Depending upon the vertical position of the gate, the key will lift each tumbler so that its gate is placed at the same horizontal location when lifted.

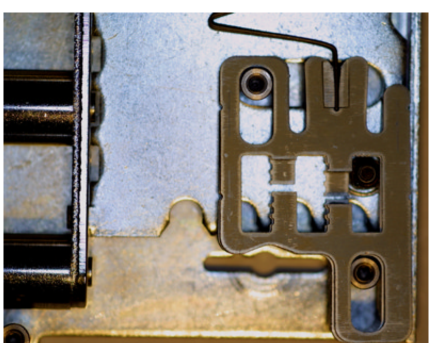
When the proper key is inserted, the bitting will cause an alignment of all of the gates. As the key continues to rotate, the tip is mechanically linked to the bolt, driving it either to a locked or unlocked position. The bolt is able to travel freely because the stump or fence is not blocked by the edges of the levers. The key is prevented from being withdrawn while any of the levers are engaged. It can be seen that different key combinations are created by the use of tumblers having their gates located in different positions. A tumbler having a high slot will require a key that raises the tumbler only slightly, whereas a tumbler with a low slot or gate requires a key with a relatively high cut.

14_2.1.1 European Lever Lock Design

A variation of the standard lever lock design has been developed in Europe. This modification features a double-bitted key, and allows for insertion in a bi-directional manner; that is, the lock can be actuated from either side of the door. These mechanisms require two distinct sets of bitting within each lever to allow multiple bolt extensions. As the key is turned to extend or retract the boltwork, the opposite side of the key comes into contact with the bellies and requires gates at corresponding positions.

In the photographs below, a Jewel eight-lever lock is shown. There are two distinct sets of levers, with the actual bolt separating them. Each time the key is turned, the moving bolt is advanced or retraced to the opposite gate position. Specific tools have been developed to pick, impression, and decode these types of locks. They are described in **Chapters 30** and **Chapter 31.**





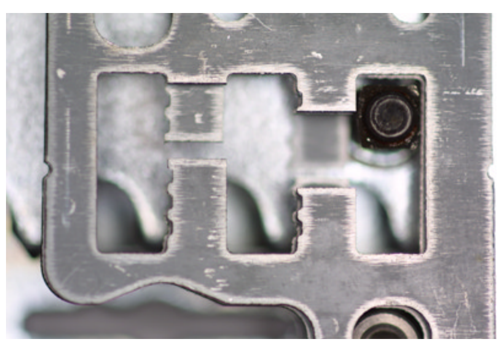


Figure LSS+1411 A European lever lock requires that are two bitting surfaces. These will make contact w distinct sets of bellies.

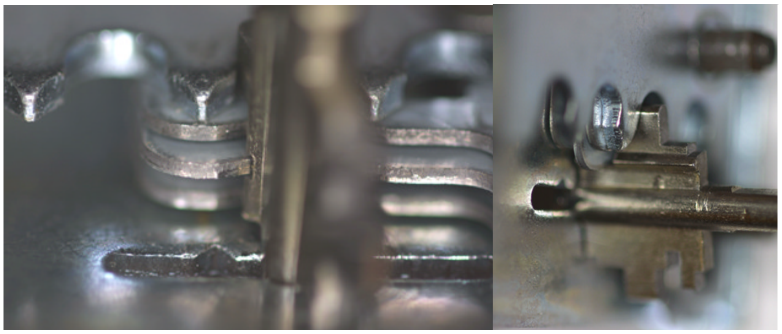

Figure LSS+1412 A European lever lock contains two distinct groups of levers to mate with the bitting on each surface of the key. The groups of levers are separated by the bolt. Each lever will have two separate gates. The photographs, from left to right, show a single lever tumbler with the fence to the extreme right. In the second photograph, two tumblers are shown. In the third and fourth photographs, the interaction of the key and the tumblers is shown. Note how the flag drives the bolt. These photographs were taken of a Jewel eight lever lock.

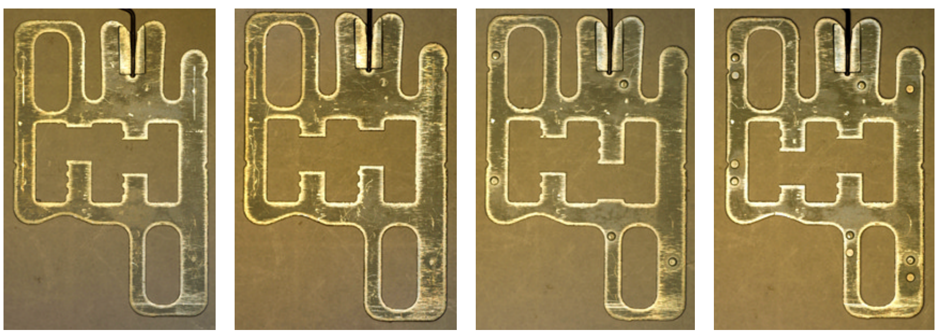

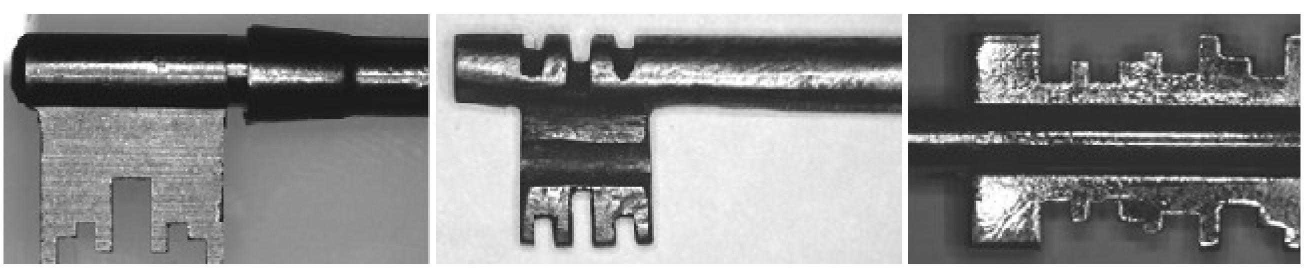

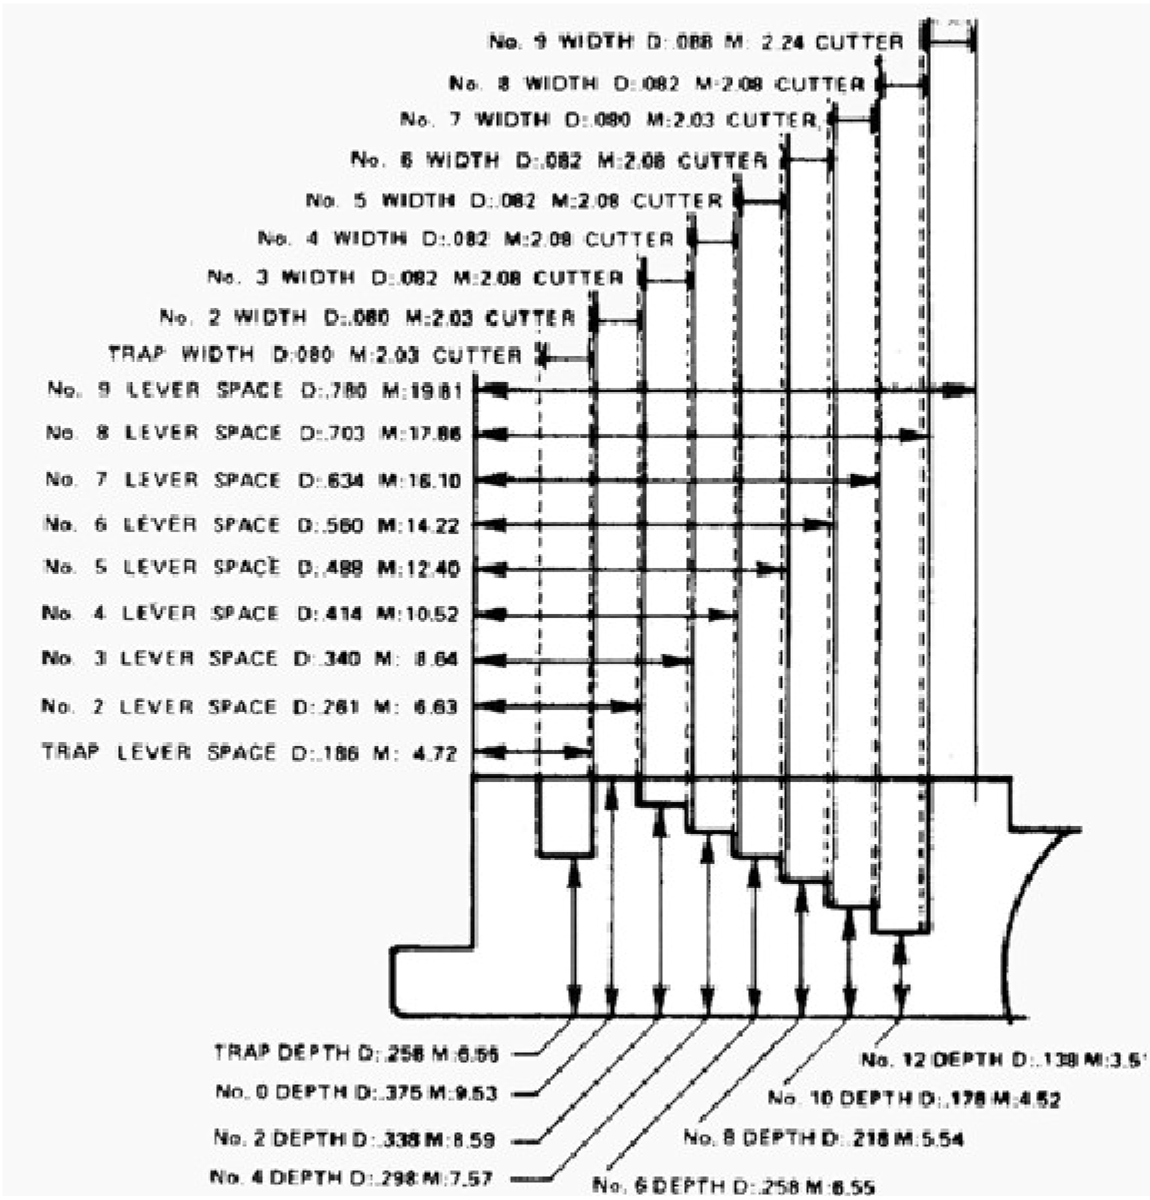

Figure LSS+1413 Four different levers from a Jewel European lever lock. Note the differences in gate configuration between each of the tumblers, and within each of the gatings for each tumbler. There are two separate gatings for each lever tumbler.

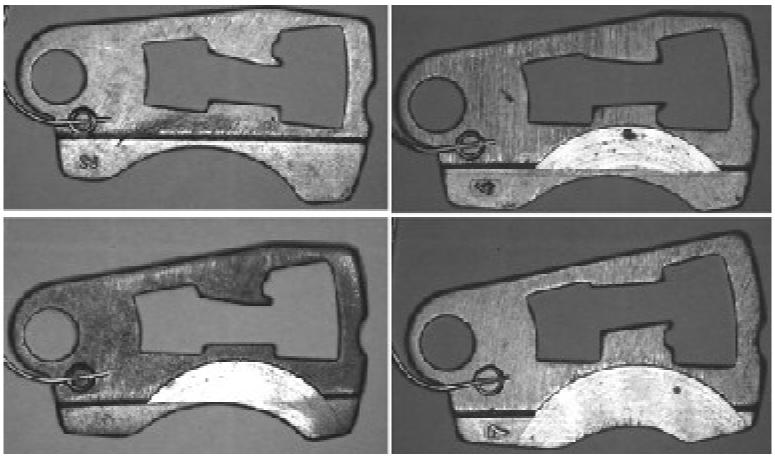
14_2.2 Keys and Keying Systems for Lever Locks

14_2.2.1 Key Combinations

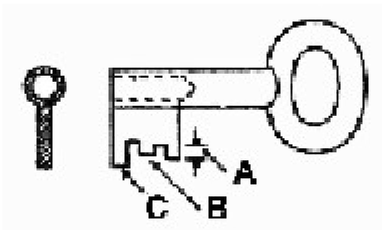


The number of tumblers found in lever locks varies from two to ten or more, contained within one or two tumbler packs. In addition, there are usually four to six different possible depths available for each tumbler. This allows for a large number of different key combinations.

14_2.2.2 Changing Combinations

Combinations can easily be changed by removing all of the tumblers and reinserting them in a different order or by

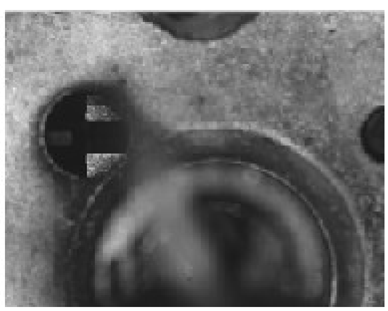
replacing them with new levers. In either case, making a different key operate the lock simply requires that the position of one or more gates be altered. Combination changing requires disassembly of the lock, unless the mechanism allows for reprogramming.



In certain lever tumbler assemblies, notably Sargent & Greenleaf safe-deposit locks, a **variable bolt stump** mechanism is utilized rather than a fixed bolt stump. This allows the lock to be easily keyed to different combinations of lever tumbler depths. See **Chapter 22**.

14_2.2.3 Duplication of Keys

Keys may be either single or double-bitted. Safe-deposit, telephone, and other low or medium-security locks having a single set of levers use blanks made of flat steel or brass. Keys for high-security lever locks used in safes and jails are often double-bitted, and may take many forms. Cuts are always rectangular and quite precise; the sides are perpendicular to each other and the root is horizontal.



Blanks are selected based upon their length, thickness, and width, and generally may be modified to work in many different locks. Unless there is a special keyway as, for example, in Western Electric, Automatic Electric, and Northern Electric telephone locks, blanks may often be interchanged. A 6" warding file is used to cut a lever key.

Flat keys are easy to duplicate, especially if a grooved keyway is not used. In most cases, blanks may be exchanged between locks with little difficulty; excess metal is removed in order to make a fit. In fact, a piece of flat metal is suitable so long as the length is equal to the source key. Although thickness and height of the blank are not critical, they should be close to the original.

14_2.2.4 Fitting Keys to Lever Locks

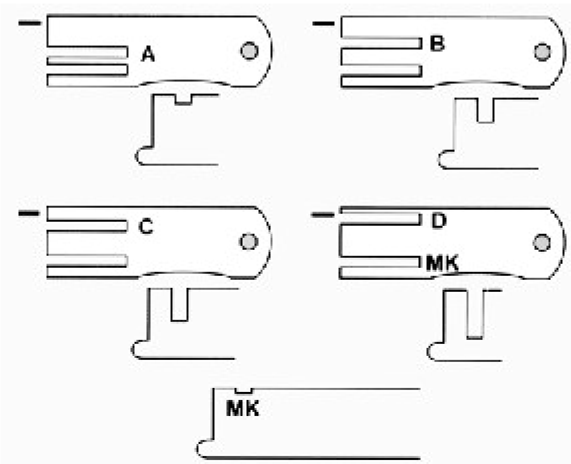
Keys are fitted to the tumbler pack in the locked position. To produce a key, the proper blank must be selected and the throat determined and cut first, so that the blade can engage the bellies. After the key is inserted, it is turned about 60° to make contact with the bellies of the levers. Then, a series of cuts is made to correspond to the depth of each gate, so that all of the gates are aligned. This will allow the fence to pass.

As noted, a 6" warding file is generally used. This must be equal to or thinner than the width of **one** lever. It is important to prevent the removal of too much metal when making a cut for a particular tumbler. This can be readily understood when one considers that each individual cut must correspond to only one lever tumbler. Remember that the purpose of the cut is to allow the key to raise a single lever to its correct position. It follows that if a cut is too wide, the key will pickup more than one tumbler at one time. If cuts are too narrow, a tumbler will be picked up but not reliably to the correct level.

The file performs two critical functions: it must shape each cut, and it must remove the amount of metal required to raise each gate to the fence. In shaping the cut, each must be equivalent to the thickness of one lever: no more and no less. In practice, marks are first produced on the blank by each lever to provide a precise guide as to where to file. A few sharp turns of the blade will accomplish this. Then, in succession, cuts are made for each mark until the corresponding gate for that lever is aligned with the fence or stump. When all of the levers are raised to the proper position, the bolt may be retracted.

14_2.2.5 Key Coding for Lever Locks

Almost all lever keys manufactured today are factory-coded using the indirect method. See **Chapter 31** for a detailed discussion of decoding techniques.



14_2.3 Master Keying Systems

Although still quite popular in Europe and many other parts of the world, lever locks have not gained wide acceptance in the United States other than for use in banks. They are not suitable for large facilities where master keying is required. There have been several schemes developed over the years to allow multiple keys to fit one lock, but none has been widely accepted. The main problem is the inability to provide for more than one extra level of keying.

Master keying of a lever lock does not markedly decrease its security against picking. Depending upon the technique, cross-keying can become an issue. This subject is more fully discussed in **Chapter 11**. Several options have been developed. These include:

- **Two sets of levers;**
- **Two sets of gates in one lever;**
- **Wide gating;**
- **Two keyholes;**
- **Two points on which the keys make contact with a set of levers (compound levers);**
- **Two plugs in one lock;**
- **Butter's system.**

Butter developed a variation of the lever lock that utilized a modified lever and allowed master keying. He determined that the vertical movement of the flat levers by the correct key allowed a toe-and-crank mechanism to release the bolt.

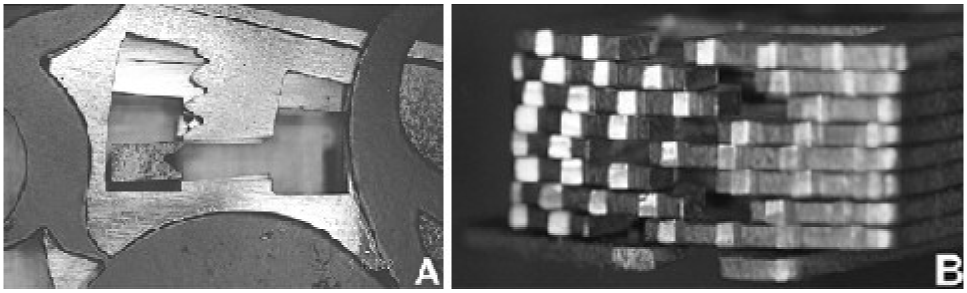
14_3.0 Security Enhancements

Lever locks are subject to surreptitious opening by picking, decoding, and impressioning techniques. Many of these methods, as well as countermeasures, were initially developed over 150 years ago by such lock masters as A. C. Hobbs, J. M. Hart, George Price, Tucker, Reeves, Tann, Chubb, and many others. **Chapter 29** provides detailed information regarding the development of anti-picking features incorporated within lever locks. Only brief mention of these will be made here.

Since its early development, the lever has undergone many changes to frustrate picking, wax casting, and impressioning. There have been several important advances to combat surreptitious opening, decoding, and production of keys. In 1989, for example, Hirvi in Sweden patented a lock (**4836000(150)**) to frustrate the reading of bellies to determine their position. Two critical design enhancements made the early lever locks difficult to pick or otherwise compromise: the stump was made to project from the bolt rather than the lever, and extra notches were cut into the levers.

Once multiple levers were utilized, the use of wax to read the mechanism became extremely difficult, at least for awhile. Then the lock pickers made more variations of false keys, finding that virtually any bit would fit through the talon to lift the levers.

Slots, rather than **notches**, were then cut into the levers. These came to be known as **gates** and added precision and greater tolerance to the "double-action" lock, forcing the lock picker to produce an exact key. Sawtooth cuts were added to the edge of the levers to provide even more security against picking. These teeth, now found primarily in safe- deposit and high-security levers locks, are very effective in frustrating picking and are discussed in detail in **Chapter 29**.

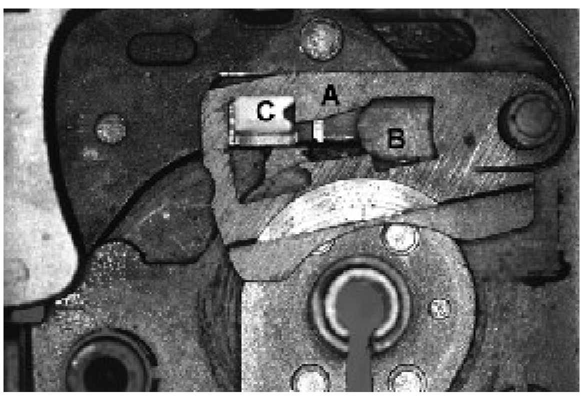


Certain special design features can be incorporated within the lever lock to increase its resistance to picking and other forms of surreptitious entry. Unfortunately, its inherent design places limits on such options in comparison to the pin tumbler lock. While the pin tumbler locks physical security can be enhanced through the use of anti-drill pins, mushroom tumblers, rotating tumblers, pin depths, and other techniques, few of those are available to the lever lock manufacturer.

Five critical parameters can be modified to affect internal security of the lever lock:

- **Design of the gate area;**
- **Interaction of the lever with the fence;**
- **Access to the levers during actuation of the bolt;**
- **Positioning of the levers during operation of the lock;**
- **Heavy, high-strength materials may also be used for most lock parts.**

14_3.1 Interaction of the Lever to the Fence



In order to provide greater security, sawtooth cuts are added to the edge of the lever tumblers. These encounter the fence during the tentative method of picking. The teeth are very effective and are discussed in more detail in **Chapter 29.** Randomly placed false gates on the edge face of the lever will also increase the difficulty of picking the lock. False gates are shallow notches near the true gate that will mask the location of the operative gate.

Exploded view of false gates.

14_3.2 Design of the Gate Area

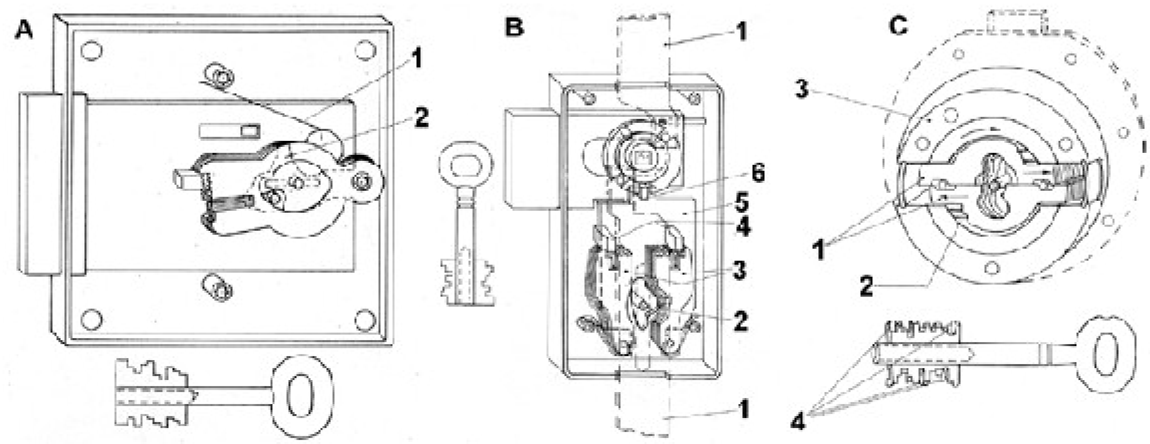
Resistance to picking is enhanced by high tolerance between fence and gate, in combination with "H" combination gating. "H" combination gating provides higher tolerances between fence and gate and performs the same function as a mushroom tumbler in the pin tumbler lock.

This form of gating requires more precision in the positioning of the lever tumbler with respect to the stump or fence and hence more security. "H" gating will make picking more difficult because false indications may be received as to tumbler position. Two stages of picking are then required in order to place the stump into the correct position.

14_3.3 Access to the Levers during Actuation of the Bolt

First developed by Chubb, the curtain and rotating barrel can prevent access to the levers during picking attempts. A metal cover surrounds the trunnion to block the entrance of picking tools, wires, feelers, and other devices. The curtain inhibits

viewing or manipulation of the levers. Baffle plates are also sandwiched between adjacent pairs of levers, making picking even more difficult.



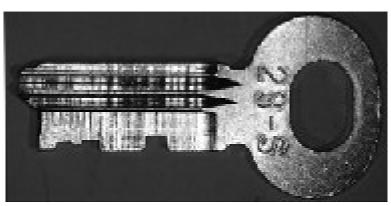
14_3.4 Positioning of the Levers during Operation of the Lock

Western Electric (WE) received patent protection for many unique security enhancements to lever locks used in coin telephones. The WE lock is especially difficult to pick due to the implementation of a spring-bias system that provides and affects tension to all levers simultaneously. This technique will remove tension from any particular lever if lifted individually with a pick. The inventors also changed the center of curvature for the top edge radius of the lever. By doing so, the "feel" for the position of each lever, acquired during picking, is destroyed.

The lock was also designed with a special plug-camming surface that rides against the leg of each lever. Plug rotation causes all levers, including those picked to the unlocked position, to return to the locked position. Also incorporated was a floating cam feature, greatly increasing the skill required for picking. A complete description of this lock appears in **Chapter 23**.

14_4.1 Special Applications

Lever locks have been designed for many uses, including United States Post Office boxes, safe-deposit boxes, telephones, and jails. Lever locks are also quite popular for use in safes and vaults, especially outside the United States. See **Chapters 17-23**, for detailed descriptions of lever locks used in special applications.



14_4.1.1 Post Office Locks

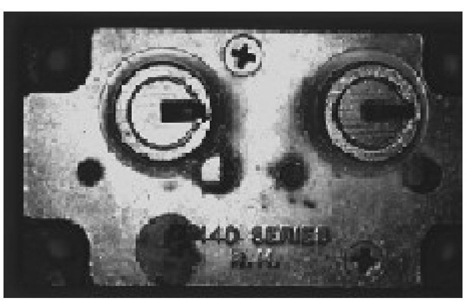
All United States Post Office collection boxes have one standardized eight-lever lock and key. Likewise, all mailboxes within post offices utilize a proprietary reversed Yale-8 keyway. It is a federal offense to possess or duplicate unauthorized keys to mailboxes. See the extensive discussion of postal locks in **Chapter 23.**

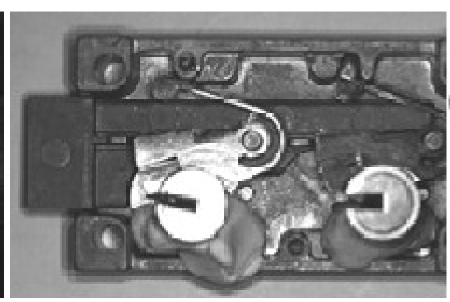
14_4.1.2 Coin Telephones

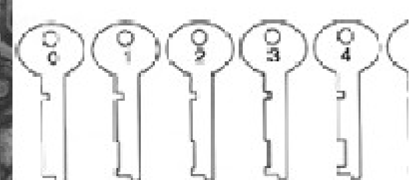
Telephone companies in the U.S. and Canada have employed special lever locks for at least fifty years. These offer a high degree of security and are covered by several patents held by Western Electric and other companies. The blanks for all telephone locks are similar, restricted, and very distinctive.

Exploded view of keys 1, 2. 3, 4.

Each coin box is keyed individually rather than master keyed. Investigators should be alert to these unique blanks if found in the possession of suspects. There have been many instances of organized gangs burglarizing coin telephones throughout the country. Since the deregulation of the Bell System, surplus coin telephones can be purchased with keys that can be used to produce keys to other Bell System telephones. Thus, although the blanks







are restricted, they are available in the U.S. and from Asia.

There are generally two locks per telephone: one to release the top housing and one for the coin box. Bell System blanks are typically stamped as follows for coin boxes: 30B (WE), 10L (AE), and NE222QA (NE). Top housing keys are identified as 10G (WE), 29S (AE), and 21B (NE). In some older telephones, tubular Chicago locks were also used. Coin telephone lever locks are very pick resistant. Their security is augmented by "key keepers" that retain an unauthorized key, once inserted. Alarm systems have also been incorporated into many telephones.

14_4.1.3 Safe-Deposit Boxes

A major application of the lever lock is in safe-deposit boxes. Usually, two locks are operated in tandem. This requires a change key to be carried by the customer and the guard key that is kept by the bank. Both must be actuated at the same time.

The guard or control key usually fits all locks in the safe-deposit vault, while each customer has a unique renter's key. A novel safe-deposit access system is in use in Europe, having only one lock for each box. Bank personnel allow individual customer access with the use of the renter's key, and a remotely activated solenoid. Each box is alarmed to advise of improper access or openings.

14_4.1.4 Jail and Prison Locks

Lever locks have been used for more than a century in jails and prisons. They have been designed to provide physical protection against both surreptitious and forced-entry, and are described in detail in **Chapter 23**.

14_4.2 High Security Lever Locks for Safes and Vaults

There are many high security lever locks that are utilized in safes and vaults, especially in Europe. There are specialized decoding tools for many of these locks. These are shown in **chapter 31**. A sample of some of the most prevalent lever mechanisms are shown below. Note the complex gear drives, gate and fence designs, and security enhancements. These locks typically contain nine or more levers and maintain extremely high tolerances.

The Rosengrens RKL10 is an extremely complex lever lock that is very popular on high security safes. A detailed **assembly protocol** has been provided as a courtesy of Owe Bengtsson in

LSS203: Rosengrens RKL10.

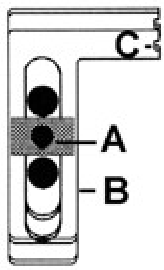
An interesting example of a high security multiple-bitted lever lock is shown in the photograph below. The key was utilized on a World War II German submarine.

14_5.0 Definitions and Identification of Parts

There are many components found within the lever mechanism, some with special application in safe-deposit locks. These parts are defined below. See also **Chapter 30**, for supplemental information regarding certain components.

Barrel and Curtain: This is a security device employed in some lever locks to block access to the keyway once a key or pick is inserted and turned. The curtain was developed by Jeremiah Chubb to prevent bypass by picking.

Belly of Lever: The edge, generally curved, with which the key comes into contact at the base of the lever.



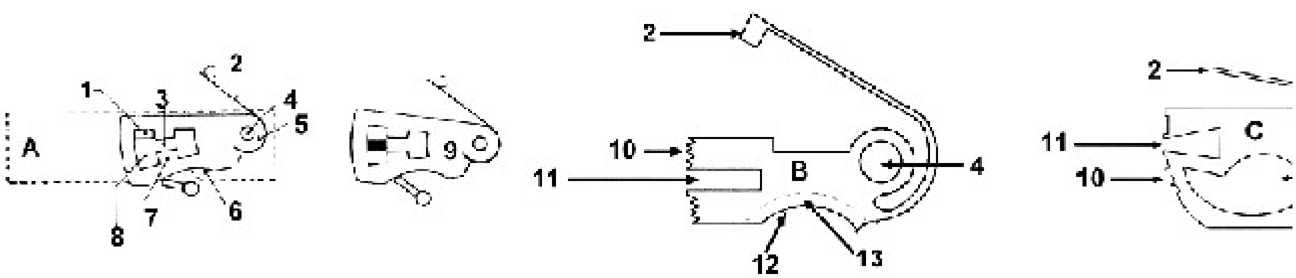
Bond Box: The removable box in which valuables are stored within the safe-deposit vault.

Butter's System: A century ago, Butter developed a modified lever that allowed limited master keying.

Change Tool: A device that is used to change the combination of the gate position without disassembly of the lock.

Changeable Fence: A multisegment fence can be made to align each of its individual components, to each corresponding gate. The combination is arranged by moving each segment.

Changeable Lever: A lever consisting of two parts whose relationship can be altered to affect the position of the gate, and the corresponding bitting of the key.



Chubb: The name of a famous English lock maker who founded a company in 1818 and which still exists today. The name Chubb is identified with many revolutionary patents, including the Detector lock. See **Chapters 1** and **34**.

Compound Levers: Certain levers have two bellies at different radii, utilized for master keying.

Detent: That portion of a changeable lever containing the gate, which can be separated from the sweep lever in order to alter the distance between the sweep and the gate.

Double-Acting Lever: A lever that must be lifted to a precise level: not too high, nor too low, to enable the stump to pass through the gate.

Dummy Lever: A special lever used for master keying, which, when raised, causes other levers to be lifted.

False Notches: Serrated notches are placed on the lever edges and on the bolt stump to improve security against picking.

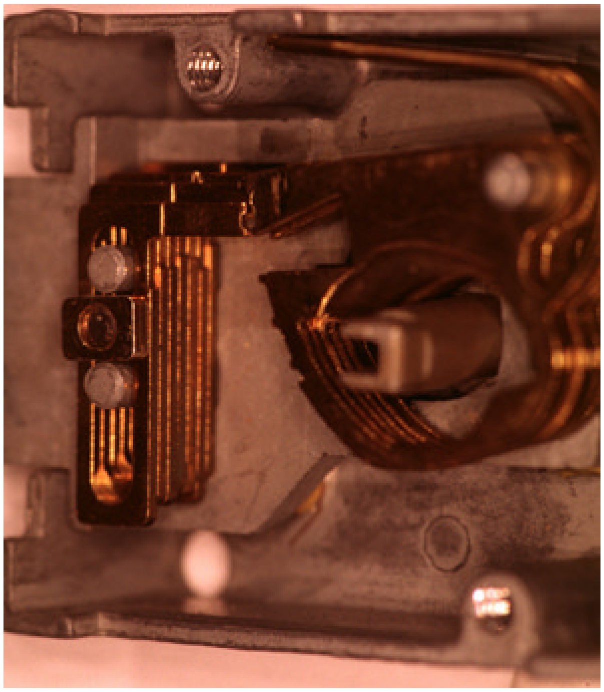
Fixed Lever: A lever for which the position of the gate cannot be changed.

Flush Bellies of Levers: When all levers are at rest and in a locked position, the lower radii or edges of the bellies are at the same level. Theoretically, the reason for flush bellies is so that no indication may be deduced as to the amount of lifting required to align the gates. In practice, as will be explained in **Chapter 31**, the relative position of the gates can be determined from an analysis of the bellies.

Gating: Square slot in a lever through which the stump of the bolt passes.

High-Lift Lever: A type of lever that must be lifted as high as possible to pass the stump. Another variation of this is a high middle lift lever, which can be over-lifted to block passage of the stump.

Lever Tumbler: A form of catch that normally holds the bolt immovable until raised by the key. It is the American name for the pivoting part in the lever tumbler lock. The term appeared in Parsons' patent in 1832 in England.



Low-Lift Lever: The lowest possible lift of the lever by the key, while maintaining some portion of the lever above the gating, to block movement of the stump.

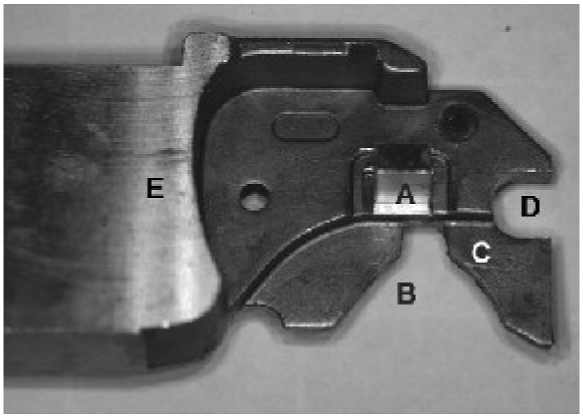
Lever Cuts: Another term for the steps or variations of the bitting of a key.

Lever Spring: The purpose of the spring is to force the lever to its lowest position. Usually the spring is made of fine wire, fitted into a slit cut in the end of the lever. The lever and spring may be combined and made from one piece of brass.

Pocket: That portion of space within the gating of each lever tumbler that allows the stump to rise and fall within the lever.

Programmable Lever Lock: A lever lock may be programmable, in order to allow the bitting pattern to be altered by changing the fence-gate relationship. In the photograph below, the relative position of the fence and gate can be adjusted by moving the individual fence pieces on the left. All of the bellies within the levers are identical. The bitting is changed by lifting the individual levers to different heights, matched by the corresponding fence. When the setscrew is loosened, the vertical pieces are free to move to any desired height.

Serrations: Shallow notches are cut in the fence and along the gate opening edge of the levers to frustrate picking.



Setup Key: A key with identical bittings. Changeable safe-deposit locks are factory set to this bitting combination.

Sweep: The portion of the lever contacted by the bitting of the key. It is generally radiused.

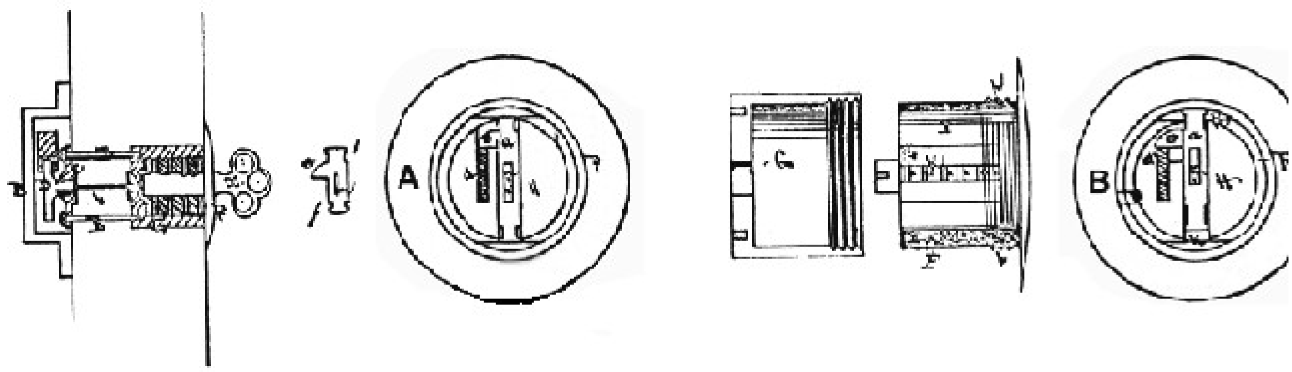
Talon: The gap in the bolt, curved to the radius of a key, which has some resemblance in shape to the talon or claw of a bird of prey. A **Fly Talon** allows a small key to give a long throw to the bolt.

Tee Piece or Slider: A scheme utilized by S&G allowing the lock to be easily keyed to different combinations or lever tumbler depths.

Trap Lever: A special lever, placed in a changeable lever lock, which will prevent the insertion or removal of a change tool until the lock is set properly.

Exploded view.

CHAPTER FIFTEEN: THE WAFER



Wafer Locks

Master Exhibit Summary

15_1.0 Introduction

The wafer or disc lock, developed during the latter part of the nineteenth century, is a low to medium security device that is versatile, simple to install, and an inexpensive substitute for the pin tumbler mechanism. It is easy to identify by looking into the keyway. The prototype was developed by Hiram S. Shepardson, and in 1870, a patent was issued for the design (**99013(151)**). The inventor had worked for Yale prior to conceiving of the lock. He formed the United States Lock Company in Massachusetts that was later purchased by Yale. The wafer lock did not gain popularity, however, until the 1930s when Chicago

Lock and Briggs and Stratton (STRATTEC) introduced the famous die-cast sidebar mechanism.

Wafer locks are used in many applications. These include: luggage, cash registers, showcases, desks, motor vehicles, electric switch and alarm controls, elevators, file cabinets, padlocks, coin boxes, money bags, mobile radios, and vending machines. The lock is known by various terms: disc, wafer, plate, blade, or flat tumbler. Detailed information with respect to picking, decoding, and impressioning can be found in **Chapters 29-30-31.** Special applications of wafer and disc locks are presented in **Chapter 23.**

15_1.1 Development of the Wafer Lock

Worldwide, the wafer or disc lock has become the most popular low-cost security mechanism. It far surpasses even the pin tumbler, due to its versatility and simplicity. There are many variations and improvements to the original wafer concept. The most significant of these are sidebar and laser-track locks used in many automobiles, and the plate wafer lock found in a majority of vending machines.

Wafer locks support single, double, and triple-bitted key designs. Cam locks, probably the most popular low-cost configuration, usually have wafers rather than pin tumblers. Double-bitted mechanisms can be found in hundreds of applications, ranging from bulletin case locks to elevator controls. Double bitting means that there are spring-biased wafers active at both the top and bottom of the rotating plug. Generally, double-bitted locks contain more wafers than do single bitted. Triple-bitted locks are utilized in applications requiring higher security. They are common in access control, motor vehicles, and storage lockers. They generally are a

modified double-bitted mechanism with a third set of tumblers riding on a superimposed ridge running parallel to bitting on one side of the key.

The sidebar lock is a variation and hybrid of both the wafer and lever design. It was developed in the 1930s, specifically for the automobile market, and was introduced by Briggs and Stratton. It is still the predominant motor vehicle lock. The mechanism is extremely pick resistant and is discussed in **Chapter 23**.

The plate wafer is another popular variation of the original design. Up to thirteen wafers are contained within a pack, held together by a spring wire. Essentially, the lock is a high tolerance, double-bitted mechanism. One embodiment of the plate wafer mechanism was described in the Christoph patent (**1287882(152)**).

15_2.0 Principles of Operation

15_2.1 Introduction

The wafer design is based upon the double-detainer locking principle and can be viewed as a modification of the lever lock concept. It was developed in response to the increased requirement for flexibility in the way that the bolt was to be used for locking.

Originally, lever locks, and to a limited extent pin tumbler locks, were produced for doors and other applications where a straight bolt was utilized. The design of the lever precluded the use of any actuating mechanism other than a straight sliding bolt, driven by the rotating action of the correct key. It would not allow use of a rotating locking cam, screw, or any other form of latch; just the sliding bolt. The wafer provided different options and alternatives for bolt activation.

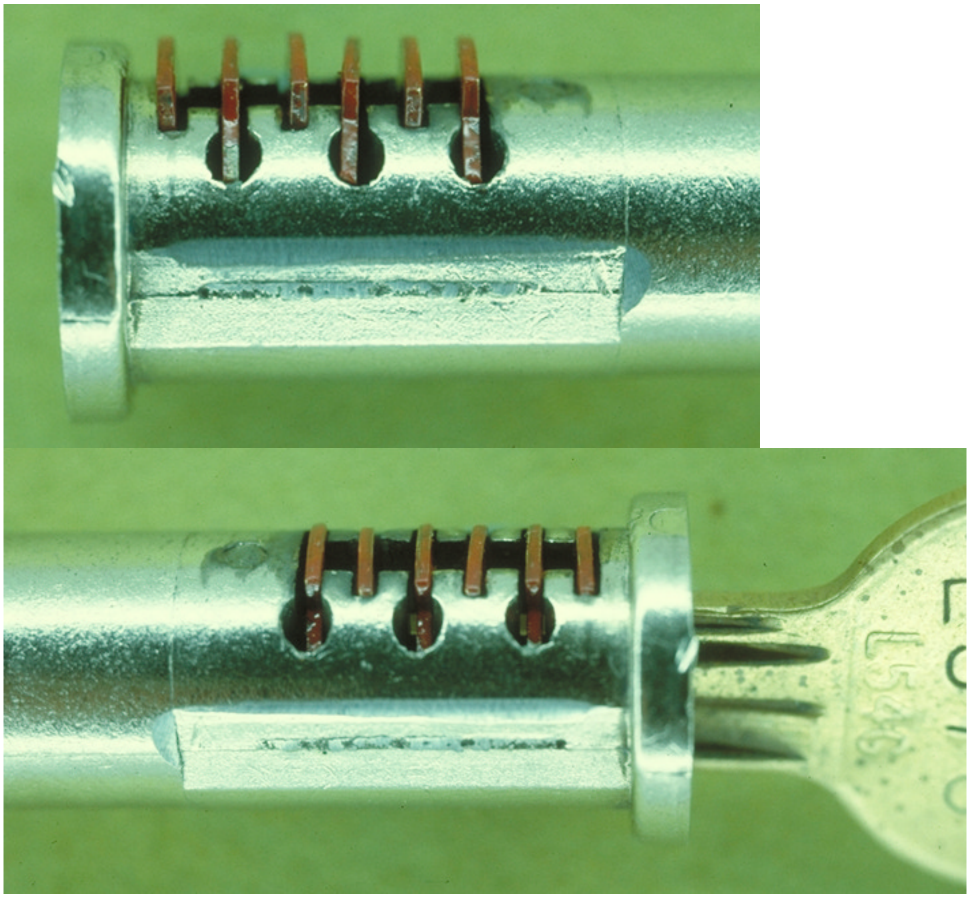


Figure LSS+1501. A six-wafer mechanism in the locked and unlocked state. The plug on the right can be turned within the shell because there are no obstructions to rotation. Courtesy of the Illinois State Police, Bill Sherlock.

15_2.2 Component Description and Identification

The basic design of all wafer locks is the same: making manufacturing, keying, rekeying, picking, and service easy. The mechanism consists of the outer shell, the plug or core, the wafer tumblers, and associated springs. The locks are usually constructed of die-cast metal. The specific function of each component is described below.

Bitting: Wafer locks are generically defined by their bitting levels. Thus, a single- bitted lock has one set of wafers, all of which make contact with the key bitting on one surface. Keys with bitting on two opposite surfaces fit double-bitted locks. If the key has bitting on three surfaces, then the lock is triple bitted.

Figure LSS+1502, example of a double bitted wafer lock in the locked and unlocked state. Courtesy of Illinois State Police, Bill Sherlock.

Cam: The cam or tailpiece is connected to the end of the plug and is used to control or cause a locking or unlocking condition. Its other function is to secure the plug within the shell.

Discs or Wafers: Disc tumbler, wafer tumbler, plate tumbler, and flat tumbler are used interchangeably. They refer to the active

locking components. Wafers are made of flat brass, are spring biased, and are individually moved by the bitting surface of the key to a precise position called shear line.

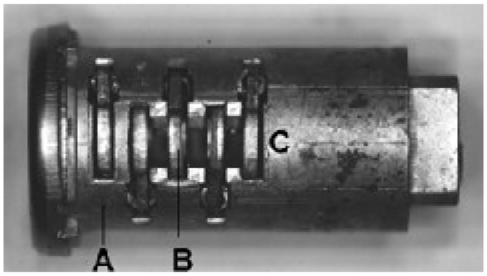
Master Pins: Special wafers used for master keying have two different stepped portions. Each meets the bitting of either the change key or master key.

Plug: The plug forms a perfectly round core containing all wafers and springs. It rotates within the shell to allow actuation of a cam, bolt, or other locking control.

Shear Line: This term denotes the level to which all wafers must be raised in order for the plug to rotate.

Shell: The shell contains all moving parts of the lock.

Shell Slots: These are the empty channels formed above and below the plug. They allow the tops and bottoms of the wafers to enter when in a locked condition.



Springs: Springs are much smaller than in the pin tumbler lock and are generally made of steel or bronze. Their function is to bias the individual wafers above or below shear line. They are held in place by the arm of the wafer.

15_2.3 Mechanical Operation of the Lock

All wafer locks contain three active locking components: the plug, shell, and tumblers. A key, with bitting that corresponds to each wafer, is utilized to move each tumbler to shear line, so that the plug is free to rotate.

15_2.3.1 Plug

The plug forms a perfectly round core containing all wafers and springs that rotates within the shell to allow actuation of a cam, bolt, or other locking control. The front of the plug has an opening called the **keyway** that guides the key once inserted through the center of each wafer. There is also a set of vertical tracks or channels cut into the plug for each wafer and associated spring. These align each wafer and allow their vertical travel as the key moves across the keyway.

The plug is held in position by an arc ring, screw-locked cam, inset pin, or by an extra disc tumbler that protrudes from the inside of the lock. When a spring-loaded disc is utilized, it can be depressed and released with a pick or stiff wire. Inset locking pins generally must be drilled to be released.

15_2.3.1.1 A Comparison: Wafer and Pin Tumbler Plugs

In comparison to the pin tumbler lock, the wafer **plug** is a great deal more complex. Whereas the plug and shell can be said to be of equal importance in the pin tumbler mechanism that is not the case with the wafer lock. Because the plug contains all moving parts, it can be completely removed with all internal parts intact. Within the pin tumbler device, there are always pins in both the plug and shell: they work interactively. That is not the case with wafers. Thus, no follower is required to take the wafer lock apart.

15_2.3.2 Shell

The shell contains all moving parts and provides the surfaces (upper and lower shell slot) upon which the rotating plug and wafers can act to create a locked or unlocked condition. If the lock is single bitted, then **either** the top or bottom shell slot will be occupied in the locked position with no key inserted. If the lock is double-bitted, then tumblers will enter **both** shell slots.

15_2.3.3 Wafers

The plug is fixed in one position by the wafers until they are brought to shear line. The wafer is the critical locking component, and performs the same function as the pin tumbler. Wafers are, however, markedly different in their design and function.

Locks generally contain four to thirteen flat stamped, rectangular metal wafers, each having a slot cut in their center. This inner space allows the key to pass through the middle of each wafer. Corresponding parallel vertical channels are provided for each wafer within the shell.

15_2.3.3.1 Wafers: How they secure the Plug

Wafers are spring biased and positioned so that they protrude into the top or bottom recessed areas of the shell. The counterforce to this spring bias is provided by the action of the key and the bitting corresponding to the position of the wafer. If the spring forces the disc to a position above the keyway, then the bitting for this same tumbler must cause the wafer to be moved **downward** to shear line. The plug will continue to be held fast until all of the wafers are brought even with its diameter (the shear line). Once all the wafers are at shear line, the plug is free to rotate, thereby turning and actuating the desired mechanism.

In the single-bitted lock, all wafers are forced to the top **or** the bottom of the plug. In the double-bitted configuration, the position of the wafers is **alternated** between positive and negative shear lines. Each wafer can occupy one of three positions within the shell: **above** the positive shear line, **below** the negative shear line, or **precisely aligned** with both shear lines. When all tumblers are at shear line, each wafer is completely contained within the plug and the plug is thus free to rotate.

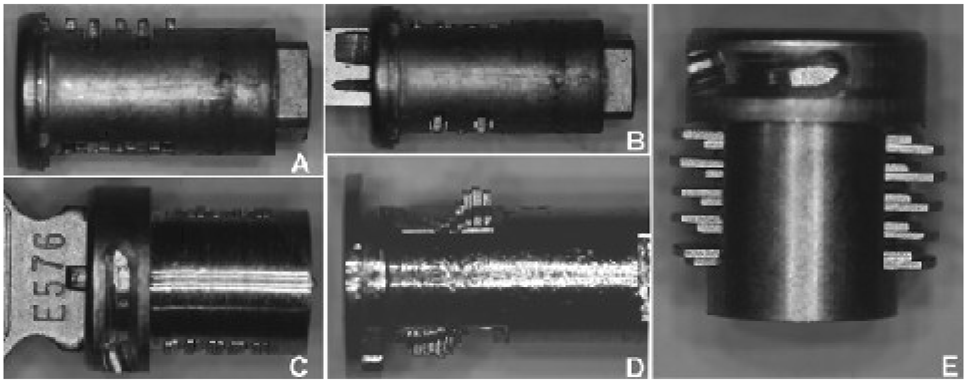
As the key passes through the center of each wafer, the bitting moves each to shear line, above or below it. The relative vertical position of the internal slot relates directly to the bitting level of the key. Each wafer has an arm that extends from its body. The function is to hold a corresponding spring within a chamber. When wafers are moved to their correct respective positions by the action of the proper key, they will all be exactly contained within the plug: no portion of any wafer will extend past its diameter. The principle of operation is the same in the double-bitted lock; all wafers must be moved to the proper level in order for the plug to rotate.

15_2.3.3.2 Size and Design

All wafers have the following physical characteristics:

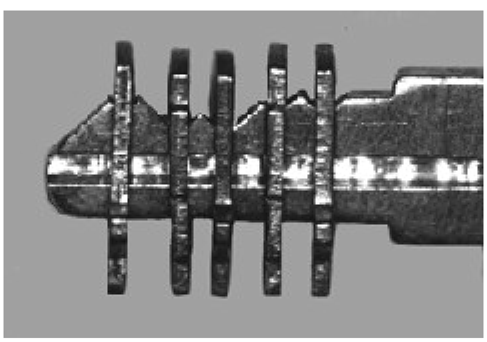
- **Each is rectangular;**
- **Each has exactly the same length as the diameter of the plug;**
- **Their width will be slightly more than the thickness of the key;**
- **All wafers will be the same length;**
- **The ends of the wafers will either be square cut or rounded;**
- **Each wafer has an internal rectangular slot to allow the key to move through its center.**

15_2.3.3.3 Modified Wafer Designs



Wafers have been developed for specialized applications. **Datsun,** for example, introduced a wafer with a notch in the top to prevent removal when rotated 180°. They were not popular due to wear, jamming, and collapse. Likewise, **Mercedes** developed the split or half wafer, allowing each side of the tumbler to work at a different depth. This utilized the same space in the lock to increase security and double the number of possible combinations. The scheme allows an eight-wafer lock to have sixteen permutations. **Winfield** made a split wafer that allows reprogramming of the bitting position to change the combination of the lock externally. See **Chapter 23**.

The **Schlage** Company produced an extremely popular and unique medium-security wafer lock that was primarily for residences and apartment complexes. The lock has been used for the past fifty years, and can still be found on millions of doors, although it has not been manufactured for many years. The 922 series was quite popular because of ease in keying, rekeying, and setting up and changing master key systems. They are easily picked and have a limited number of key combinations. A detailed examination of this lock was presented in **Chapter 7** of the first edition of this text.



15_2.3.4 Shear Line

The shear line is a physical barrier to plug rotation that changes its shape and characteristics to correspond to the bitting of an inserted key. When all of the tumblers move to their correct position, then the shear line becomes imaginary.

Its function is to allow or block turning of the plug, depending upon the relative position of each wafer or disc. At least two shear lines will always be created in the wafer lock. In this text, these are referred to as **positive** and **negative**.

A positive shear line means that the wafers "break" or are brought even with the diameter at the top of the plug (positioned at the top of the keyway or bitting of the key). Conversely, the negative shear line is formed at the bottom of the plug where the wafers drop **below** or opposite to the bitting of the key. If the bitting is not deep enough, then a particular wafer will be over-lifted and thus protrude above the shear line. If the bitting is too deep, then the wafer will extend from the plug in the opposite direction, also blocking rotation.

15_3.0 Keys and Key Systems

The function of the correct key is to force the individual tumblers to shear line. A tolerance of at least .01” must be maintained when cutting the wafer key. Bitting level and position will correspond with the number of wafers and their orientation. Thus, in single-bitted locks, plugs may be configured so that the bitting makes contact with only one set of wafers, all in the

same vertical orientation.

The double-bitted wafer lock will provide for the bittings to appear on two vertical surfaces of the key, generally the top and bottom. In this configuration, alternately oriented wafers are used. For example, the first wafer will be raised by the top bitting of the key; the next wafer will be biased in the opposite direction and moved by the bitting on the opposite side of the key.

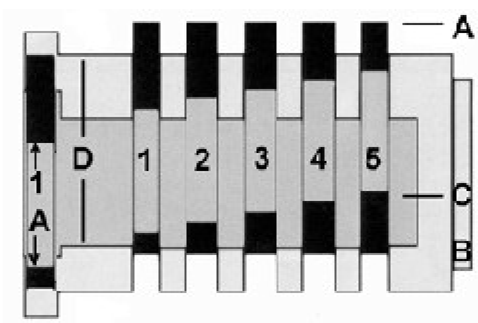
Triple and quad-bitted keys may also be found in certain high-security control locks and in some foreign cars. Mercedes, Volvo, and other manufacturers utilize what is known as a laser cut key. Actually, these may have a third and sometimes a fourth set of bittings that are overlaid on the primary bittings. They simply lift secondary wafers at different contact points.

Depending upon the design of the lock, the fact that a key has bitting on two, three, or four sides may not mean that there are actually different corresponding tumbler sets. Some double-bitted keys are actually made for a single-bitted lock and simply mirror the bitting pattern on the top and bottom. Ford does so for the convenience of the car owner, so that the key may be inserted using either vertical orientation.

In true double-bitted locks, the cuts will be of a different pattern on each surface of the key. This is because different tumblers with different depths are being moved. Note that if the top bitting for a particular tumbler is high, for example, then the non-active position for that tumbler on the opposite bitting surface of the key will be a mirror image. This is because there is only so much clearance within the interior portion of the disc through which the key passes.

15_3.1 Producing Keys for Wafer Locks

Keys for wafer locks are easily produced by direct duplication, by hand, by code, by visual decoding, impressioning, and by taking the lock apart. Most key machines are capable of duplicating both single and double-bitted patterns. Making keys by impressioning is discussed in **Chapter 30**.



If the lock is to be disassembled, the plug is first removed. The correct blank is selected and inserted. Pressure may then be applied to the surface of each tumbler to cause the blank to mark, defining their positions. Filing is done with a small

rat-tail; the key is then reinserted into the plug to check the level of the tumblers. The key is repeatedly removed and filed until the tumblers are all at shear line. After the key is completely cut, the plug is reinserted into the shell and secured.

15_3.1.1 Decoding Wafer Locks and Producing Keys by Code

Reading wafer locks, courtesy of Harry Sher.

Wafer locks may be visually decoded simply by looking into the keyway. The direct code for each wafer can be determined, thereby allowing the production of a key. The underlying theory is simple: all wafers come to rest at the same position. The bitting pattern mirrors the key, but the position of the wafer pack is shifted because of the spring tension. All tumblers are in perfect alignment just not at shear line. Thus, the **relative** position of the bitting surface of each tumbler may be observed.

In practice, all but the last tumbler is raised, so that the relative position of the first wafer is determined. Each tumbler in succession, is similarly read. If master pins are employed, the same side of each tumbler must be examined and decoded. A borescope or magnifying otoscope, wafer depressor and reading tool, spring door retaining tool, slip coder, depth and space keys, and a code cutter are the tools which will enable the lock to be read easily. **Chapter 31** presents a thorough discussion of techniques for decoding wafer locks.

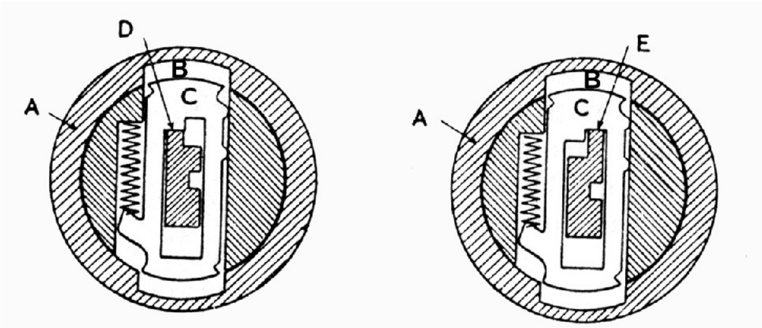
15_3.1.2 Key Codes

Generally, keys for wafer locks are coded by the manufacturer and may be duplicated by such direct or indirect codes. Numbers denoting the depth-cut will generally be stamped on each wafer.

A two-digit code on a master pin will indicate the bitting depths for the change and master keys, for right and left bitting.

15_3.2 Changing Combinations

Changing the combination may be accomplished quickly and easily in single and double-bitted locks. This may be done by either varying the order of the individual wafers, or by filing them. It is preferred, however, that tumblers be switched rather than filed. It is important to understand that the combination cannot be changed by filing the **tops** of the wafers but only by modifying the internal slot.



Due to the type of construction in the **plate wafer** lock, all the individual tumblers come in a "pack." This tumbler pack may be entirely removed from the plug and replaced with another, having a different combination of depths. Individual tumblers are not changed.

15_3.3 Differs

Due to the limited number of tumblers and possible depth cuts, relatively few differs or key combinations are available for most wafer locks. The number of permutations may vary from a few hundred to several thousand. The Chicago Lock Company, which is possibly the largest manufacturer of double-bitted wafer locks, will have an average of six hundred key changes per keyway on any double-bitted mechanism. Differs may be determined by taking the number of depths, raised to the power of the total number of tumblers. Thus, a lock having four depth differences using five wafers would theoretically produce 4^5 or 1,024 different key changes.

15_3.4 Master Keying

Wafer locks may be master keyed using special tumblers having two stepped areas or contact points. The change key lifts the left side of the wafer, while the master key raises the right side. No cross-keying occurs in a mastered wafer system, because different blanks are required for the master and change key. A thorough discussion of master keying is presented in **Chapter 11**.

CHAPTER SIXTEEN: THE PIN TUMBLER

Pin Tumbler Locks

Master Exhibit Summary

16_1.0 History and Development of the Pin Tumbler Lock

There is evidence that the first use of a moveable pin within a lock occurred about four thousand years ago in Egypt. The initial pin tumbler mechanisms, as described in **Chapter 1**, consisted of moveable pegs which held a sliding bolt in position until the proper key was inserted. The lock provided a measure

of security that was previously unknown. What can be referred to as "picking" was made difficult because of the length of the key- up to three feet.

The design was both simple and ingenious. The original lock housing was made entirely from a block of teak or other hardwood. The locking mechanism was within the bolt itself, isolated by up to three feet from the staples securing the assembly to the timbers of the door.

Inside the locking mechanism were from three to seven square slots in an uneven pattern. Within each of these slots or chambers would be a wooden pin or tumbler, free to move vertically. Although there were no springs, the mere weight of the pins would force them downward into the bolt, resting on a shoulder so as not to fall out of the lock. The key was fashioned of wood, with metal pins protruding from the active end that was inserted into the entire length of the bolt. This actually formed the keyway.

It is almost certain that whoever conceived of the original Egyptian mechanism did not recognize that the double-detainer locking principle had been invented. Although it would take another four thousand years for the concept to mature into practical locking devices, nonetheless, the genesis of the idea was brilliant. It set the stage for the evolution in design upon which all modern locks would be based.

The Egyptian design established two rudimentary concepts:

- **The use of a moveable detainer (pin) whose physical**

position would cause a locked or unlocked condition to occur within the housing;

- **Creation of a "shear line" and corresponding physical barrier to movement of the bolt until the detainer was placed in the correct position.**

In the Egyptian lock, there was only one set of pins (drivers). The bolt did not rotate; it was slid to a locked or unlocked state. When thrown into the jamb or placed in a locked position, the pins projecting from the fixed staple would enter corresponding holes in the bolt and prevent any movement.

The purpose of the key was to raise each of the pegs within the lock casing so that they would not interfere with the movement of the bolt. The location of pins on the key would precisely match the position of the corresponding pegs within the lock that protruded from the upper housing. The key could be likened to the end of a toothbrush: the pattern of "brushes" would be different for each lock. Once the key was fully inserted, it was lifted straight up. The pegs on the end of the key would pass through holes on the upper surface of the bolt. These would raise the projecting pins to a point where all of them would be resting above the bolt. When this occurred, the bolt and key could then be pulled back to the unlocked position. The reverse procedure was followed to secure the bolt. The security of the lock was based upon the location and number of upper pins. The "shear line" was created by simply lifting all pins above the bolt, rather than to a precise point in relation to its surface.

The Egyptian lock makers realized that their "pin tumbler" devices suffered from serious problems: each took a great deal of time to construct because of the craftsmanship involved, and locks could be picked or wax impressioned. For no known reason, the Egyptian pin tumbler lock faded into history and was essentially forgotten for forty centuries until rediscovered by Linus Yale, Sr. The principle established by the Egyptians appeared in locks all over the world. In fact, India, Japan, Scotland, and the Faeroe Islands all produced similar designs. Even the Romans adopted the use of pins, until wards were invented. It is interesting to note that the Scottish, around the eighteenth century, used square rather than round pins in their locks.

16_1.1 The Yale Lock

Linus Yale Sr. was born in Middletown, Connecticut in 1797. He

was a talented inventor and successful manufacturer of bank locks, who, in 1844, developed the first practical pin tumbler cylinder lock. His son, Linus, Jr. was born in 1821. He began his career as an artist. Although never in partnership with his father, Linus Jr. soon followed in the elder's footsteps, designing and making locks in his own factory. He is credited with the introduction of the grooved keyway and mass production of the Yale cylinder.

Linus Yale, Jr. improved the pin tumbler lock between 1860-1865, based upon the original Egyptian principles and the work of his father. In 1868, Yale, Jr. began working with Henry R. Towne, a young engineer who had been employed in the Port Richmond Ironworks during the Civil War and later had studied at the Sorbonne in Paris. In 1883, the Yale Lock Manufacturing Company became the Yale and Towne Manufacturing Company and is now Eaton, Towne, and Yale.

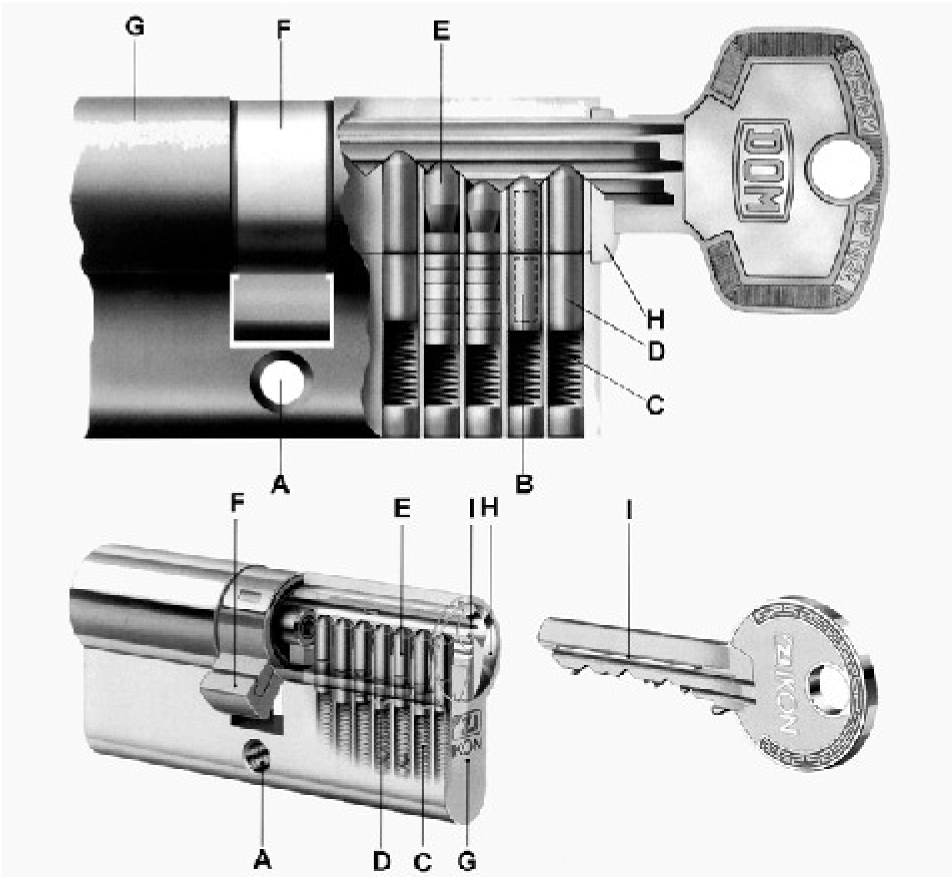
16_1.2 The Egyptian and Yale Designs: A Comparison

The Yale invention bore little resemblance to the original Egyptian lock, but Yale clearly based his design upon the initial concept. Within the Egyptian lock, the pins kept the bolt from sliding; Yale adopted the idea to a rotating plug within a stationary shell. In both cases, the pins would hold the actuating component fast until raised to a proper level. Yale improved upon the ancient design and made it practical by taking the pegs that were affixed to the end of the key and making them part of the internal mechanism. Thus, the Yale lock would have **two** sets of moveable tumblers: **upper pins**, which were in the Egyptian design, and **lower pins**, which were originally part of the three-foot key.

In order to make the locking system functional, Yale also had to conceive of the rotating plug as the actuating device to control the bolt. This required that a shear line be created; hence the use of two pins per chamber. Once Yale made the fundamental alteration to the original Egyptian design, he was able to produce a lock having a small key (not three feet in length) that was capable of a great number of different combinations. The final Yale cylinder had several sets of spring-biased pin tumblers, each split in two segments and aligned in a straight line, corresponding with the bitting of the key. Yale required that a moveable pin be lifted to a precise position to allow free

rotation of a concentric internal plug. When the Yale key was inserted, its upper edge would raise each pin to the correct height so that the inner plug could be turned. In his lock, a difference of .02" in pin length was sufficient to prevent rotation.

16_1.3 The Modern Pin Tumbler Lock



The pin tumbler design appears in many configurations and applications, from bank vaults to padlocks. Any sort of bolt or locking cam may be controlled, adding to the locks versatility. There is inherent security because of the tolerances required for functionality and the use of the double-detainer principle.

The number of tumblers, keyway configurations, pin chamber design, and tolerances may be altered to increase security. Most modern cylinders contain five to seven pin sets. The term **"pin tumbler"** is generic: it does not denote size, quality, security or pattern of the key. It simply indicates the use of moveable pins to block rotation of the plug.

There is a vast difference in the quality of locks. As will be detailed in this chapter, those differences are based upon many complex factors. Today's mechanism is a small, secure, virtually trouble-free and inexpensive device. It is found in every part of the world and is heavily relied upon by all societies to provide security.

16_2.0 Lock Part Identification, Definition, and Characteristics

Cylinders are available in many different configurations and levels of security. All conventional pin tumbler locks have ten basic parts: shell, plug, keyway, key, pin tumblers, pin chambers, springs, chamber seal, cam, its retaining mechanism, and actuation link, and lock face. In addition, there are terms generic to this mechanism relating to disassembly and maintenance. This section shall describe each part and define relevant terms.

Bottom Pins: The bottom or lower pins make direct contact with the bitting surface of the key, and create one portion of the shear line, when combined with the top pins or drivers.

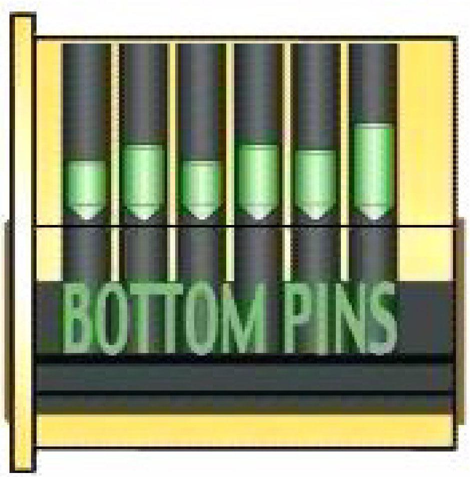


Figure LSS+1601 The bottom pins and top pins form the pin stack within each chamber. Courtesy of HPC Interactive Learning Series.

Broaching: The process of cutting, forming, and shaping the keyway in a brass plug during the manufacturing process.

Figure LSS+1602 A broach for creating a keyway profile.

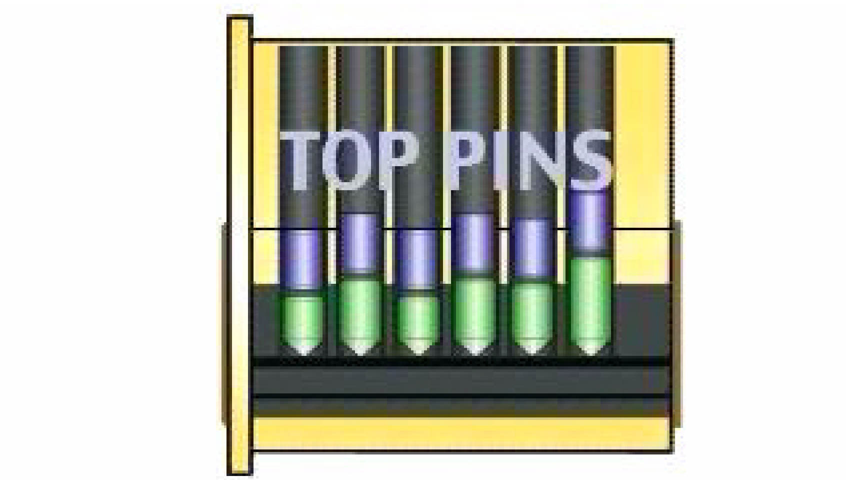
Bumping or rapping: A method of opening a pin tumbler mechanism by using shock and vibration applied to the shell. The technique utilizes a wooden or rubber mallet, or requires rapping the lock against a hard rubber or wood work surface.

Cam: The cam is attached to the back of the plug. Its primary purpose is to transmit the action of rotation to the bolt or other locking device. The cam-retaining mechanism, usually held by screws or a spring loaded screw-cap, has two functions: (1) it maintains a precise alignment between the upper and lower chambers and (2) keeps the plug from being removed when the correct key is inserted.

Cylinder Lock: A pin tumbler lock having its mechanism contained within a cylinder. A bicentric cylinder contains two plugs and pin sets and allows separate operations by change keys and master keys. See Chapter 23 for a description of the Winfield lock.

Cylinder Ring: A collar or washer applied under the head of a cylinder, often to increase security.

Driver Pins (top pins): The upper set of pins that project downward into the plug. They are also known as roller pins.



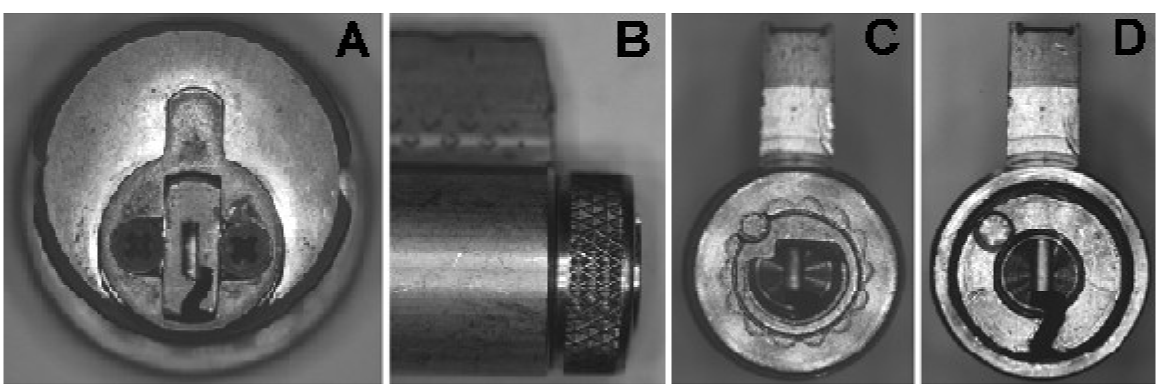


Figure LSS+1603 The top pins or drivers allow for the creation of a shear line. The drivers place downward pressure or bias on the bottom pins and create the pin stack. Courtesy of HPC Interactive Learning Series.

Following Tool: A round, dowel-shaped tool having the same diameter as the plug. It is used to disassemble a pin tumbler lock. Its purpose is to follow and fill the space left when the plug is withdrawn. The follower keeps the drivers and springs within their chambers.

Keys, Design Parameters: A number of terms are used to describe design components involving keys: **Center of Cut, Root, Slope, Valley.** These are discussed in Chapter 6.

Keyway: The keyway limits the number of keys that can enter the lock and thereby increases security. They can also make picking difficult. By varying the design, sophisticated keying systems are made possible. Keyways can be infinitely varied and are created through broaching.

If all locks had but one keyway, key control would become impossible. Manufacturers would very quickly run out of combinations because keys intended for one lock would fit numerous others. There are thousands of different keyways in use today. Each is copyrighted and unique to one manufacturer. The purpose of the keyway is to guide the key through the plug, and position it in order that the bitting may precisely lift the pins. Many vendors offer special system keyways. These are for use in large complexes where complicated master keying is required. Each area or section can be given a unique keyway that prevents the use of keys from other areas. Master keys can be designed to fit all of the different keyways of the system.

Lock Face: The face acts as a protective shield to the internal parts, allows the lock to be mounted on a hard surface, and offers a stop for the shoulder of the key.

Master Key: A key designed to operate two or more locks having different change keys.

Master Pins: The tumblers used specifically for master keying. They are generally sandwiched between the driver and bottom pins in order to create additional shear lines.

Paracentric Keyway: A keyway that has wards or obstructions protruding from either side, past the vertical centerline. A flat piece of metal is prevented from entering, without matching grooves corresponding to the obstructing wards.

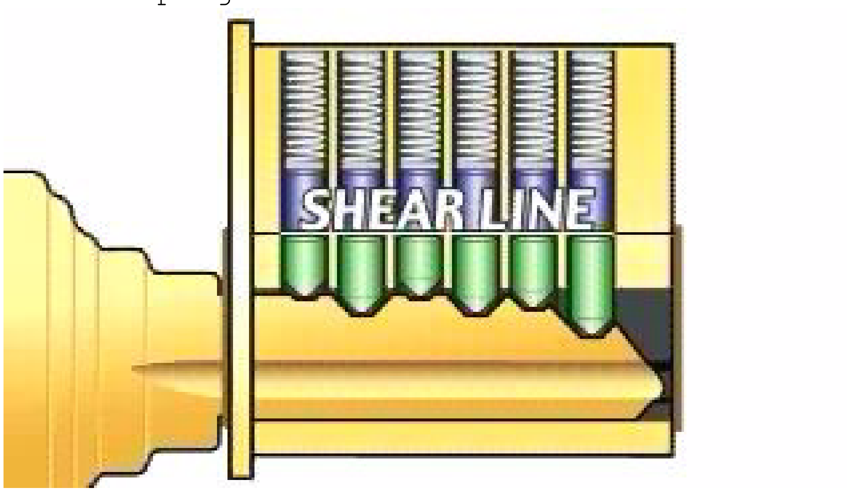
Pin Chambers: Each pin tumbler and associated spring (pin-stack) is contained within a bored chamber located in the shell (for drivers) and the plug (for lower pins). The upper chambers are generally drilled completely through the shell; lower chambers are only drilled partially through the plug and into the keyway. The upper and lower chambers are in perfect vertical alignment to allow the pins to freely move above and below shear line. The pin chambers are at the heart of the double-detainer locking principle. Without them, the lower tumblers could not be raised into the shell, nor could the driver pins enter the plug. See the discussion below regarding tumbler classifications, below.

Plug or Core: This is the active, rotating component of the pin tumbler lock. The plug contains all lower pins, held within chambers that are bored to correspond with the precise position of the top pin chambers. The plug or core is the part which, when all of the pin tumblers are in perfect alignment, can be turned

with the key to actuate a bolt mechanism.

Security Tumblers: Security is enhanced by the use of special tumblers that make picking more difficult. These are generally referred to as spool, serrated, and mushroom pins. See the discussion below.

Shear Line: The level to which all pins must be raised in order for the plug to rotate.



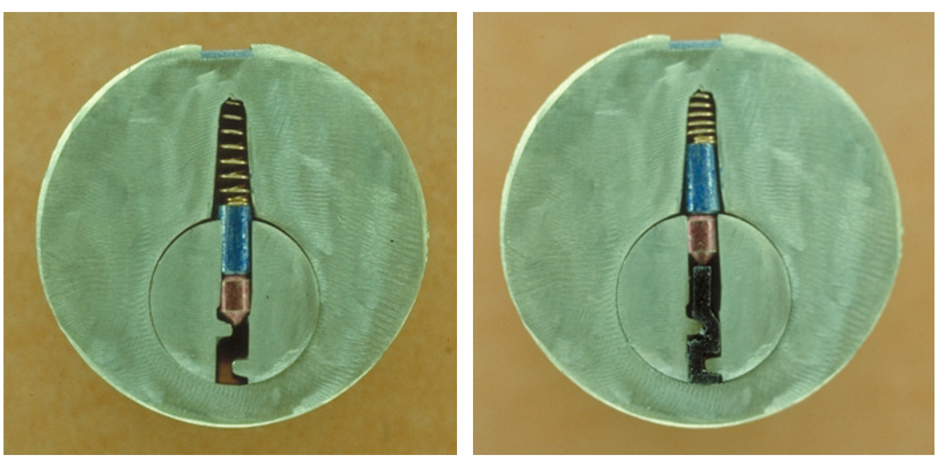


Figure LSS+1604 the shear line is the break point between bottom and top pins. Courtesy HPC Interactive Learning Series.

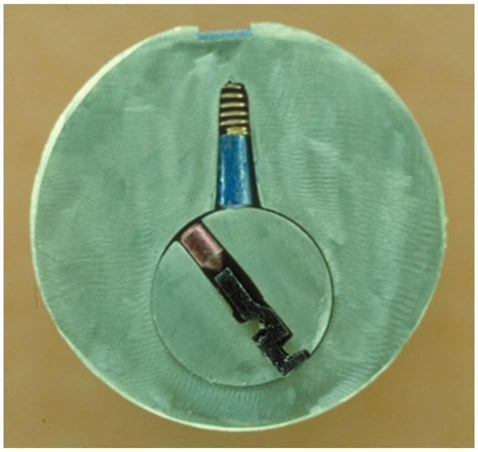

Figure LSS+1613. These photographs show the driver and lower pins in their three states.
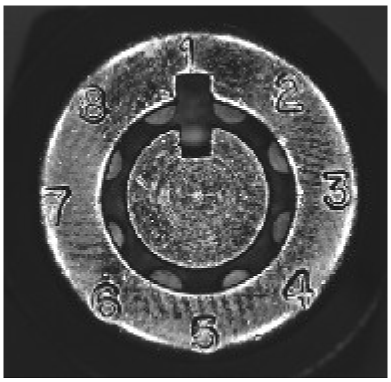
(Left), driver is blocking the rotation of the plug, (center) driver and lower pin are
split at shear line, and (right) plug can rotate. Courtesy of Bill Sherlock, Illinois State Police.

Shell: The shell contains all of the internal components: the upper and lower sets of pins, the springs, and the plug.

Springs: Springs provide the bias to force each tumbler-set into the plug and to maintain the integrity of the pin-stack while the key is inserted and removed. Proper functioning springs are very important: they insure reliable and continued operation and security against surreptitious methods of attack. For every driver there must be a spring, if jamming of tumblers and unreliable operation is to be avoided. Without them, dust and dirt will build-up in the lock, eventually freezing the tumblers in one position. The correct springs must be used: if too short, too long, or incorrect tension is produced, operational difficulties will occur.



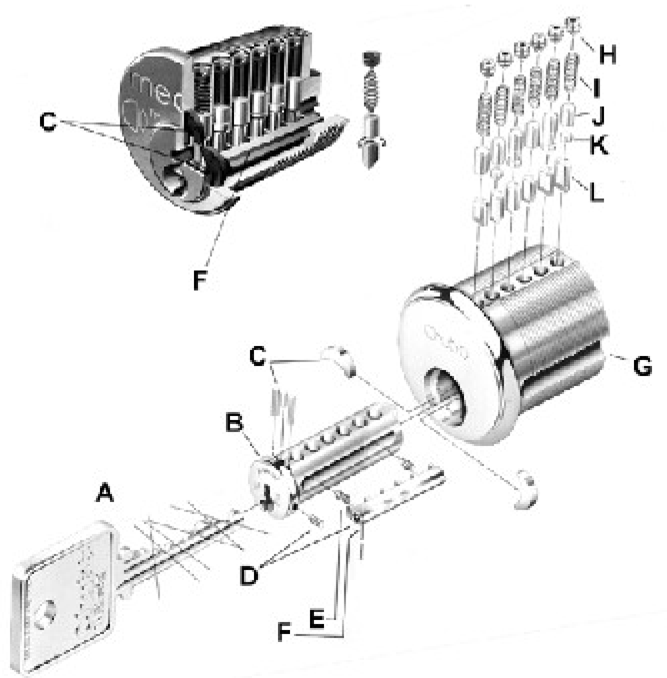
16_2.1 Mechanical Configurations

The double-detainer pin tumbler system of locking has been modified for a number of different mechanical configurations, for specialized applications. Regardless of the design, however, the basic operating theory is identical. Any lock that utilizes a split pin to create a shear line will block the rotation or movement of a plug, unless all of the tumblers are in alignment. Whether the pins are arranged in a straight line, axially, or in several planes around a circle, the theory is identical.

16_2.1.1 Conventional Design: Vertical or Horizontal Orientation

Locks utilizing the pin tumbler principle are produced in conventional form, aligned in one vertical or horizontal plane. All chambers or bores are co-located along one axis within a rotating plug.

16_2.1.2 Axial

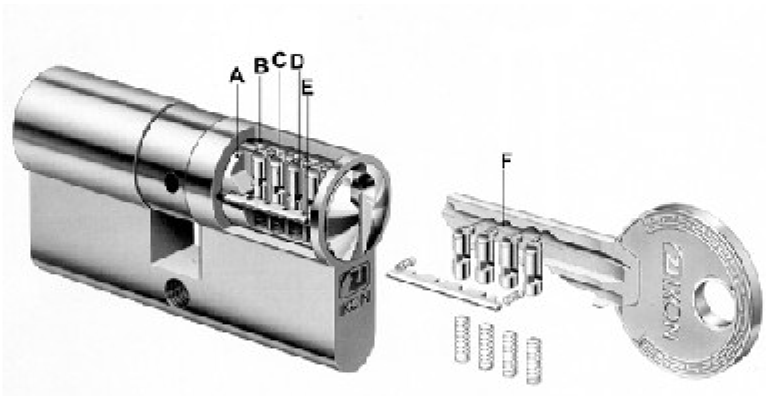


Locks are produced in an axial configuration, where up to eleven pins are organized around the circumference of a plug. The operation of the lock is identical to the conventional design; only the placement of the pins is different. Certain variations of the axial pin tumbler mechanism are described in **Chapters 17** and **23**.

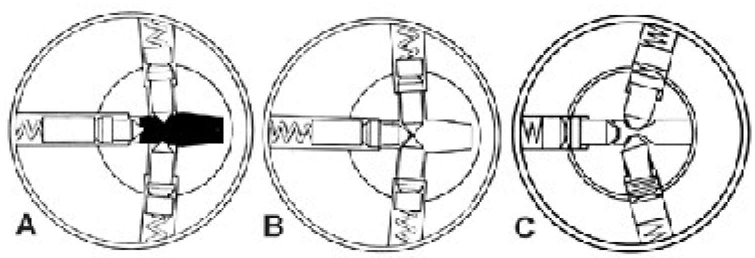
There have been many significant patents issued for rotary pin locks and security enhancements thereto. Relevant cites are included here. Picking and decoding tools for axial locks are described in **Chapters 29-30-31**. Kerr was granted three patents for a tamperproof lock (3267706, 3541819, **3813906(153)**). Buschi (3604231) invented a lock with sliding tumblers that controlled access by the key to a locking pin. Szova produced a lock based upon the same theory in 1977 (4006615).

16_2.1.3 Sidebar

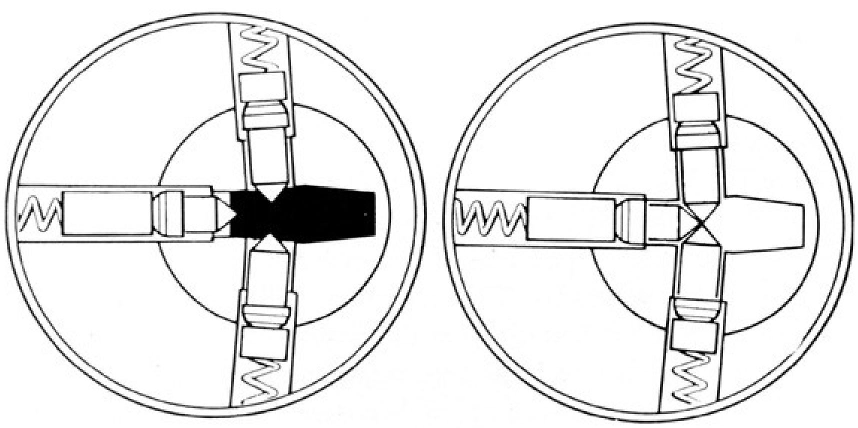
A sidebar pin tumbler lock utilizes conventional pins in combination with a secondary locking arrangement. In the best-known example, Medeco utilizes vertically oriented pins that must also be rotated to one of three or six angles in order for a secondary sidebar to engage. See Spain (**3499302(154)**,



3499303(155)) and Oliver (**4723427(156)**) for a description of the original Medeco designs.

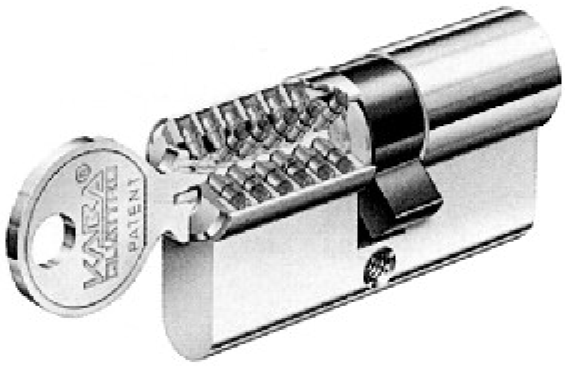


Some hybrid locks combine pin tumblers with other sidebar locking techniques; magnetic discs are probably the most popular. See **Chapters 17-23** for information on specialized applications.



Lopez, in 1973, was granted a patent (**3837197(157)**) for a sidebar lock that utilized dual- locking tumblers with detents. Likewise, in 1992, Folger Adam Company was assigned a patent from Stefanek for a high-security pin tumbler lock with a second set of angled pins (**5079936(158)**). Other patents have been granted for using auxiliary tumblers in different radial directions to prevent picking and impressioning. See Prunbauer (4434636), Hofmann (4343166), Gerlach (3802234), Crepinsek (3393542), and Bauer (3181320).

Other relevant patents for sidebar design include Oliver (39,910), Taylor (758026), Fitzgerald (1965889), Crepinsek (3393542), Besseches (3455130), Surko (3667264, 3713310, 4208894)), Gartner (3857263), Genakis (**4078406(159)**), Pechner (4185480), Vorob (4194604), Widen (4356713, 4393673, 4453432), Wolter (4377082), Reder (4380163), Hennessy (4404824, 4524593), Litvin (4429554), Prunbauer (4434636, 4250725), and Fits Gerald (1965336).



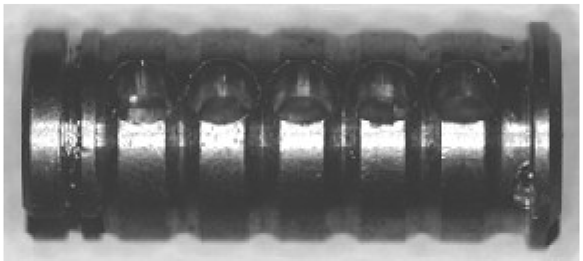
16_2.1.4 Multiple Interlaced Tumblers (Dimple Locks)

Keso, in 1968, introduced the dimple concept for high-security locks. Today, many manufacturers produce mechanisms that employ one or more rows of interleaved pin sets that encounter multiple bitting surfaces. Keso, DOM, Ikon, Evva, and Mul-T-Lock are the most popular in the industry. These locks are discussed in **Chapter 17**. Crepinsek (**3413831(160)**) was granted a patent in 1968 for a rotary cylinder lock that was the forerunner to more sophisticated devices in production today.

16_2.2 Tumblers

All pins have certain design characteristics relating to length, diameter, chamfer, and curvature. Security tumblers are a sub-class of the top pin and have variations in the number, location, and size of indents. Each manufacturer specifies pin chamber diameter and overall length for each lock they produce. This determination will control the number of depths that are available. This, in turn, allows calculation of differs.

The ends of the bottom pins that encounter the key may be **rounded**, **pointed**, or **square-cut** with a chamfer or bezel. For higher tolerance between the pin and valley of the cut, the surface may be flat-bottomed. Driver or top pins are generally square cut on both ends, with chamfering. There are three primary tumbler classifications: upper pins, called **drivers**, **lower pins**, and **master pins**.

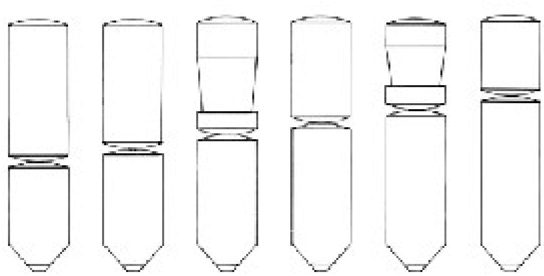


16_2.2.1 Driver Pins

While the lower pins make contact with the bittings of the key, the driver pins (or upper pins) press down on the lower set of pins and actually provide the locking function. The drivers are constantly biased by the springs directly above each chamber. There are four basic types of driver pins: **standard driver**, **mushroom**, **serrated**, **and spool tumbler**.

16_2.2.1.1 Standard Driver

The normal top pin is simply a flat-topped and flat-bottomed tumbler. Its function is to project into the plug or withdraw



into the shell and create a shear line in combination with the bottom pin when raised to the proper level. For the lock to operate smoothly, drivers must be perfectly flat-bottomed, or convex, depending upon the design of the plug-shell interface. In high-security locks, the plug is perfectly rounded; the tumblers will correspond in shape.

A lower pin with flat-bottom down may also be used as a driver. If driver pins are worn from use or old pins are reused when changing combinations, the plug may rotate roughly, catching edges of the tumblers at shear line. This is especially true if pins have been hand-filed or have worn at an angle. In such case, the lock may operate smoothly when turning the plug in one direction only.

Drivers are normally provided in three standard lengths, depending upon the space displaced by the lower pins in the plug. In a properly designed keying system, the drivers are said to be **balanced.** This means that the length of the pin-stack is **constant**, regardless of the length of the bottom pin. This parameter becomes important in preventing the use of a comb to pick a lock, discussed in **Chapter 29**.

LSS204: Brian Chan discussing balanced drivers

16_2.2.2 Lower Tumblers

The lower tumblers are those pins that are in direct contact with the bittings of the key. They are usually rounded on the bottom and flat on top and come in a variety of lengths and diameters. They are generally color-coded as to length. Tumbler size is based upon the diameter of the plug, the dimensions of the keyway, and the number of depths chosen for use by the lock maker.

Certain bottom tumblers resemble drivers in that both ends are flat. In such cases, the keys are cut specially with flat rather than rounded valleys. The Best Lock Company uses flat-bottomed tumblers to attain a closer tolerance between the bitting and pin. A flat-cut tumbler is not used with a rounded valley. A number of manufacturers insert steel balls below one or more lower pins. These have the effect of prolonging the life of the tumbler and allowing for smooth operation of the key.

16_2.2.3 Master Pins

Master pins are miniature drivers, sandwiched between lower and upper pins to create additional shear lines. They can vary in thickness from one depth-cut to many, depending upon the complexity of the master key system. Medeco patented a unique master key system in 1973, based upon their twisting tumbler sidebar design (**3722240(161)**). This approach to a multilevel keying system virtually eliminated the potential for cross-keying.

16_2.2.4 Security Tumblers: Mushroom, Spool, Serrated

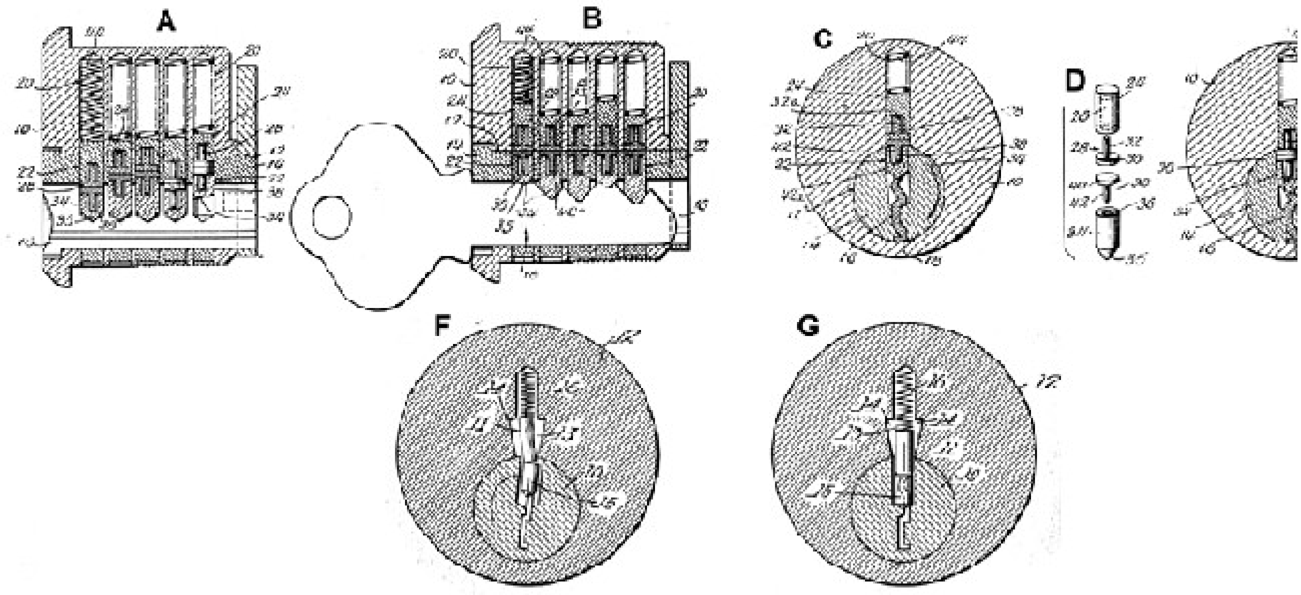
Forensic issues regarding the bypass of security and mushroom tumblers. Courtesy of Hans Mejlshede.

Security tumblers are installed in order to make picking more difficult. They are interchangeable with standard drivers and are used by many manufacturers, especially in more expensive locks. Security tumblers can be picked, but special procedures are required. As a rule, a five-pin lock will have up to three security tumblers; a seven-pin lock, up to four tumblers. It is not possible to fill every chamber with these special pins because the lock would not function properly.

Although there are many different tumbler designs, the function of all security tumblers is the same: **to create a false**

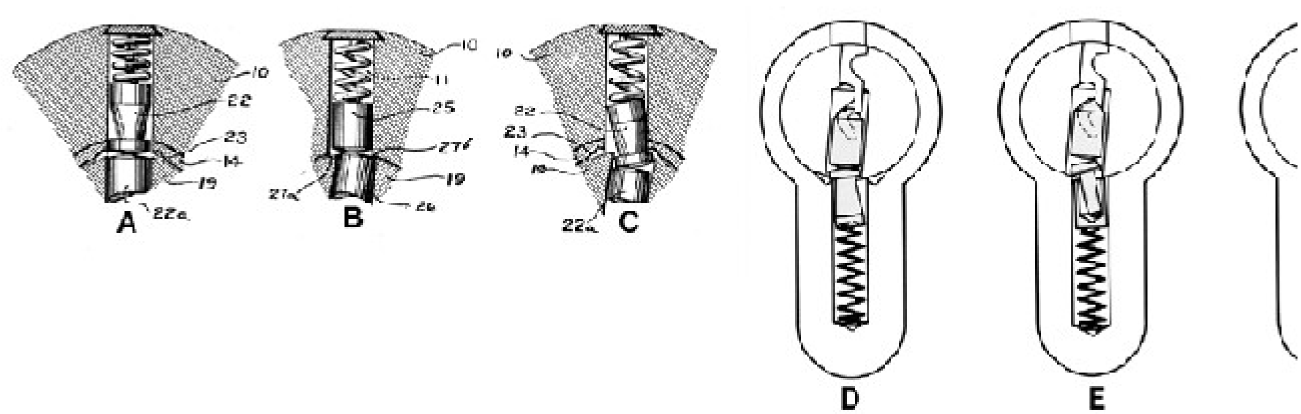
indication of shear line. Ironically, while these pins can make picking very difficult, certain security tumblers, such as serrated, may make impressioning easier. A discussion regarding picking and impressioning of these tumblers is presented in **Chapters 29-30-31.**

Although their use is standard in most high-security locks, the installation of security tumblers to replace driver pins has become common in the less expensive cylinders, also. Whether mushroom, spool, serrated, “S” design, or a combination of variations, their dimensions will always include indented gaps, ridges or notches that will “catch” between the shell and plug.



There have been many attempts to deter picking, impressioning, and decoding through the alteration of pins and their chambers. Many significant U.S. patents have been granted for such designs. It appears that the first U.S. patent to issue for a security tumbler was in 1865. Several other patents have been granted for variations upon the original concept, but the security tumbler, regardless of form, always has the same purpose.

A number of patents have been issued for modifications to pin tumbler locks to prevent picking. The following patent cites relate to the alteration of pins and bores in order to trap tumblers that are the subject of pressure or torque caused by picking: Hainline (1739964), Thompson (2043205), Fremon (2194469), Rauh (**2281714(162)**), Crousore (2283489), Spiegler (2565531), Pastor (2596720), Mendelsohn (**2629249(163)**), Crepinsek (3393542), Wolter (3731507), Neale (3824818), Genakis (4068508, 4068509), Raskevicius (4098103), Schlage (4107966), Voight (2149959), Taylor (457753), Maxwell (**2059129(164)**), Voight (**2194959(165)**).



In 1989, Johnson invented a high-security axial lock for the Fort Lock Corporation (**4802354(166)**) that included notches in the driver tumblers.

16_2.2.4.1 Specific Parameters for Pins

All pin designs are based upon the fundamental technique of lock-picking: the application of turning pressure on the plug in order to bind pins above the shear line. Whether pins individually are forced into the upper chamber with the pick or are initially moved there, then released to fall back to the plug, all security tumblers will essentially perform the same function.

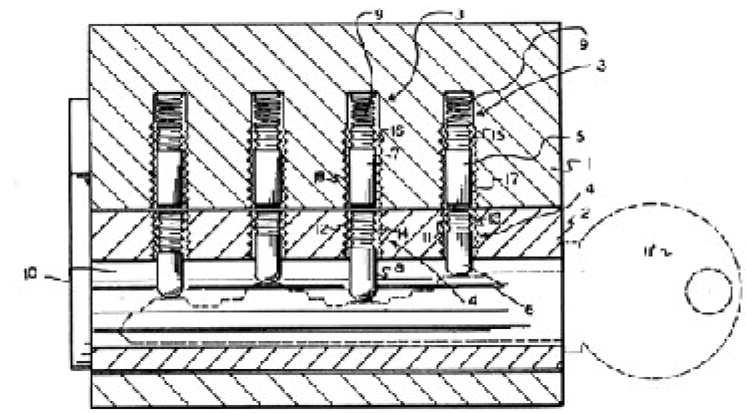
In order to enhance pick resistance, the size, shape, diameter, and striations of the lower and upper tumblers as well as their bores have been altered.

Exploded view 1, 2.

16_2.2.4.1.1 Cylinder Bores

Many structures have been patented based upon serration or grooving of the cylinder bores, the plug bores, the driver pins, and the lower pins. Where transverse grooves are provided in the pins and bores, the pins cannot move freely during the picking process. The diameters of the upper and lower chambers have been altered in some locks so that the upper bores are slightly

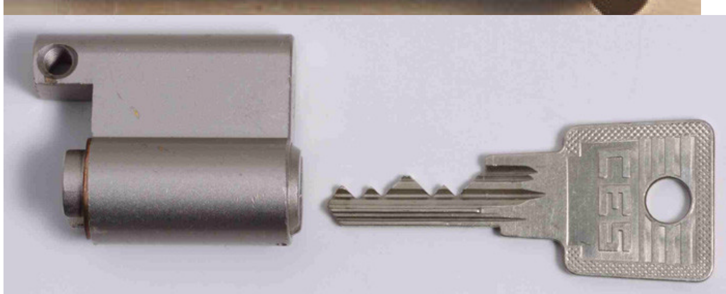
larger. In other designs, the bores and pins have been threaded and provided with sufficient tolerance that when torque is applied to the plug, the top pin will be caught in the threads.



In the Genakis patent (**4078406(167)**), bores are modified to trap tumblers when upward pressure and torque are applied simultaneously. Eizen, in his 1989 patent (**4856309(168)**), describes a system of grooves within the plug to prevent picking. This invention was incorporated into the Mul-T-Lock and is further described in Chapter 17. Embry, in 1990 (4977768), incorporated specially designed pins and bores in an axial lock to defeat picking attempts. In 1932, Gutman altered the size of the upper chambers to make picking more difficult (**1860712(169)**). In 1938, he devised a multisegment pin with shoulders to prevent decoding, vibrating, and picking (**2158501(170)**). Then Liss, in 1934, patented a type of serrated pin (**2070233(171)**) for securing the plug against picking. Crusore, in 1942, developed a tumbler that was grooved and would cooperate with recesses in the bores to make picking very difficult (2283489). Hucknall, in 1973 (**3762193(172)**), developed a pick resistant lock utilizing special pins and milled bores, and Mendelsohn patented a lock with grooved pins and bores (**2629249(173)**) that frustrated picking.

16_2.2.4.1.2 Indents, Grooves, Ridges, and Serrations

The number, spacing, depth, and diameter of the grooves have been changed, both with respect to the pins and their chambers. Telescoping pins have also been employed to create false indications of shear line.

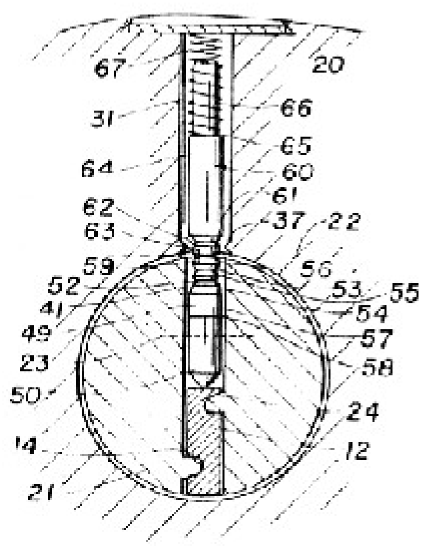


False ridges, shoulders, and serration patterns have been employed within the bores to freeze the movement of pins, except under prescribed conditions. This would occur when their dividing line is coincident to the shear line between the cylinder and plug. The materials used for the production of pins have even been changed to allow shearing or flexure, depending upon design.

In 1990, Embry was granted a patent (4977768) for a specially designed pin to be incorporated in an axial lock in order to frustrate picking. This tumbler was a modified spool that would catch whenever pressure was applied to it.

An interesting approach was taken by CES by creating a special pin in the third bore of this plug that requires a correspondingly high cut on the key. This makes picking extremely difficult.

16_2.2.4.1.3 Spring Bias



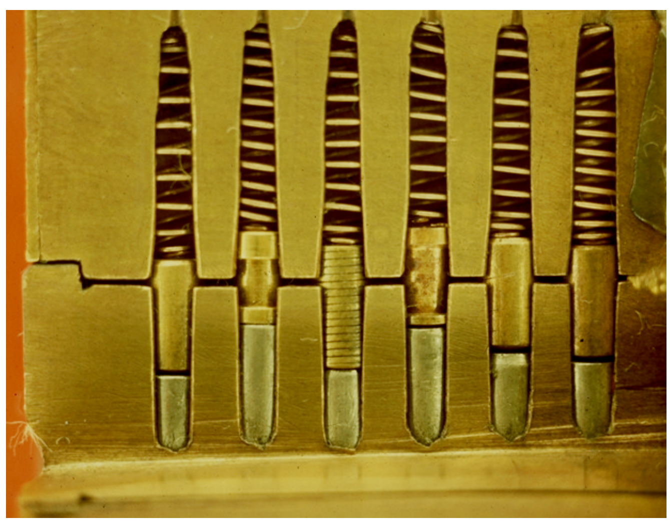
Kerr received a patent in 1966 for an invention to defeat pick tools specifically designed for axial pin tumbler locks (3270538). He describes the incorporation of springs with varying tensions within a lock in order to frustrate picking and decoding.

16_2.2.4.1.4 Secondary Locking Pins

Secondary locking pins have been utilized to block access to primary tumblers in an effort to prevent picking. In 1975, Steinbach was granted a patent (**3916657(174)**) for an axial lock that allowed pins to be rotated to a secondary position.

16_2.2.4.1.5 Mushroom and Spool Tumblers

The design of mushroom and spool tumblers is quite similar. Unfortunately, they cannot be used to replace all of the driver pins in the lock. This would cause the plug to rest in an off-center position with respect to the shell, creating a misalignment between upper and lower pin chambers and making key insertion difficult. In contrast, "S" pins may be used in all chambers. Often, they may be detected by looking into the keyway.



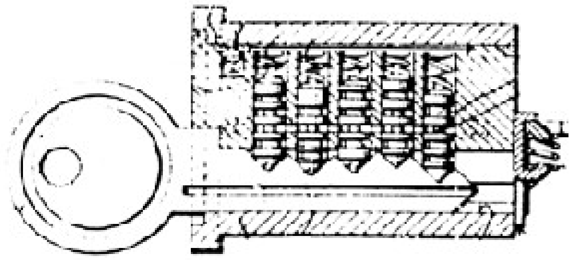


Figure LSS+1614 This sectional view graphically illustrates the location and function of the mushroom tumblers in positions two and four. Courtesy of Illinois State Police, Bill Sherlock.

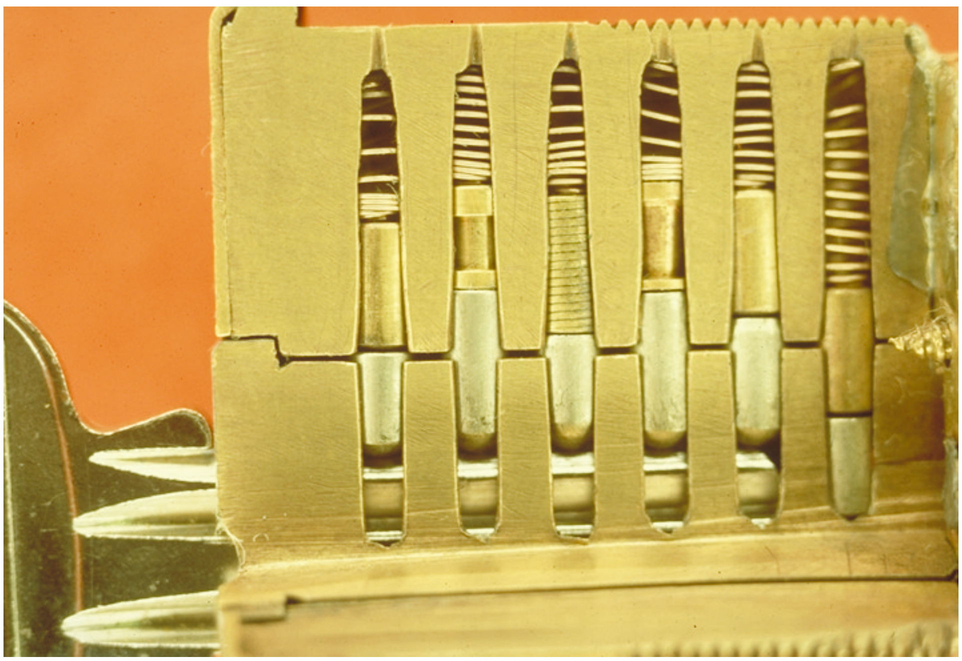
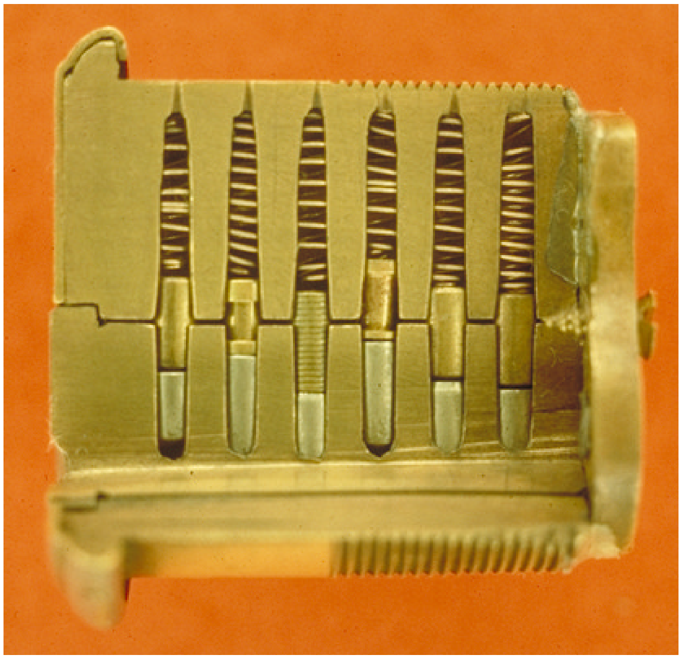


16_2.2.4.1.6 Serrated Tumblers



Serrated tumblers actually contain many segments common to the mushroom or spool. Generally, serrated tumblers have a series of ridges on the tops, bottoms, and sides. Pin chambers may also be serrated. Master pins are never serrated.

16_3.0 The Pin Tumbler Mechanism: Principles of Operation

This section describes the theory and principles of the pin tumbler mechanism.

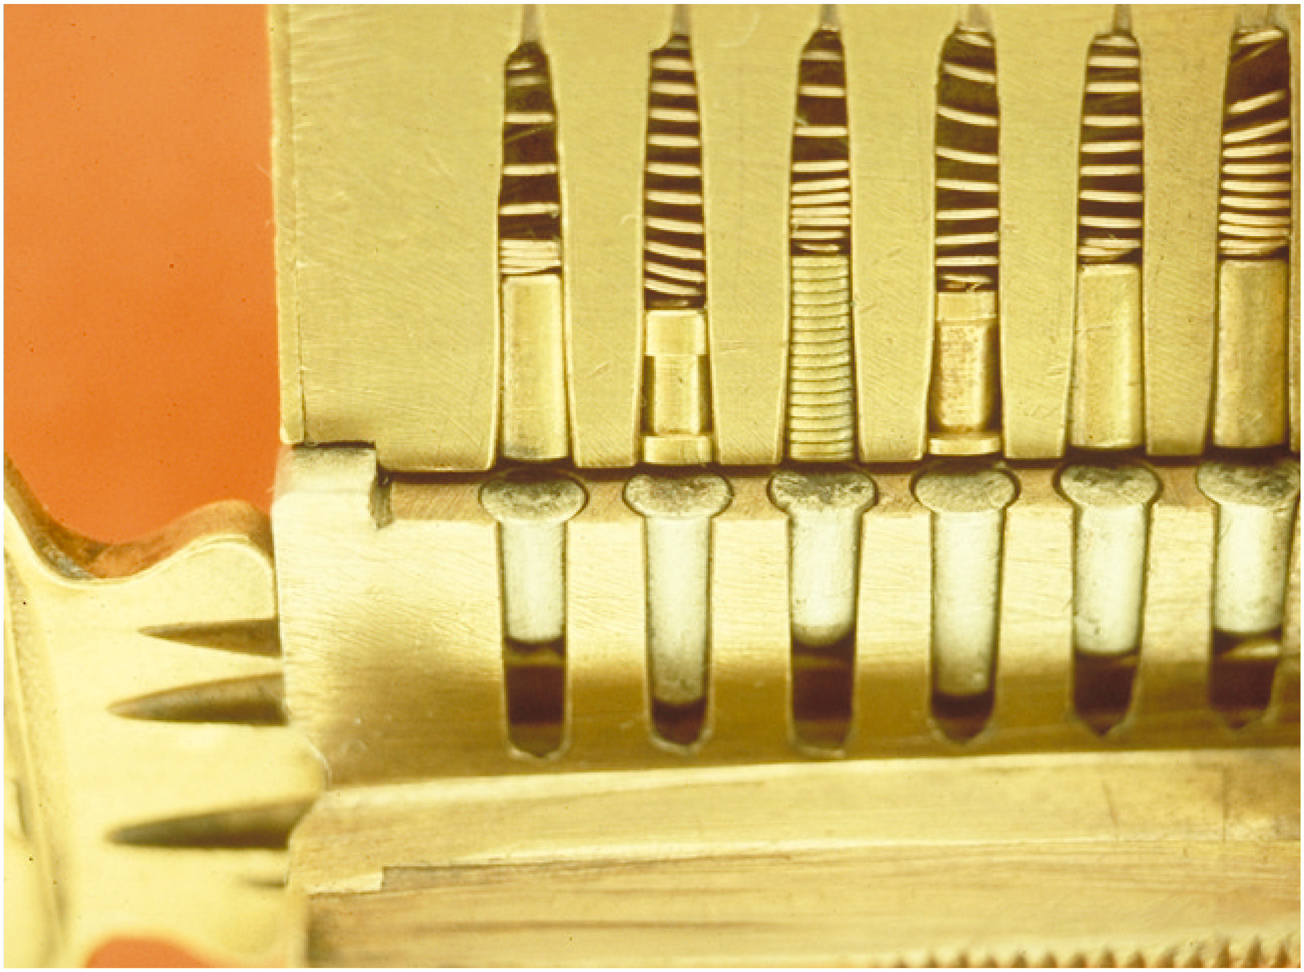


Figure LSS+1615 Sectional photographs showing the status of driver and bottom pins in the locked and plug rotating unlocked position. Courtesy of Illinois State Police, Bill Sherlock.

16_3.1 Introduction

Every lock has relied upon some mechanical means to keep a specific part (bolt) from moving (opening or locking) until the correct device, code, or combination is inserted or applied to the mechanism. The pin tumbler design probably offers the most inherent security and flexibility of all the different mechanical locks presented in this text. Its operating principle is based upon the double detainer theory of locking which is actually quite straightforward.

Let us begin our discussion by examining the pin tumbler cylinder in terms of its mechanical operation and security, from the

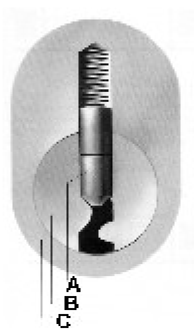
perspective of a design engineer such as Linus Yale of 150 years ago. Yale set out to construct a lock that utilized split pins as the basis of its security. He knew that 4,000 years earlier, the Egyptians had invented a lock which also used pins but in quite a different configuration. Once he conceived of the shear line, the other design requirements were obvious. Based upon the underlying theory of operation, its evolution and required mechanical components become logical and easy to understand.

16_3.1.1 The Simple Mechanism that only controls a Bolt

At one extreme, a lock could be constructed which simply controlled the operation of a bolt or latch without regard to security. At the other extreme, a high-security device could be built that maintained close tolerances and required a precision key to allow actuation of the bolt.

In the first instance, all that is needed is a housing (shell) that contains a rotating member (plug) connected to an actuating mechanism (cam) which transmits action (rotation) to a bolt. This "lock" in its simplest form would consist of a housing with a hole drilled through it. A solid plug with a slot in the front would be inserted into this hole and attached to the bolt. Turning the plug, with a screwdriver, flat piece of metal, or key would transfer the motion to the cam and thus the bolt.

There would be no security in this lock; any blade could rotate the plug. It would simply be a matter of communicating a turning motion to the bolt via the plug. The important mechanical consideration in our most simple lock is the interaction of the plug with the shell in allowing a turning motion. **The plug rotates within the shell; the shell provides a bearing surface and stability.**



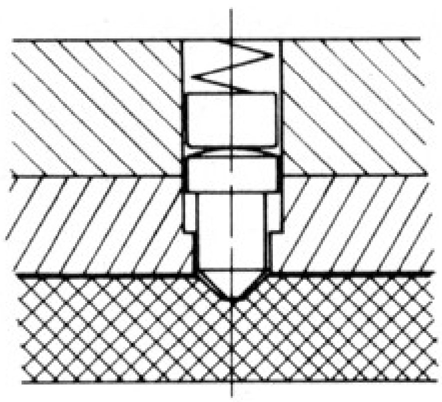
The mechanism just described will perform one function: it will allow anyone with the proper tool to turn the plug, thereby extending or retracting a bolt. What if we now want to add **security** to this lock? Enter Linus Yale.

16_3.1.2 A Lock that provides Security

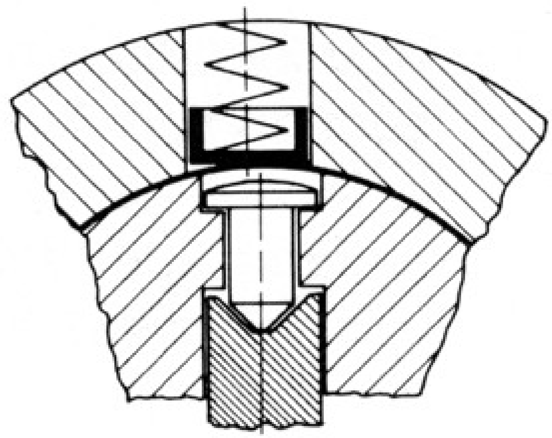
Now, we must provide the mechanics to accomplish several tasks, depending upon **how much security** we desire. The critical action that must be controlled is the movement of the plug, because it is directly linked to the bolt. In the final analysis, the

purpose of every component within the lock is to actuate the bolt. That is where we shall concentrate our efforts regarding security.

Security in every lock is a function of access to the bolt by the authorized user. The level of restrictions that can be placed on access provides an index of security. We must create a method to stop or block rotation of the plug until a defined event occurs. That event is the insertion of the correct key, code, or combination. With this in mind, we shall now add components to create our modern pin tumbler lock, first conceived 4,000 years ago and made practical by Yale.



Once Linus Yale determined that he needed to rotate a plug within a shell to control a bolt, the Egyptian design provided the basis upon which to block that rotation: the **split pin tumbler.** Yale thought that if a moveable piston or pin was allowed to travel vertically within chambers or bores between the shell and plug, then he had a means to control plug rotation. The position of each pin could independently control whether the plug could rotate. When multiple pins were utilized, then the security of the lock increased dramatically.



The Egyptian lock used several moveable **solid** pins that were lifted above the plug to allow rotation. The means to raise each of the pins was provided by placing corresponding pegs on the end of the key. Yale modified the ancient design by incorporating a **split pin** within the lock housing, creating an upper (driver) and lower pin. Yale then drilled vertical holes through the shell and plug and placed a pin and spring in each hole or chamber. The pin segments would be separated at the place where the plug **met** the shell. This would be called the **shear line**.

These channels would allow the pins to travel together within each pin chamber. The moment the pin was inserted into the

shell, each of the top pins (drivers) would be forced partially into the plug because of the spring bias applied to the top of the driver. The system is said to be one of **positive locking.** That is, the plug is frozen in position at all times, except when the correct key is inserted. In contrast, a **negative locking** system would provide that when any but the correct key was inserted, the plug would be prevented from moving because the pins would be forced out of alignment. The distinction is subtle but important.

Positive Locking

Negative Locking

LSS204: Brian Chan on positive and negative locking.

It can be seen that once a pin occupies space in **both the shell and plug at the same time,** the plug is not free to move until the pin is lifted to a point where blockage does not occur. That point is called shear line. It is defined as the place where the lower pin is precisely level with the diameter of the plug. When the lower pin is lifted to shear line, there is no longer an obstruction to rotation. This is because the driver is fully contained within the shell and the lower pin is completely within the plug; no part of either pin is protruding. The upper and lower pins are "split" at the exact point where a gap occurs between plug and shell.

If we add a **keyway** to limit what can enter the plug, we have a modern pin tumbler lock. Once the key clears the wards within the keyway, the bitting will physically raise each of the lower pins to shear line. The bitting replaced the pegs in the Egyptian key.

All of the modern modifications to the Yale lock are but refinements of the simple principle of blocking rotation of the plug. Thus, the rotating tumbler (Medeco); dimple (Keso, DOM, and Ikon); magnetic rotating tumbler (Ikon, Evva, Chubb); axial (Chicago Lock); and other designs are all based upon the use of the split tumbler to stop rotation until all pins are lifted to one or more shear lines.

16_3.1.3 Operation of the Modern Pin Tumbler Lock

In operation, the key is inserted into the keyway: only the proper blank is allowed to enter. If correct, the bittings will raise the lower tumblers to the same level as the outer diameter or top of the plug. The lower tumblers must be raised just to the top of the plug and no further. If the bitting is cut too high, causing the lower tumblers to be raised **above** shear line, then they will be forced up into the shell. Conversely, if the bitting is too low, the drivers will fall **below** shear line, also resulting in a locked plug.

Because of the close tolerances achieved in manufacturing, the tumblers must be precisely leveled at shear line. If they protrude or are recessed > ±.002", the plug will not turn. This tolerance depends upon the quality of the lock.

16_3.2 Security of the Pin Tumbler Lock

The rating of a lock is affected by many factors. The mere fact that the mechanism is a pin tumbler does not guarantee any measure of security. Protection against forced and surreptitious entry depends upon the following factors:

- **Manufacturing tolerances;**
- **Materials utilized and their metal content;**
- **Number and type of pins;**
- **Differs;**
- **Keyway design;**
- **Use of security tumblers;**
- **Master keying levels;**
- **Anti-drill pins;**
- **Special variations of the lock design (as with Medeco, for example);**

- **Other enhancements to increase security.**

Perhaps the most important criteria in the analysis of the security of any cylinder is manufacturing tolerance between plug and shell, the design of the keyway, and the use of security tumblers.

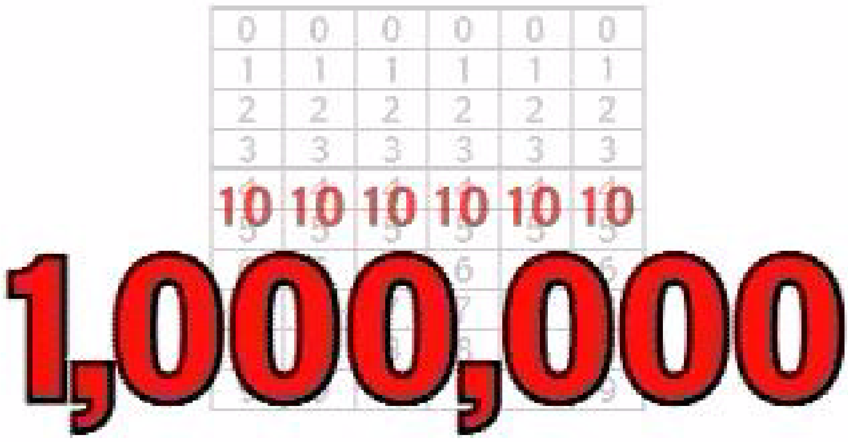
16_3.3 Keyway Design

There are hundreds of thousands of different keyways in use worldwide. Keyways provide security by limiting the global number of keys that can enter the lock. The keyway is the first limiting criteria to restrict access to the internal mechanism. Keyways can be designed through a combination of square, rounded, curved and angled bullets or fixed wards, to make entry by all but the correct blank very difficult. Thus, the paracentric keyway will contain obstructions that cross the vertical centerline of the entrance to the plug. Such designs make the insertion of a pick tool difficult.

16_3.4 Depth Segments and Differs

The manufacturer will decide how many different depths shall be available for a given key bitting. That will define how many "segments" the lower pin can be divided into and, thus, its overall length.

0	0	0	0	0	0
1	1	1	1	1	1
2	2	2	2	2	2
3	3	3	3	3	3
4	4	4	4	4	4
5	5	5	5	5	5
6	6	6	6	6	6
7	7	7	7	7	7
8	8	8	8	8	8
9	9	9	9	9	9



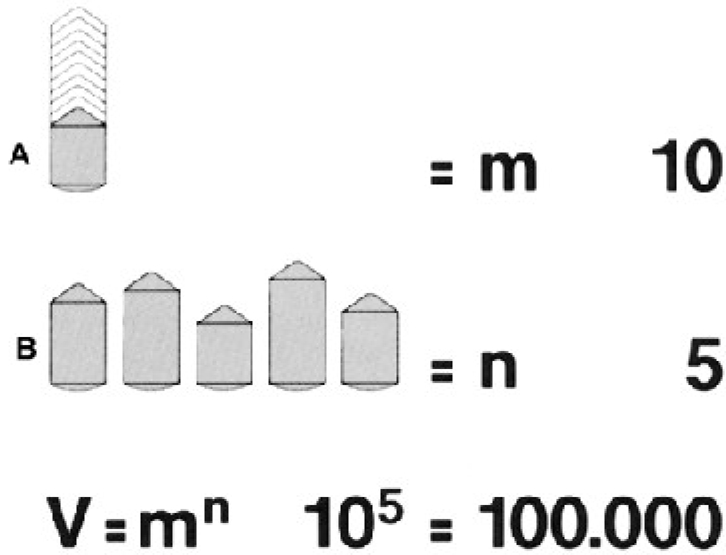


Figure LSS+1605 In a six pin tumbler lock with ten depth segments per chamber, there are a total theoretical number of combinations of 1,000,000. However, this number will actually be far less, depending upon tolerance and master keying levels. Courtesy of HPC Interactive Learning Series.

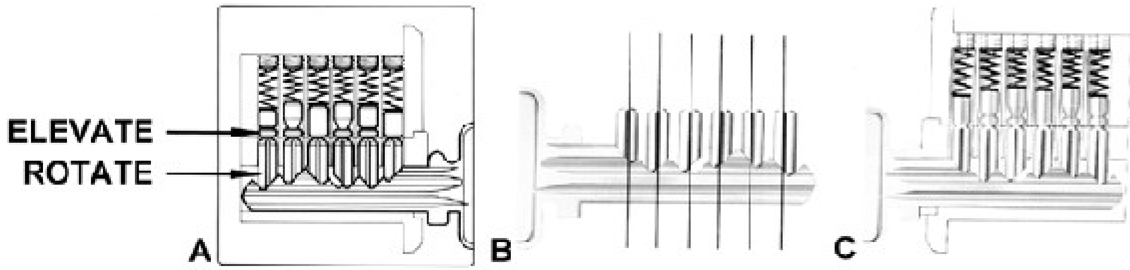


It can be seen that the greater the number of increments or segments into which the lower pins are divided reduces the distance between segments. Plug-shell tolerance must be such that the smallest pin segment must be at least twice or three times the plug-shell gap in order to prevent the pin from becoming caught between moving surfaces.

Shell-plug tolerance relates directly to differing, or the number of theoretical different key combinations available to the manufacturer. A greater precision between moving parts allows a larger number of bitting depths to be utilized. The gap between plug and shell must be factored into the distance that the lower pin is allowed to travel.

A five-tumbler lock, for example, allowing for ten different depth cuts, will offer $\mathbf{10^5}$ or 100,000 different combinations. When using six tumblers with ten depth cuts, we will have 1,000,000, or $\mathbf{10^6}$ different combinations. A thorough discussion of manufacturing tolerances is presented later in this chapter and is critical to an understanding of picking and impressioning. Rarely are pin segments less than .023". This relates to the tolerance of most locks, the potential for cross-keying, and the fact that master pins would be too thin to operate reliably. Note that the number of theoretical combinations will be different in master key systems, and will in part depend upon whether the rotating constant or total position progression method is utilized. The number of differs with master key systems will also relate to whether one or two-step progression is chosen. A thorough discussion of this subject is presented in **chapter 11**.

The decision as to the distance between pin chambers depends upon a number of factors. Because each lower pin must rest in the center of the valley (root) of each key cut and not on the slopes, the key will take on certain design constraints. There must be enough spacing between cuts to allow proper seating and smooth operation in tumbler movement. Thus, a specified minimum spacing is required between cuts. This will dictate inter-chamber distance and the number of chambers for a given plug. Medeco, in their Biaxial lock, has utilized this principle to increase the number of possible combinations by controlling **where** the bottom tumbler rests on the bitting surface.

The length of the top pin for a given chamber will be dependent upon the length of the lower pin. If a deep cut is present requiring a long lower pin, then the corresponding driver will have to be relatively short. This will prevent the spring from being compressed in the upper chamber. Standard pinning kits are available for all lock manufacturers. HPC, for example, contains color-coded pins for all lengths used in driver, master pin, and bottom pins. This kit is highly recommended when any cylinder work is to be performed.

16_4.0 Keys for Pin Tumbler Locks

There are three basic profiles used in pin tumbler locks: **regular bitting**, **dimple**, and **laser track**. Each type of key must meet stringent design parameters to function properly in a given cylinder. Angle of cut, ramps, valleys, spacing between pins, difference between depths, and other factors all must be considered. A unique patent was issued in 1994 to Escribens (**5355702(175)**) for s security key that will open several different locks by adjusting moveable sliders to simulate the proper tumbler combination.

Cutting tolerance must be maintained between .0075"-.003" for correct key duplication. A .005" variance per copy is acceptable. The tolerance in making blanks should be held to .001"-.003." Key machines should be capable of maintaining tolerance for ten generations in the duplication process.

16_4.1 Changing Combinations

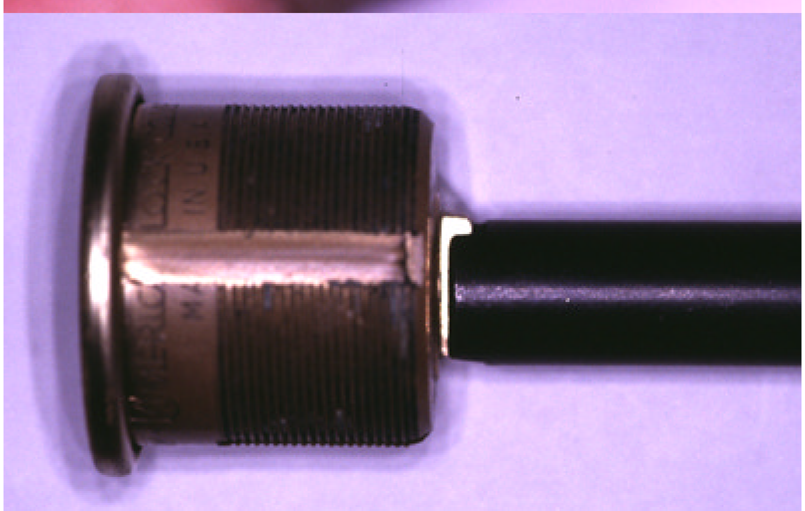
Depending upon the complexity of keying within the lock, changing combinations can be simple or complicated and generally requires that the lock first be disassembled. There are, however, certain mechanisms in which the tumbler combination can be altered externally. See **Chapter 22** for a discussion of Instant rekey locks. The plug can be removed by a variety of techniques.

Depending upon what is to be accomplished, only the lower pins may be changed, or all pins may be exchanged by emptying each chamber of the spring, driver, lower pin, and any master pins.

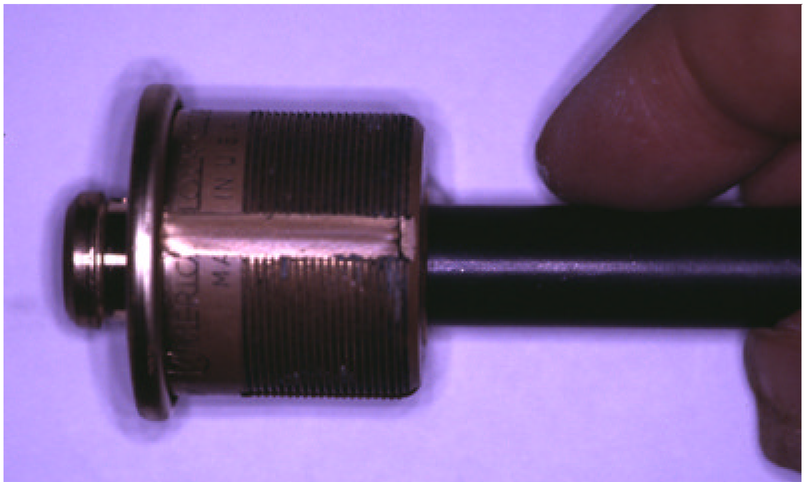
If the lock is not master keyed, the lower pins can be switched or new tumblers inserted. Generally, the new key will be cut by code prior to taking the lock apart, so all that is required is to insert the new tumblers. If change keys are altered within a master key system, then new master pins as well as lower pins will be substituted within the pin-stack.

16_4.2 Procedures for Disassembly of Pin Tumbler Locks

There are many reasons to take apart a lock, including keying, rekeying, master keying, maintenance, decoding, and forensic examination. Methods of non-destructive disassembly include use of the correct key, shimming, rapping, "999" rapping, picking, impressioning, and removal of all pins through the pin chambers. A discussion of these methods, in the context of producing keys, is presented in **Chapter 9.** Specific procedures for disassembly to allow forensic analysis are presented in **Chapters 24-27.**

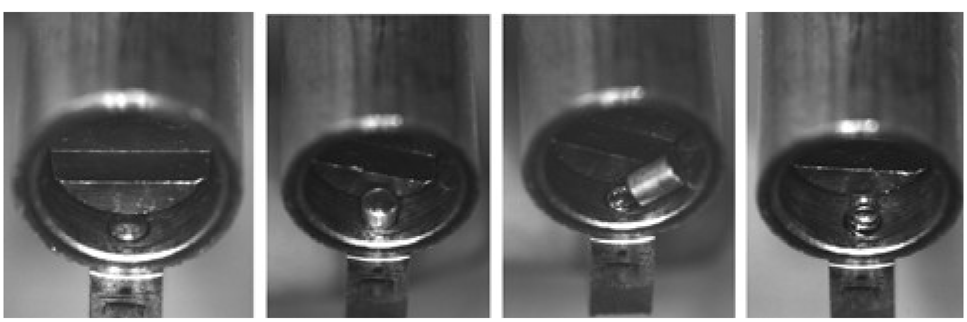


Certain precautions must be observed whenever a lock is disassembled, unless there is no concern for loss of components, and retention of the combination is not important.



16_4.2.1 Use of a Following Tool

A follower must be utilized to fill the void left by the plug as it is withdrawn from the lock, unless pins are removed through the brass retaining strip at the top of the cylinder, shown below. If the tool is not utilized or it is used improperly, one or more springs, driver pins, or master pins can be ejected from their chambers.



The series of photographs demonstrates the proper procedure for removing the plug from a cylinder without disturbing the driver pins, and for repinning a cylinder once all of the pins have been removed.

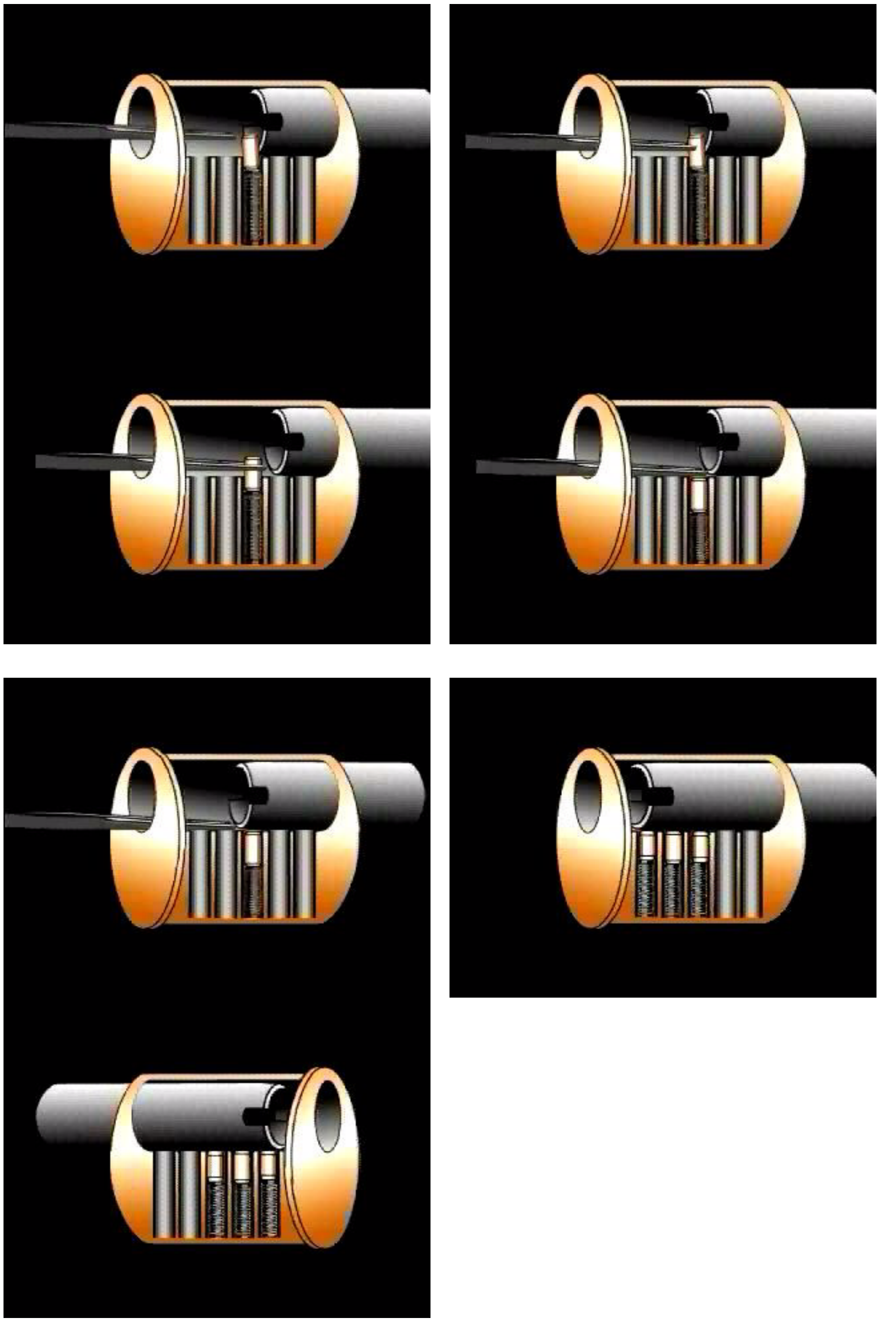


Figure LSS+1606 The repinning of the top pins requires the use of a follower tool, or removal of the spring retaining strip. In this series of photographs, the driver is inserted from one end of the cylinder and moved to the center chamber, which is loaded with a spring and top pin. It is depressed by a pick until the pin resides partially within the chamber. The follower is then abutted against the pin to freeze it into position. The pin is then depressed entirely within the chamber, and the follower then moved over the top of the pin, thereby retaining it in position. This process is then repeated for each

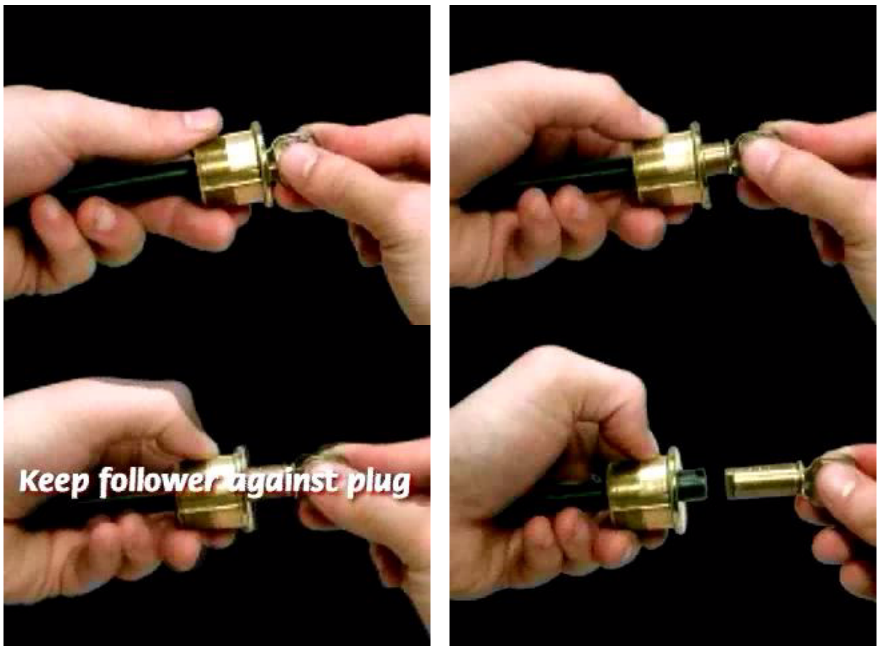
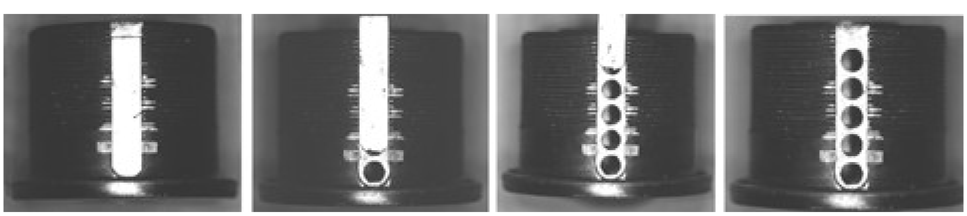
pin to either side of the center chamber, until all pins are loaded into their respective chambers. It can be seen that once three chambers are loaded (from center to the edge of the cylinder), the follower's direction is reversed and the remaining chambers are loaded. Courtesy of the HPC Interactive Learning Series.





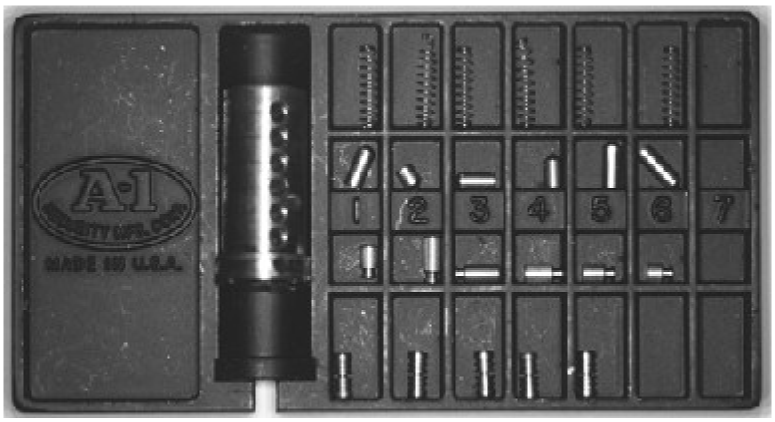


Figure LSS+1607 Once all of the top chambers have been loaded with driver pins, the plug containing the lower pins is inserted into the cylinder, and the following tool removed. The procedure to accomplish this requires that the plug and follower be placed against each other and inserted as one complete entity, as if the end of the plug and follower were connected to each other. In this way, none of the driver pins have the opportunity to eject from their chambers. The process is reversed during the disassembly of a cylinder, as shown in the above series of photographs. In such case, the follower is inserted at the rear of the cylinder and the plug is pushed forward as the follower takes its place. Take care not to allow a gap between the two, and that the rotation of the plug prior to removal is such that the pins within each of the bottom plug chambers can be controlled so that they do not fall out. Also, it is very important to insure that the plug be turned at least twenty degrees prior to removal to insure that drivers do not enter the lower chambers during removal. Courtesy of HPC Interactive Learning Series.

16_4.2.2 Use of Setup Tray

A setup tray provides an orderly means for preserving the position of all pins removed from the lock and thus allows for keying to be documented and reproduced. When the lock is disassembled, extreme caution should exercised as the driver pins are removed.

The use of a pin tray or setup tray is required for forensic disassembly of a lock. Courtesy of Hans Mejlshede.

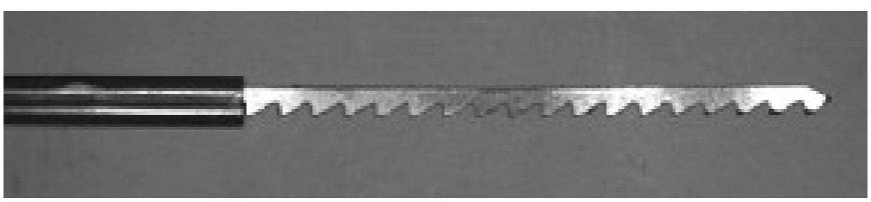
If more than one pin is present in each of the top or bottom chambers, the lock is master keyed. Depending upon the level of master keying, there may be one or more master pins in one or more pin chambers.

16_4.2.3 Use of Pin Tweezers

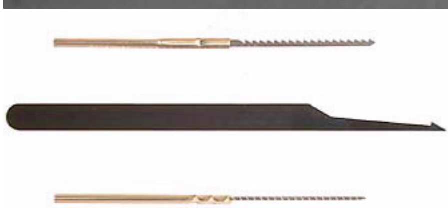
Special pin tweezers referred to elsewhere in this chapter are recommended for pin removal and insertion. If a forensic examination is to be conducted, then wooden or nylon tongs should be employed rather than metal tweezers.

16_4.2.4 Removal and Insertion of Pins

When pins are to be removed or replaced, the proper procedure must be followed in order that the pin-stack order and combinations not be altered. As each pin is withdrawn, it is placed in its respective position in the setup tray. The lock can be decoded and repinned directly from the setup tray, if required. As each top pin is released from the shell, attention must be given to the possibility that one or more master pins may



be present. Pressure is applied to the follower to control the ejection of each pin from each chamber. Once tumblers are removed, a micrometer may be utilized to read the length of each pin segment. The manufacturer specifications may then be consulted to determine the direct code for all permutations present in the lock.

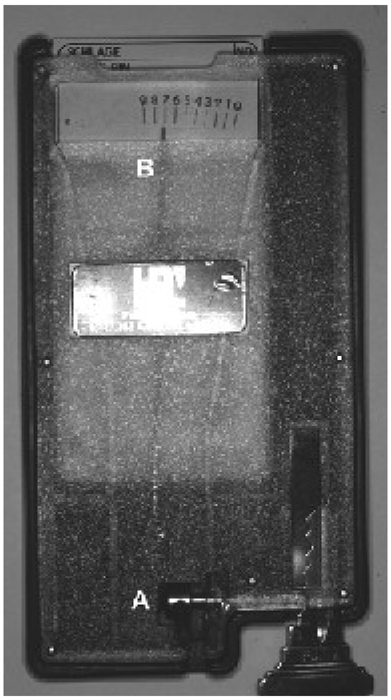


16_4.2.5 Lubrication

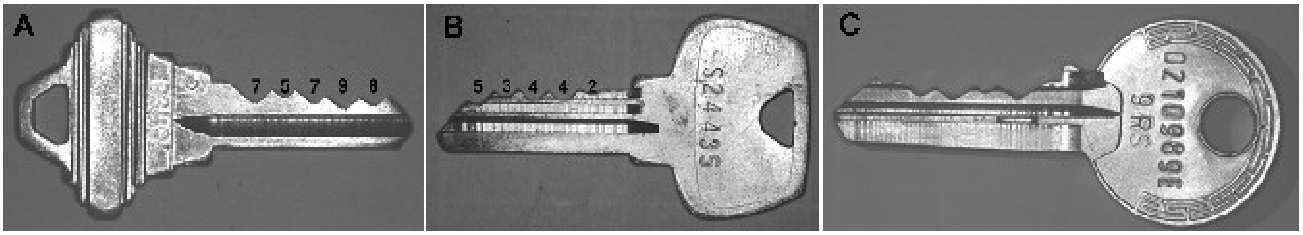
Ideally, a brass lock should be lubricated at least once a year. A lubricant such as oil that thickens or mixes with other materials cannot be used. In contrast, iron and steel parts must be lubricated regularly, especially in damp or moist climates, using grease or light oil. A dry lubricant such as graphite or WD-40 may be used for pin tumbler locks. The material is squirted into the lock, although the old way was to run a lead pencil over the key.

16_4.2.6 Broken Keys

A broken key lodged in the keyway can be removed by an extractor. This tool is either inserted to the side of the key or above it to catch the bittings. A straight or curved pick or a straightened fishhook can also be used. If the key was back cut, the tumblers must all be raised before the key can be withdrawn. See the Kimzey patent, granted in 2000, for a unique extractor design for removing inaccessible portions of a key from the keyway (**6052883(176)**).



16_4.3 Keys by Code

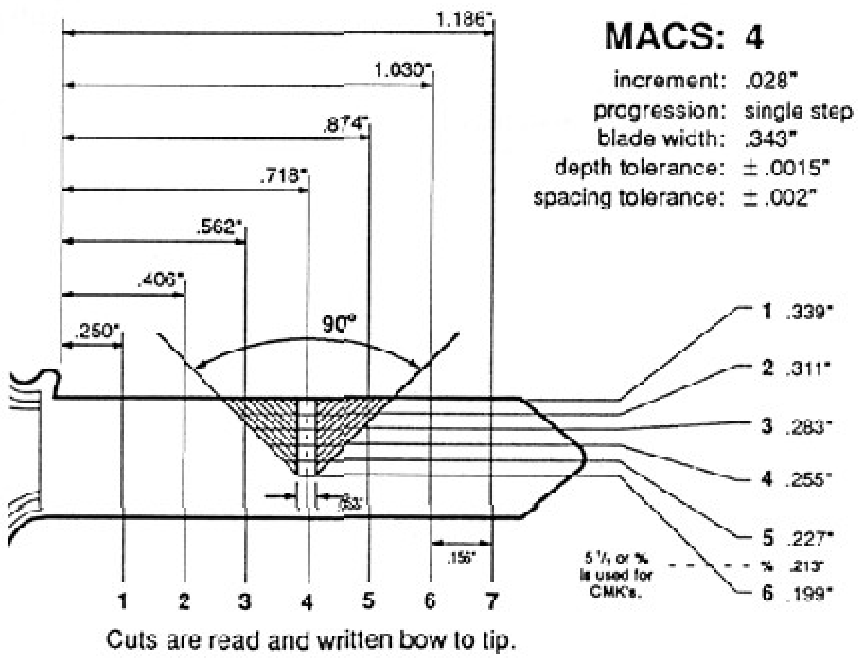


Keys are coded by the manufacturer during production and by the locksmith during the keying or rekeying process. The direct code

numbers from keys or equivalent derived information can be used to produce duplicates. A key can also be decoded using a micrometer, depth keys, or by visual estimation and experience.

Locks can be disassembled, the tumblers carefully removed, and then all of the possible combinations determined. In this instance, the pins are measured and correlated to specifications as set forth by the manufacturer for a particular lock.

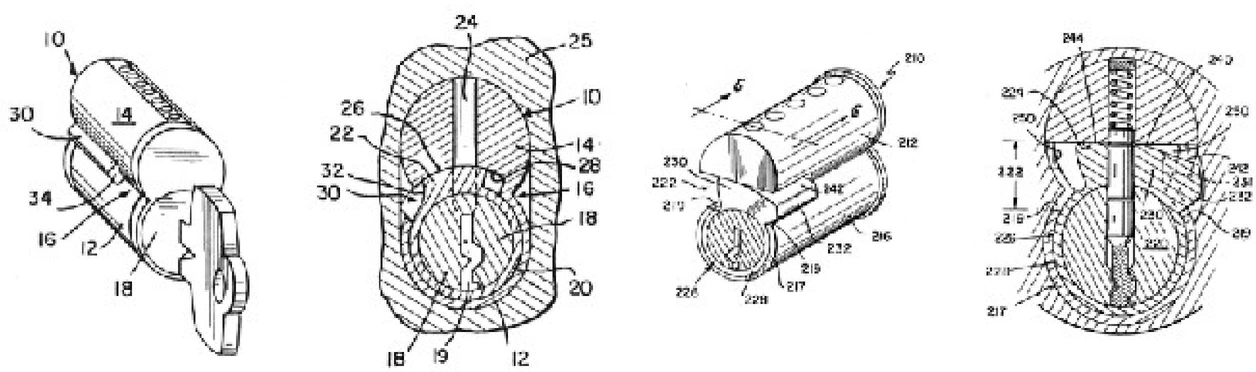
Once a lock has been decoded, keys can be produced that will open that lock or others within a system. Thus, a master keyed cylinder can be taken apart, all combinations determined, and a key produced which will open every lock within the master key system or group. **Direct or indirect** coding is the method used by the manufacturer to differentiate tumbler depths for each key. Coding is required to facilitate multilevel keying, and to allow for orderly manufacturing, distribution, and maintenance of locks.



16_4.3.1 Manufacturer Depth and Spacing Specifications

Every manufacturer will set different bitting standards relating to spacing and depth assignment. The number of depths for a given key blade surface, their designation, the increment between consecutive depth cuts, and the inter-pin spacing must all be specified. This manufacturing data determines key coding and will provide the locksmith with the following required information:

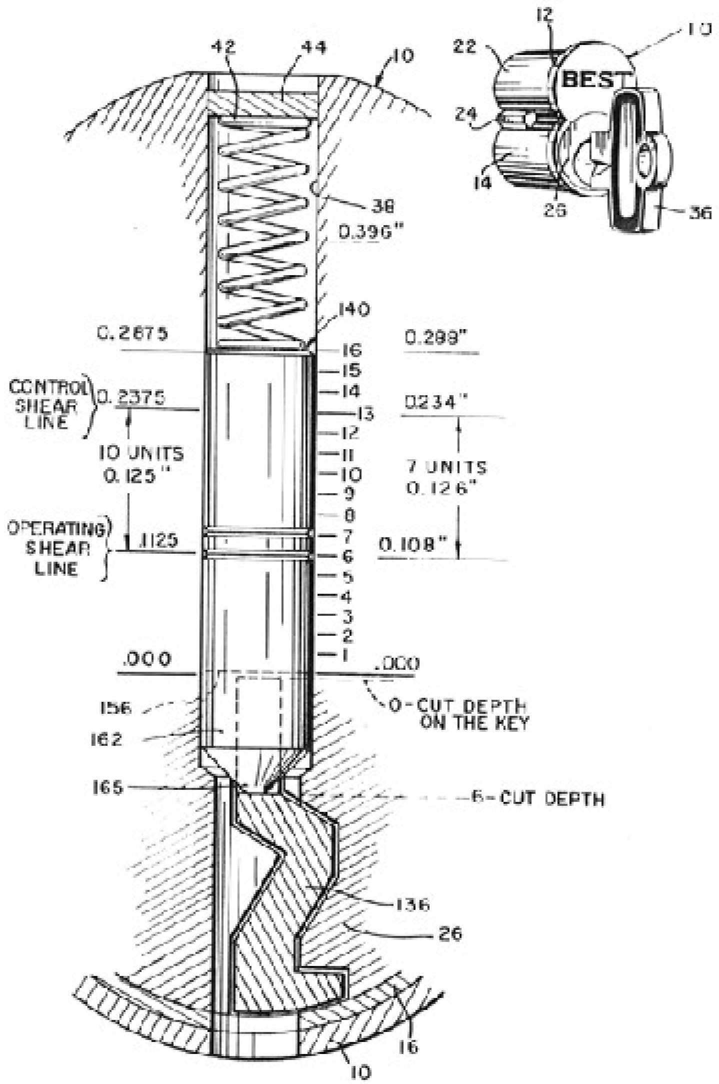
- **Distance from the shoulder to the first pin chamber;**
- **Distance, center to center, between pin chambers;**
- **Total length for bottom and top pin chambers;**
- **Pin diameter.**



In any coding scheme, the bitting is divided horizontally into different levels, each separated by a defined space. For example, one manufacturer may divide a key into ten segments, and assign the following code depths for bitting levels: 1=.165” 2=.180 3=.190 4=.205 5=.220 6=.235, 7=.250 8=.260 9=.275 0=.290. The spacing between pins will also be designated. Failure of the locksmith to adhere to coding standards will result in reduced security, mechanical and operational problems, cross-keying, and even broken keys.

The manufacturer stamps many keys with code numbers. If the codes are direct, then they can be correlated to depth measurements and a key reproduced using a code-cutting machine, micrometer, or depth keys. If the codes are indirect, then a code list from the manufacturer must be consulted to first determine the direct reading code.

A more thorough discussion of coding and decoding can be found in **Chapter 31.**



16_4.3.2 Decoding Master Key and Interchangeable Core Systems

Master key systems may be decoded to determine keying levels, cross-keying, and removable core control-key combinations. Decoding may be necessary for many reasons. These include:

- **Producing keys to locks;**
- **Matching specific locks with criminal suspects;**

- **Determining cross-key potential and the ability of a given key to open one or more locks;**
- **Assessing the pick resistance of a lock;**
- **Intelligence operations.**

If the system was designed properly and master keying rules were adhered to, then decoding can be a straightforward procedure. However, if a craftsman with limited knowledge implemented the system or basic rules were not followed, then the task can be somewhat more difficult. Special precautions must be observed in disassembly of master keyed cylinders in order to preserve the pin-stack order. These are discussed in Chapters 24-27, in the

context of forensic examinations.

16_4.3.2.1 Decoding Procedures for Standard Cylinder

Perhaps the simplest task is to decode the top master key. This can be a **GGMK** (great grand master key) to a simple **MK** (master key), depending upon the complexity of the system. The most straightforward method is to select a lock for which a change key is available and which is not cross-keyed or is a single lock keyed differently. The manufacturer must first be identified in order to learn if a one or two-step system is in use. In the case of Corbin, for example, a master ring is utilized which prevents cross-keying.

Generally, there will be one or two bottom pins and one top pin. In some cases, there can be additional master pins in certain chambers, depending upon the sophistication of the system. If, when the lock is disassembled, there are in fact two pins in each lower chamber, we can determine the top master key if the lock was keyed consistent with standard industry practice. In order to decode the master key, the individual change key bittings must first be ascertained.

In our first example, let us assume, after disassembly, that we find one bottom and two top pins in each chamber. This would indicate that the lock is master keyed and that there is one master pin for each cut. Once the lock manufacturer is identified, the depth for each cut will be known. In this example, it is assumed that we have a physical change key as our reference.

From the change key we can determine the actual length of each of the bottom pins through correlation with manufacturer data. The direct code and the physical pin lengths are required in order to compute the bitting for the master key. Once the pin-stack is determined for each chamber, the bitting depths will be known. For this cylinder, the following is learned:

CHANGE KEY BITTING	***1 2 1 5 3***
Cylinder Pinning:	
Master Pins:	***4 6 8 2 2***
Bottom Pins:	***1 2 1 3 1***

Master Key	***5 8 9 3 1***

If this lock has been pinned to standard industry practice, then the master key code can now be determined. It must be remembered that the introduction of each added master pin exponentially increases the possible differs, or key combinations. Thus, a five-tumbler cylinder will have the following number of permutations, depending upon the number of lower pins and master pins within each chamber:

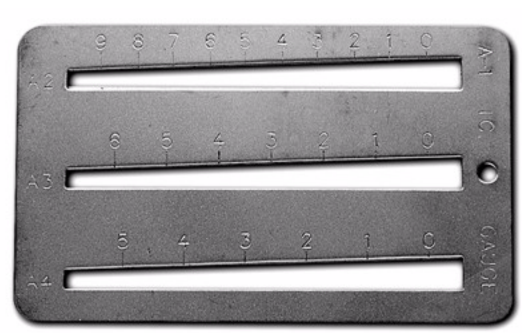
1	***pin per chamber = 1 key***
2	***pins per chamber = 32 keys***
3	***pins per chamber = 243 keys***

Thus, a five-tumbler lock with one lower pin and one master pin in each of the chambers will have **32** different shear lines. As shown in Chapter 11, there would be 32 different keys that could open this lock. It can be seen that in our first decoding example, we have 32 possible master key combinations.

Based upon industry practice, no depth-cut used for the master key can be used in the same position for any change key. With this information, we know that the master key in our first example can be one of two combinations: 12131 or 58953. Applying our rule, the top master key must be **5 8 9 3 1**, because the other combination reuses pins in the change key.

Now let us say that we must decode a cylinder with two master pins in two of five chambers, one master pin in three of the chambers, and one bottom pin in all five chambers. This scenario could occur when a cylinder is intentionally cross-keyed. In this example, the pins are decoded as follows:

CHANGE KEY BITTING	***8 5 4 7 4***
Cylinder Pinning:	
Master Pins:	***- 2 - 2 -***
Master Pins:	***4 2 2 4 4***
Bottom Pins:	***4 1 2 1 0***



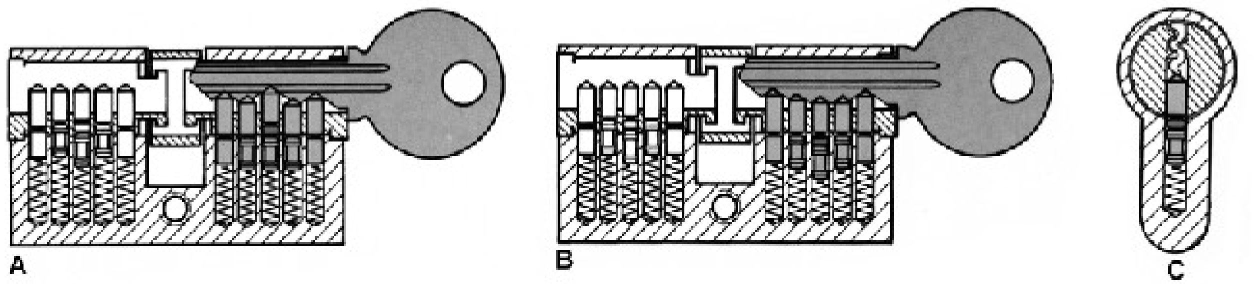
From a possible **72** different bitting combinations, we can reduce to 4 the number of possible master keys:

41210
43210
41250
43250

The only way to determine the actual master key is to try each key in several locks.

16_4.3.2.2 Removable and Interchangeable Core Locks

In the case of the Best-Falcon types of interchangeable core locks, a few comments are in order. There is no relationship between the top master key and the control key. Assuming there is a change key and one has an understanding of the physical construction of the lock, decoding is the same as for standard cylinders. There will always be three or four pins per chamber (bottom pin, master pin, build-up pin for control shearline, and top pin. In rare instances, there may be a master pin for the control key. In the Best lock, the top set of pins is used to decode the control key, because the pin stack for each chamber will always be a constant length. In the A2 series, the pin stack will always be a total of 23 depth increments. By measuring the top pin for each chamber, we can determine the bitting for the control key. There are a total of three series of Best locks: A2, A3, and A4. A simple depth decoder made by A-1 Security Manufacturing for the three Best series is shown below.

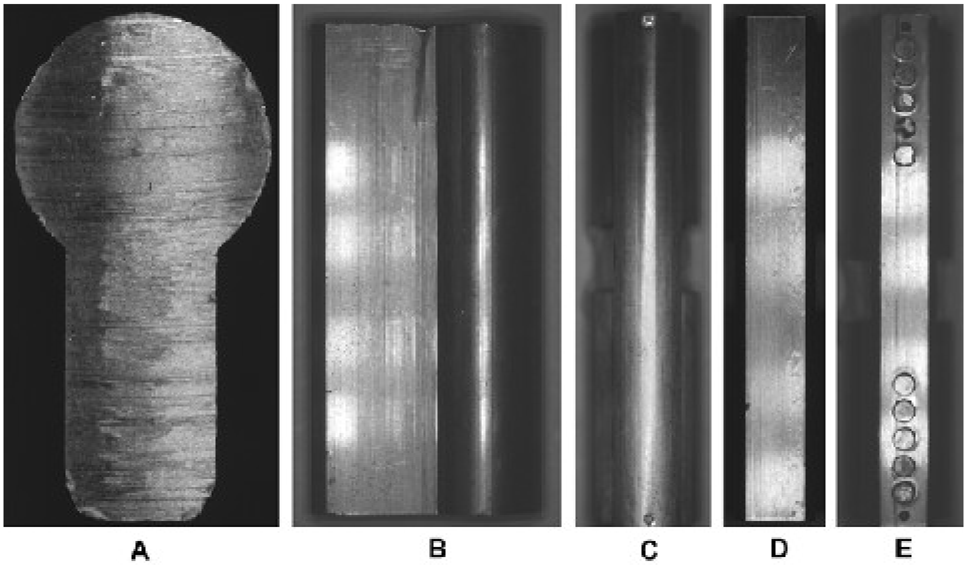


Decoding the Best removable core lock for the control key, courtesy of Harry Sher.

16_4.4 Master Key Systems

Master keying allows and defines access to one or more locks

within a system by one or more keys. Pin tumbler locks may be master keyed to many levels, depending upon individual requirements for each installation.



The underlying theory for all conventional master key systems is the same. It provides that more than one shear line is created within the pin-stack in order to allow different combinations of bitting to raise pins and master pins to a particular shear line. There are several techniques to accomplish secure master keying within conventional pin tumbler locks. The predominant schemes are referred to as Total Position Porgression (TPP) and Rotating Constant (RC). These are more fully discussed in **Chapter 11**.

There may be several defined shear lines for any given lock, dependent upon the complexity of the system. Tolerance errors can be a factor within a master key system, because up to 2000 or more effective shear lines may be created if the tolerance is poor between plug and shell. **Positional systems** rely upon the position of the pin, rather than its depth level, to define master keying levels. Sargent Keso was perhaps the first high-security pin tumbler lock to utilize this principle. Corkey, Showa, and other magnetic card lock vendors also use the scheme. **Chapter 11** describes master key systems for all types of locks.

16_5.0 Manufacturing Pin Tumbler Locks

The manufacturing steps for the production of pin tumbler cylinders involves many processes. These can affect the tolerance and commensurate security of the lock, the number of available differs, and pick resistance. The relationship between tolerance and the ability to pick the lock is vital to an understanding of surreptitious entry. The subject is covered in this chapter and in **Chapter 29**.

The modern cylinder is manufactured in an automated environment. The security rating of the lock determines the standard of tolerance maintained and thus the level of automation. Ikon produces its high-security locks in one of the most sophisticated factories in the world located in Berlin, Germany.

LSS101: Ikon factory, Berlin, Germany: How locks are made.

The entire procedure within the Ikon facility is automated, from the input of raw brass bar stock to the production of a finished, pinned lock. A brief description of that process is presented here.

In their high-security lock, Ikon maintains a plug-shell tolerance of between .016 mm-.07 mm, or a maximum gap of about .003."

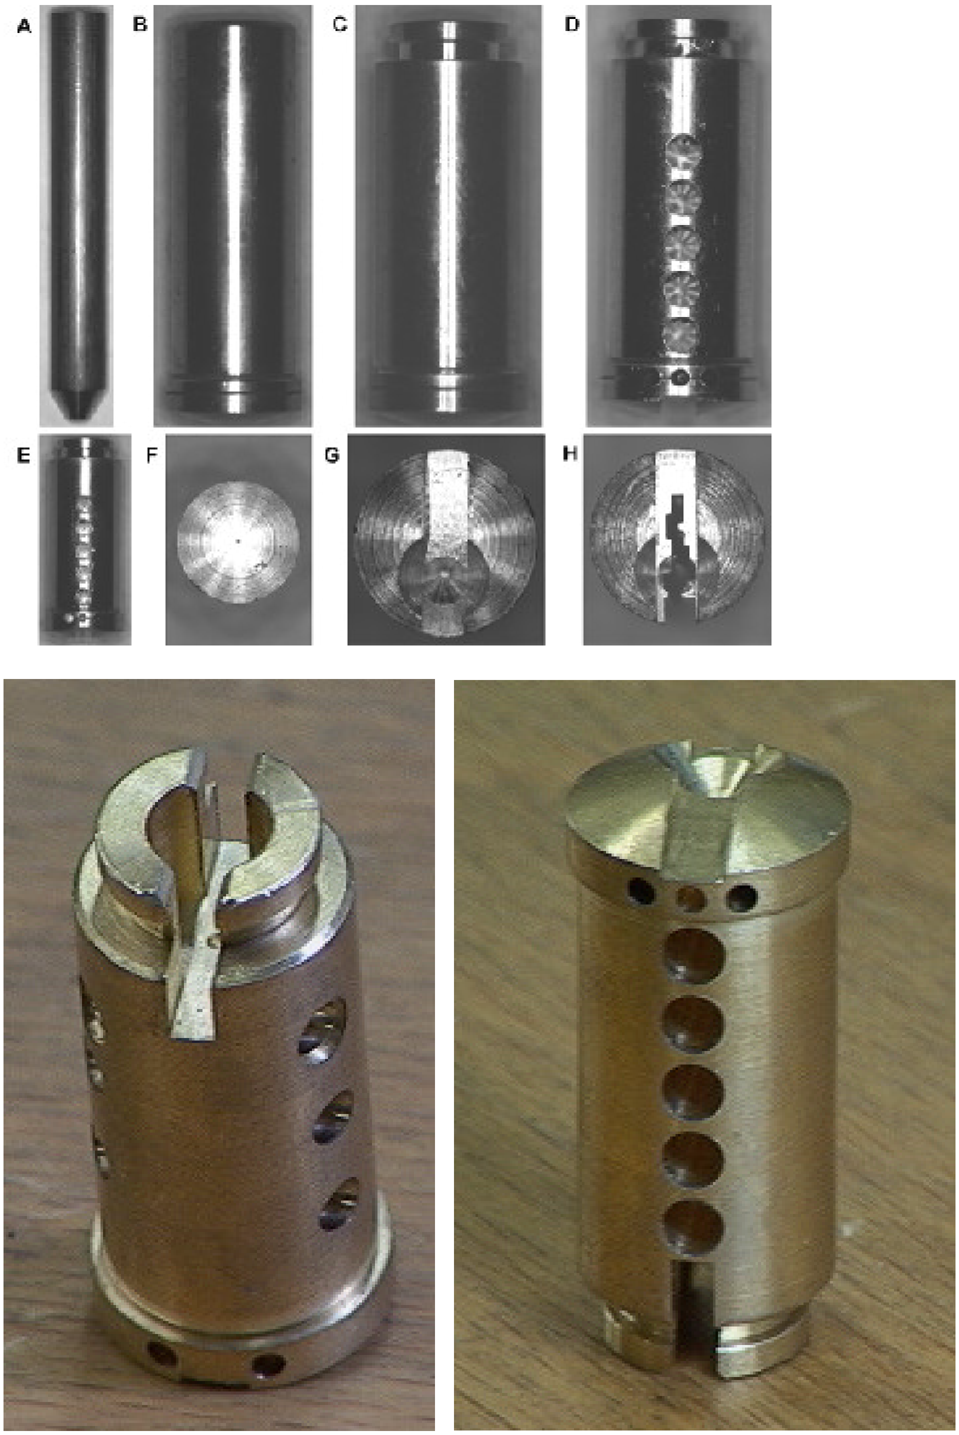


Figure LSS+1608 A plug is formed; drill resistant pins are inserted, then the individual chamber holes are drilled.

The process begins with unfinished brass bar stock. The stock is cut to the length of one lock, then the solid block of brass is

bored to the precise diameter of the plug. Chamber holes are then individually drilled from the top of the cylinder. It should be noted that some manufacturers, such as KABA, drill both the shell and plug simultaneously.

At the same time, round brass plugs are milled to very precise tolerance, from round bar stock. They are then drilled for lower chamber holes. Each hole is made individually with one bit, at 10,000 RPM. Broaching the plug then creates the keyway. The keyway is created within the plug by ramming it across the tool steel broach at high pressure. The die removes the metal as it is forced through the plug. The photographs show the sequence utilized at the Ikon factory in Berlin. Chamber holes are sealed in the shell with fixed pins, and the top of the cylinder is finished and rounded.

Pins are produced by cutting and chamfering brass wire to the proper length. The wire is produced in long rolls, and is fed into a machine that generates millions of pins. See the accompanying video for a detailed explanation.

Producing pins for cylinders. Courtesy of Hans Mejlshede.

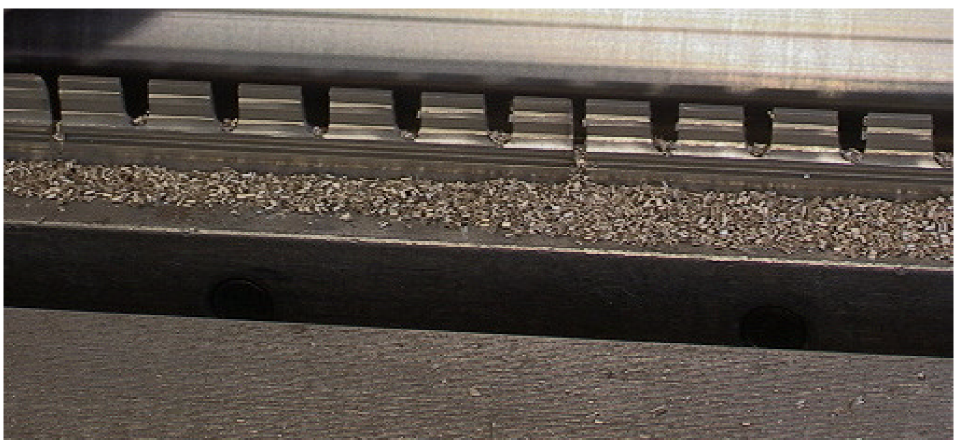

Figure LSS+1609 A broach is made of tool steel.

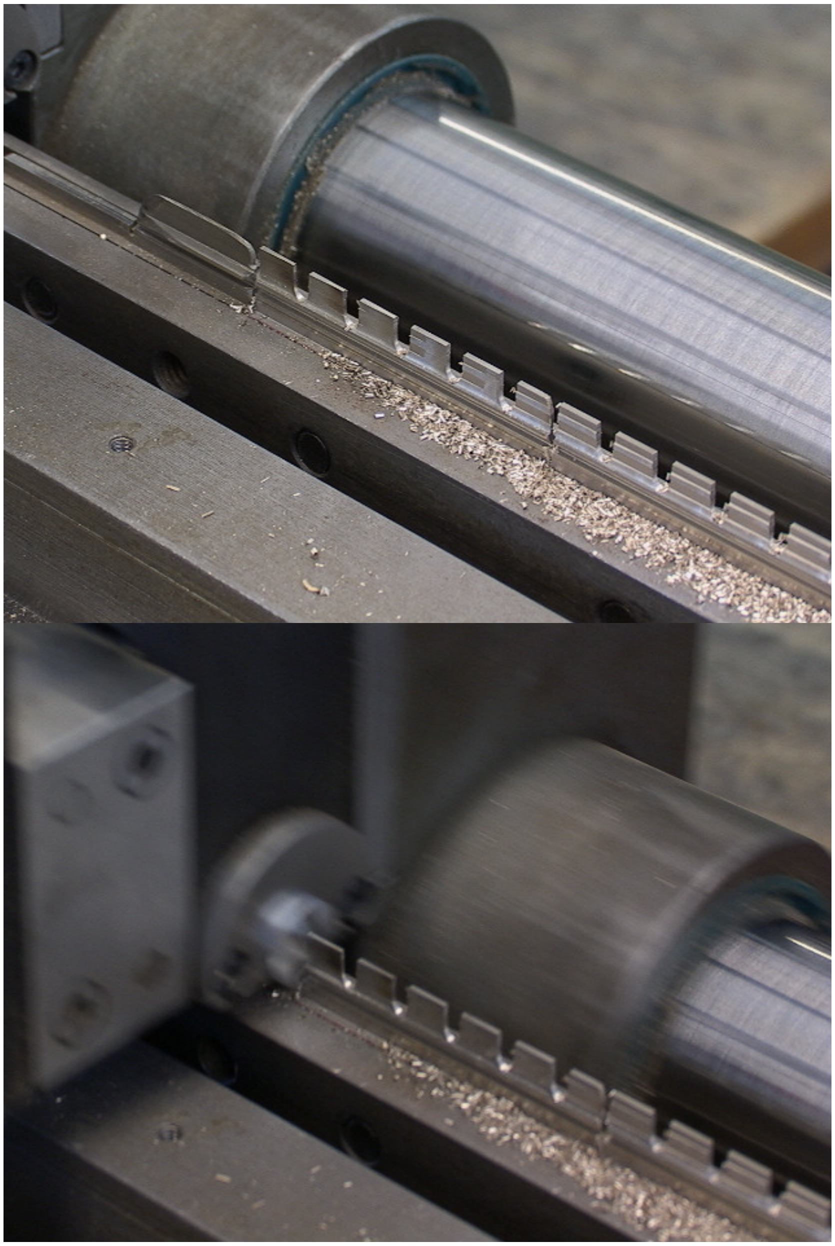

Figure LSS+1610 The broach is forced into the plug to form a keyway. The photograph on the right shows the plug being driven across the broach.

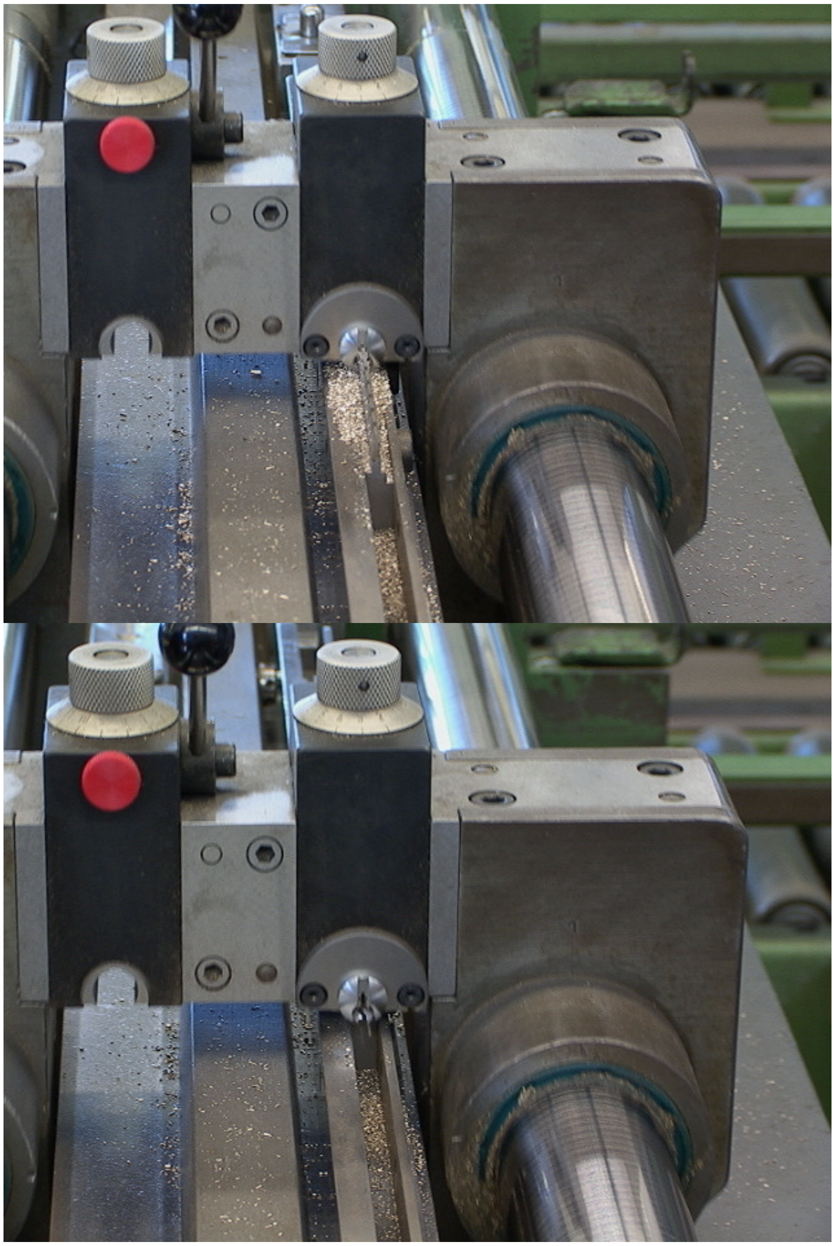

Figure LSS+1611 Photographs showing a plug partially and completely broached. Note how the hydraulic ram is designed.

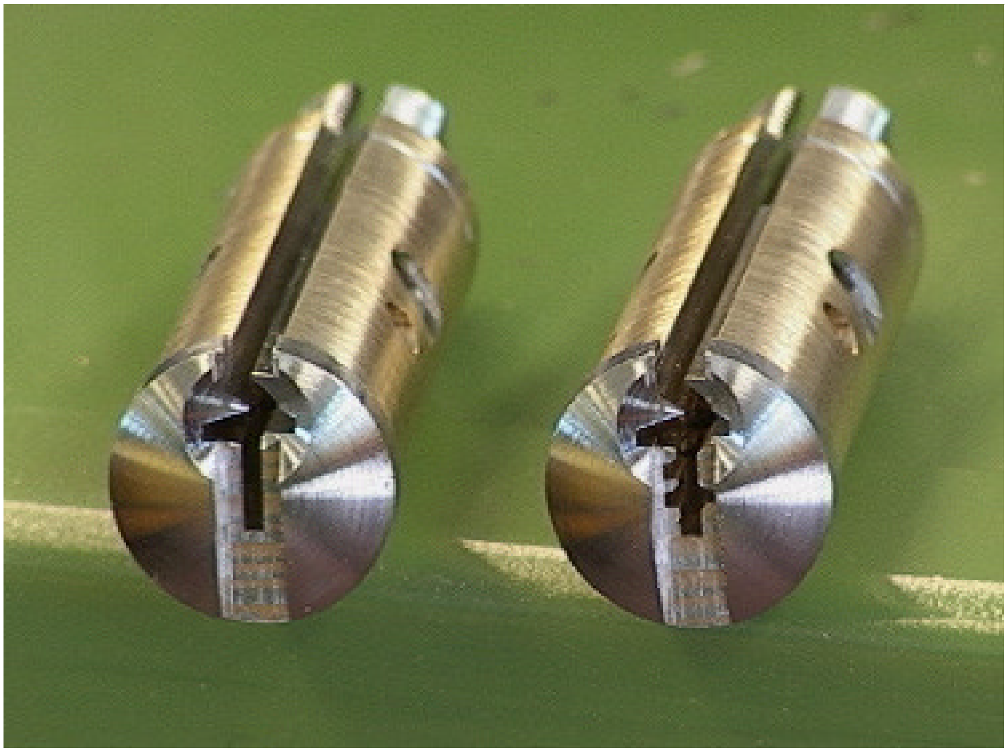

Figure LSS+1612 Ikon produces profile locks with over 3500 different keyways at its factory in Berlin. This photograph shows a basic keyway profile, and a special variety for a specific customer. Different sub-broaches are utilized for this process.

Finally, the plug and shell are married together, and the cylinder is pinned automatically to the correct combination. Pinning is accomplished by loading all upper tumblers and springs from the center of the shell. The plug is loaded in a separate operation, and inserted into the lock.

16_5.1 Tolerance

At every step of the manufacturing process, tolerance is a critical factor, because errors are **cumulative.** As tolerances diminish due to such errors, the security, pick resistance, and chance for cross-keying increase. There are four critical tolerances within the pin tumbler cylinder: **plug-shell, keyway, pin chamber, and key (cuttings and profile).**

16_5.1.1 Plug-Shell Tolerance

Plug-shell tolerance actually encompasses several issues:

- **Diameter and concentricity or roundness of the plug;**
- **Actual diameter of the plug;**
- **Diameter of the bore within the shell;**
- **Gap between the plug and the shell.**

There must be some difference in the clearance between the plug and the shell to allow unrestricted rotation. The minimum acceptable tolerance is .0025", which means an effective tolerance of .005". If the clearance is less, the plug will bind; if more, sloppy operation will result.

An optimum tolerance of .0025" could be maintained if the plug actually rested in the center of the shell. Unfortunately, this does not happen. The plug really rests slightly off-center at the bottom of the bore, leaving up to a .005" gap at the top of the plug. The gap between the plug and shell is actually somewhat less than .005". The closer the fit becomes between these two components, the greater the security of the lock. The tolerance is affected by the amount of metal removed from the bottom of the keyway in the broaching process, generally less than .0005". It is also influenced by the design of the top of the plug where the driver pins enter the lower chambers.

In most cylinders, the tolerance between the plug and shell is approximately one-third of one depth-cut. Thus, if the depth increment between cuts is .015", the tolerance would be between .005"-.010", although generally about .006"; just slightly more than one-third of a cut. This variance in tolerance is the reason why keys cut on inexpensive cutters will still open most locks.

In most cylinders, the surface of the plug is flattened across the shear line, because the top of the pin is flat. A slight gap is created at the point where driver and lower pins meet, making picking easier. Generally, the amount of metal removed at the top of the plug is between .005-.015." The amateur locksmith that files both tumbler and plug when fitting keys may also cause flattening of the top of the plug. In the true high-security lock, the entire plug is round; thus reducing the tolerance between plug and shell.

The **effective** diameter of the plug is thus different from the actual diameter. In the high-security lock, they are in fact almost identical. In the standard cylinder, the effective diameter takes into account the flat portion at the top of the

plug and will be less than the actual diameter. This affects the tolerance between plug and shell.

16_5.1.2 Pin-Chamber Tolerance

There are several considerations affecting pin-chamber tolerances:

- **Diameter of the pin;**
- **Diameter of the pin chamber;**
- **Linearity of the pin;**
- **How the chamber is chamfered;**
- **Alignment of the chambers.**

Drilling, either individually or all at one time creates pin chambers. The spacing and vertical positioning of the pin chambers is critical. The location of the holes drilled in the shell and in the plug must be precise and in perfect alignment. Some manufacturers bore holes in the shell and plug together for higher tolerance; in others, it is a separate operation. Gang drilling will produce results that are more varied. This is because of the use of different drill bits for each chamber and the varying replacement cycles for each drill.

The chambers and pins are chamfered with a reamer or drill bit in order to create a beveled or flared end. Unevenness in this process can result in a tolerance error. Chamfering and flattening the plug at shear line has the same affect; an error of from .005"-.015" can occur and can be likened to the difference between a flat versus rounded mating of plug and shell. Pin diameters may slightly vary, creating excessive play between pin and chamber walls. This will also reduce the pick resistance of the lock.

Depending upon the method of drilling, pin chambers may not all be the same diameter, nor have precise center-to-center alignment. Although the operation of the lock may not be affected, pick resistance can be markedly decreased. The concentricity or roundness of each chamber may also be affected by the drilling method. Each of these errors can have a significant impact upon:

- **Interaction and movement of the pin within each chamber;**
- **Relative position of each pin at shear**

line;

- **Position at which each pin binds between plug and shell when torque is applied during the picking process.**

As noted in **Chapter 29**, the significance of the foregoing discussion relates directly to the ability to pick a given lock. Picking is based on cumulative tolerance errors; if there were no errors, picking would be almost impossible. **The misalignment of moving components allows the lock to be opened by manipulation.**

16_5.1.3 Keyway Tolerance

Keyways are created through a process called broaching. A die having the exact mirror image of the keyway is forced into the plug lengthwise at high pressure. Metal will be displaced precisely equivalent to the shape of the die.

Depending upon a number of factors, broaching can be extremely accurate, or poor tolerances can be produced. In less sophisticated processes, a small amount of metal will be removed from the bottom of the keyway, adversely affecting the concentricity of the plug and the plug-shell tolerance. A consequence of the failure to maintain tolerances in the broaching process will be the improper alignment of grooves or wards, resulting in keys not indexing properly when inserted into the keyway. An error of up to .0005" can occur.

PART D: Locks and Keys

Specialized Locking Systems and Applications

Chapter 17, divided into seven sections, provides information regarding special locking systems that incorporate unique alterations to standard lever, wafer, and pin tumbler designs. In addition, combination locks, hybrid designs incorporating more than one technology, and high-security locks are covered. The many different types of locks that are discussed in the following sections have been selected based in part upon criteria defined below.

There are many variations in each design class; the most unique is described here. Each lock is illustrative of a different approach taken by their inventor to solve one or more security or mechanical concerns, evident in previous designs. Unique variations and applications of existing technology are presented in the following seven chapters. Each of the mechanisms has been selected by the author to represent specific design classifications for a particular group of locks. A brief description of each lock is presented that detail operating theory and uniqueness, together with illustrations showing functionality.

Locks have been included based upon the following criteria:

- **Unique and clever design;**
- **Security rating;**
- **Resistance to surreptitious, covert, and forced-entry;**
- **Commercial universal acceptance;**
- **Patent protection;**
- **Product life;**
- **Resolution of security issues raised in similar products.**

AUTHORIZED LAW ENFORCEMENT AND GOVERNMENT AGENCIES MAY CONTACT THE AUTHOR FOR DETAILED INFORMATION REGARDING BYPASS OF MANY OF THE LOCKS DESCRIBED IN CHAPTERS 17-23. IN CERTAIN CASES, REPORTS HAVE BEEN PREPARED REGARDING THE OPERATION OF A SPECIFIC LOCK, AND ARE AVAILABLE FROM WWW.SECURITY.ORG.

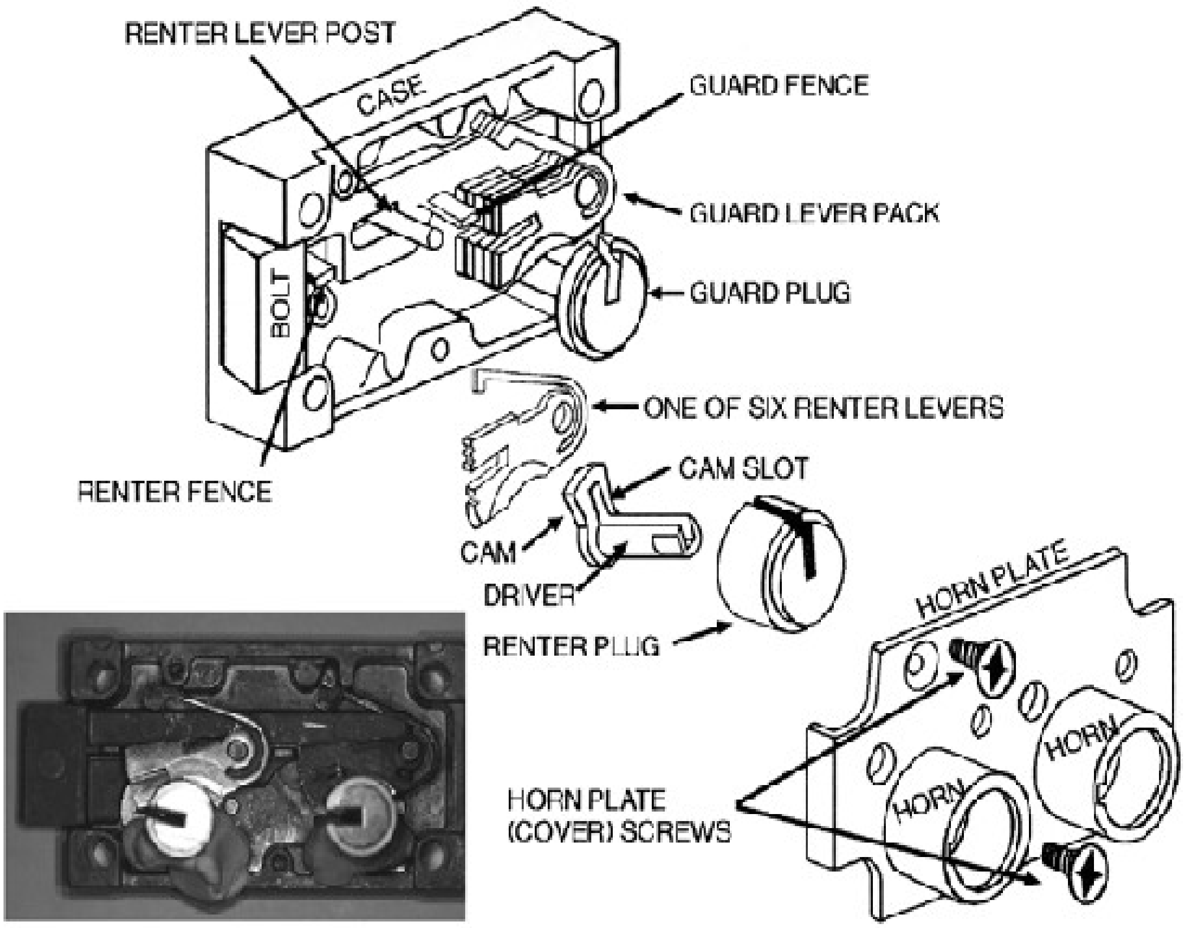
Section 1: Lever Locks



SAFE-DEPOSIT AND SECURITY CONTAINER

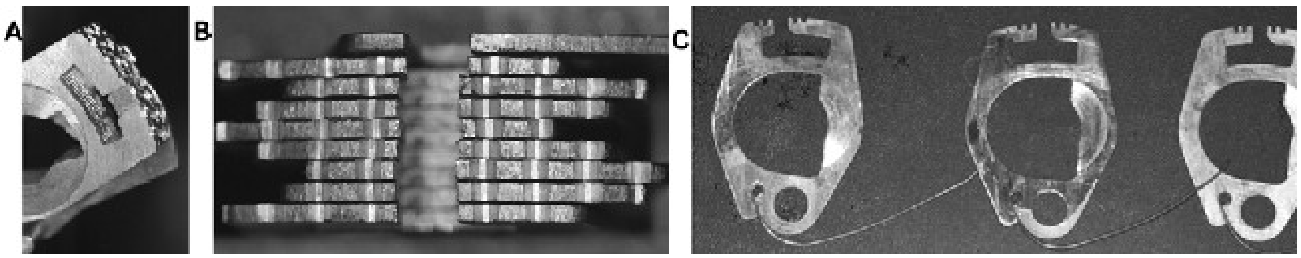
Information regarding basic lever locks can be found in **Chapter 14**. This section will describe three special applications: coin telephones, safe-deposit boxes, and prison locks. Lever locks can provide equivalent or greater security to that offered by a pin tumbler mechanism. They have found their way into many special applications, including post office boxes, safety-deposit boxes, coin telephones, and safes.

17_1.0 Safe-Deposit and Security Container Locks

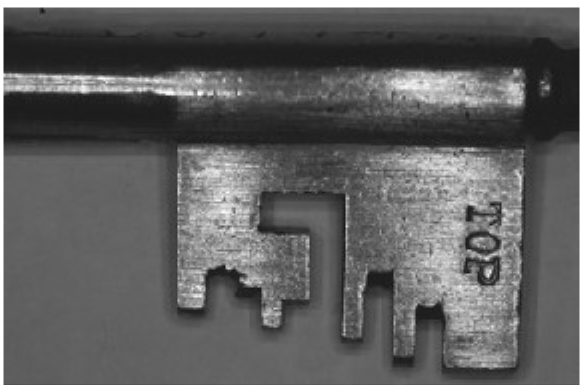
Locks for safe-deposit boxes are generally lever mechanisms that contain security enhancements including pick resistance, dual control, and combination programmability. Sargent & Greenleaf dual-control designs are described here. See also **Section 4** regarding the **DOM** split-key approach to dual-key control. S&G manufacture a variety of safe-deposit locks that are used throughout the world. Models 4440 and 4110 are the industry standard for banks. Models 4110 and 6805 are changeable fence locks that allow the lever-fence relationship to be altered to fit any key. They are described in **Chapter 22**.

17_1.1 S&G 4440 Dual Control Lock

Exploded view.



The S&G 4440 is a dual-horn five-guard lever plus six renter lever lock, that must be opened with two different keys. The guard and renter keys must lift the lever packs simultaneously. The lock is designed so that both of the gates are an integral part of the bolt upon which the lever packs rest.

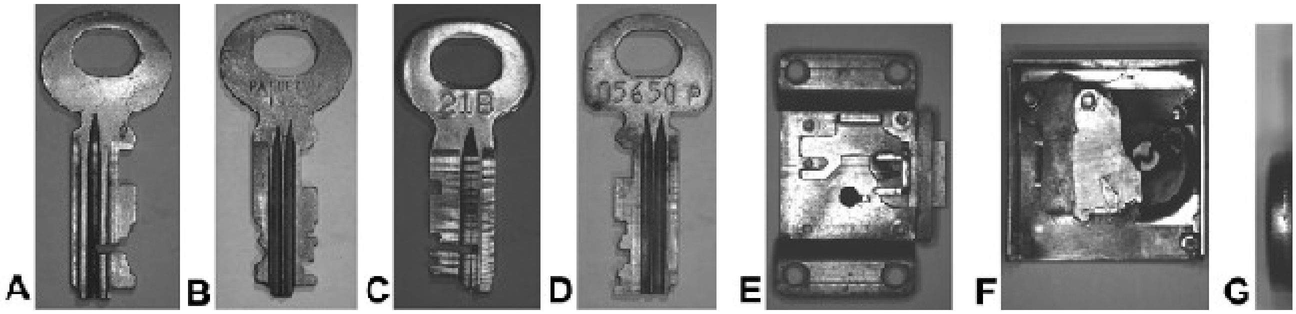


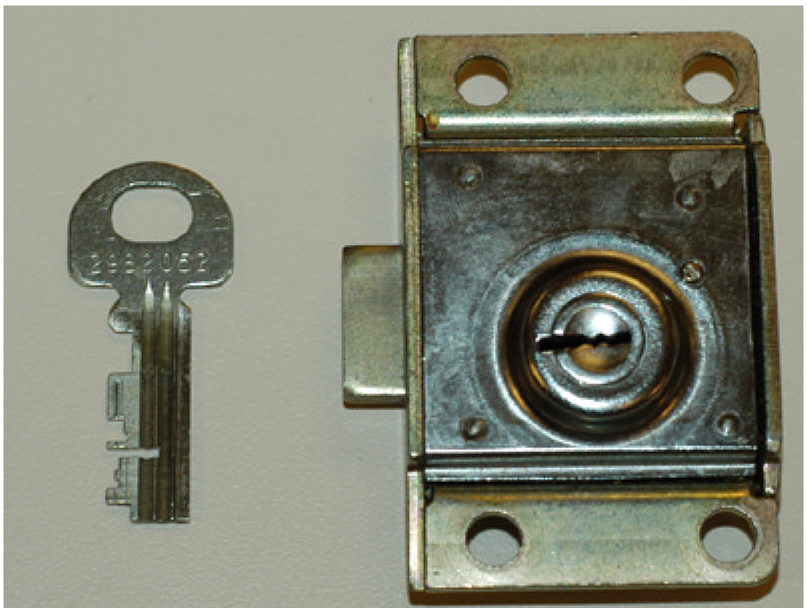
This is a **fixed lever** lock, meaning that each lever tumbler has a fixed sweep and gate position. There are six possible depths for each lever gate, or 46,656 differs for the renter's key and a similar number of differs for the guard key. Note that there are serrations around the gating of each lever to make picking difficult.

17_1.2 Safe and Vault Lever Locks

Lever locks used in safes and vaults utilize a number of

different designs to increase security, but all incorporate the basic gate and stump theory. Depending upon the lock, there will be more levers, higher tolerance gate designs, and often two separate packs of levers. In addition, serrations, traps, and false gates will be employed to frustrate bypass. One of the original Tann locks (made in England) utilized an ingenious guard lever to prevent all but the proper key from gaining access to the bellies.



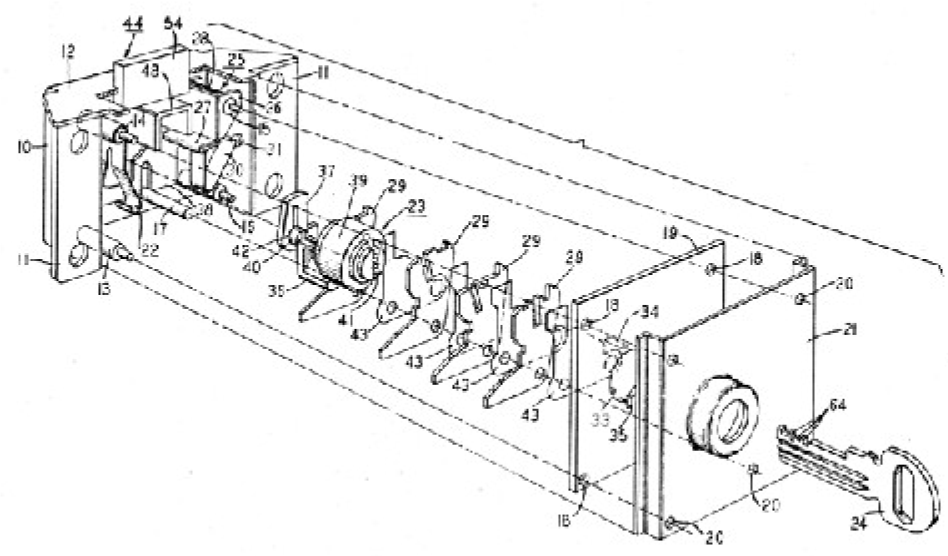


In perhaps the earliest design, Chubb patented his **protector** to double-lock the mechanism whenever picking was attempted.

17_1.3 Coin Telephone Locks

Coin telephones throughout North America have special security requirements. These have been met by the development of unique lever locks, developed and patented by Western Electric (WE), Automatic Electric (AE), and Northern Electric (NE)(3402581). Lever locks for coin telephones have evolved over the past fifty years to offer a high degree of security.

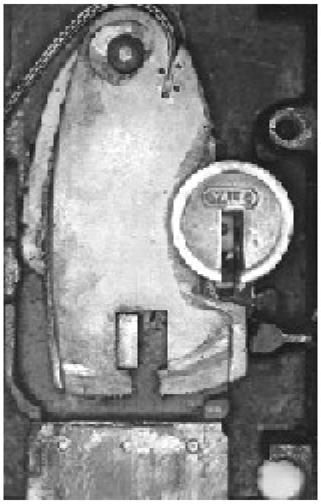
A
B
C
D
E
F
G

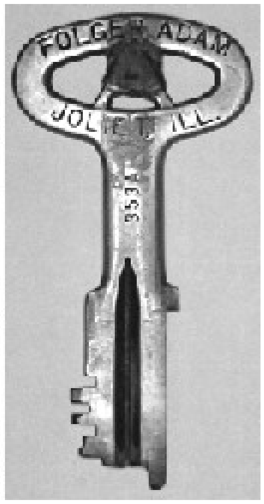


The locks used in coin telephones are extremely sophisticated in their design. They generally employ six levers and often have added pin tumblers (up to three) which contact the lower bitting of the key. The two photographs above show a 29B lock and key, a current model.

The Bell Labs patent describes a highly pick resistant mechanism with levers that pivot around a floating or unattached cam. The lock picker cannot gain any reliable sensory data from the application of tension on the levers as in traditional designs. The center of curvature of each of the radii of the levers has also been altered to make manipulation difficult. One common spring provides bias to all levers within this lock. This effectively destroys any feeling as to the position of an individual lever. Finally, an alarm switch will sense the movement of a single lever.

Locks used by **WE**, **AE**, and **NE** are very similar in their mechanical design and operation. Coin telephones require a dual-locking system to protect the upper housing and the coin vault. These separate compartments require controlled access by maintenance and collection personnel. The upper housing, which contains the electronic components and coin control devices, will have a lever lock keyed differently than the lower coin vault. The coin vault generally consists of a removable faceplate that covers the coin box. The lower vault is constructed of heavy-gauge steel and usually employs a four-point locking system to secure the vault cover. This makes penetration extremely difficult.

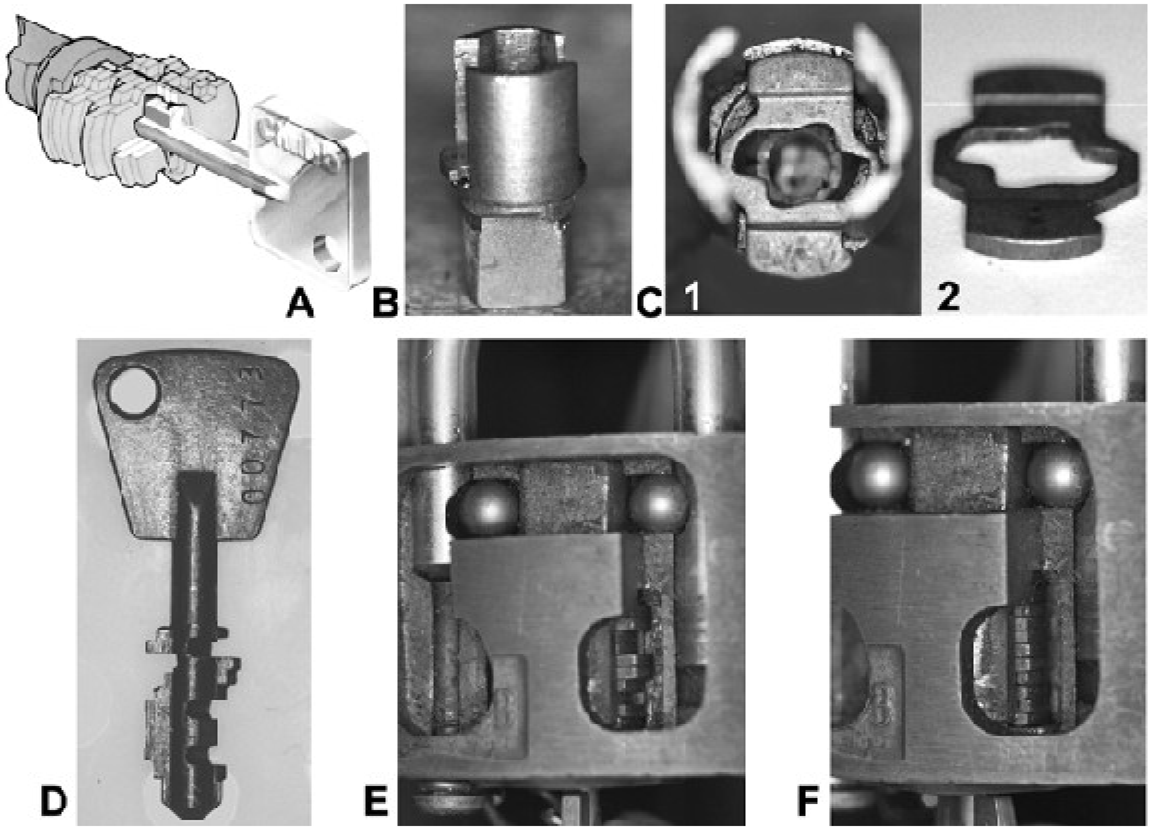




The keyway is limited in terms of access to the lever tumblers. Keys for these locks are quite distinctive. The design of the levers provides for pick resistance through a variety of patented features. There are three basic types of coin telephones in current use: the **Western Electric**, **GTE**, and **Intellicall** (privately owned) design. Although the lever locks described above are the most popular, Medeco, Abloy, Chicago, and other cam locks may also be encountered.

Possession of traditional WE, AE, and NE keys may indicate illegal activity, although the prevalence of private pay telephones has made these previously restricted locks and keys readily available.

17_1.4 Detention Locks



Detention locks used in jails and prisons are classified by security rating and are actuated by key, electricity, air pressure, or hydraulics. In many of the older facilities, large lever locks, replicating those used in safe-deposit vaults, are in wide use. Low-security locks are employed on individual cell doors and non-critical internal access points. For this application, standard high-security cylinders are utilized, such as Medeco. Generally, they are mounted into the door frame for added security. Medium- security locks are placed on certain exterior doors where inmates do not have access. Maximum-security devices are most often used on access points to the outside world.

Section 2: Wafer Locks

Detailed information regarding wafer locks can be found in **Chapter 15.** Wafer mechanisms are perhaps the most popular in the world as a low to medium-security device. There have been many variations of the original design; some in combination with other locking technologies.

17_2.1 Chubb AVA Wafer Slider Lock

This mechanism is found in Chubb padlocks, handcuffs, and other applications. It relies upon ten sliding wafers that move laterally as the key is inserted. The bitting has angled depth cuts corresponding to different sliding distances. The travel of each wafer is controlled by the rotation of the key and the angle of engagement.

This is a double-sided mechanism, much like the Chicago wafer lock. However, depth cuts are offset on each side of the key by a specified angle. The operating principle also resembles the Abloy DiskLock that is discussed in **Section 3.1** below. The mechanism provides a high level of security against picking and manipulation. It is used in Chubb's highest security padlocks and handcuffs.

17_2.2 Abloy DiskLock

Although the Abloy Disklock can be classified within the wafer tumbler family, that description is not altogether accurate. The design utilizes rotating discs rather than traditional single-plane traveling wafers. This lock is discussed in detail

in **Section 3,** Disk Wafers, because of the designs of the tumblers and the sidebar locking technique.

17_2.3 Briggs and Stratton Sidebar

The Briggs and Stratton lock was originally introduced about 1935 for use in automobiles. It is described in **Section 6.** See Johnstone (**3367156(177)**) for a description of a modified sidebar lock incorporating different sized wafers to be more resistant to forced-entry.

17_2.4 Winfield

Winfield produces a unique instant rekey wafer lock that is used predominantly in the hotel industry. The lock can be reprogrammed for any of 1,024 change keys, as well as different master keys, maintenance, and emergency access keys. See **Chapter 22** for a detailed description of this lock.

17_2.5 Evva 3KS

The **EVVA Three Curve System (3KS)** utilizes 12 locking pins and 18 control pins that ride in three separate tracks along the surface of the key. The keys are reversible for ease in use. Keys are also profile-coded, both top and bottom, for added security. The design of the 3KS was modified in 2001 to incorporate a modular concept that allows all EVVA systems to be interchanged within a profile cylinder system.

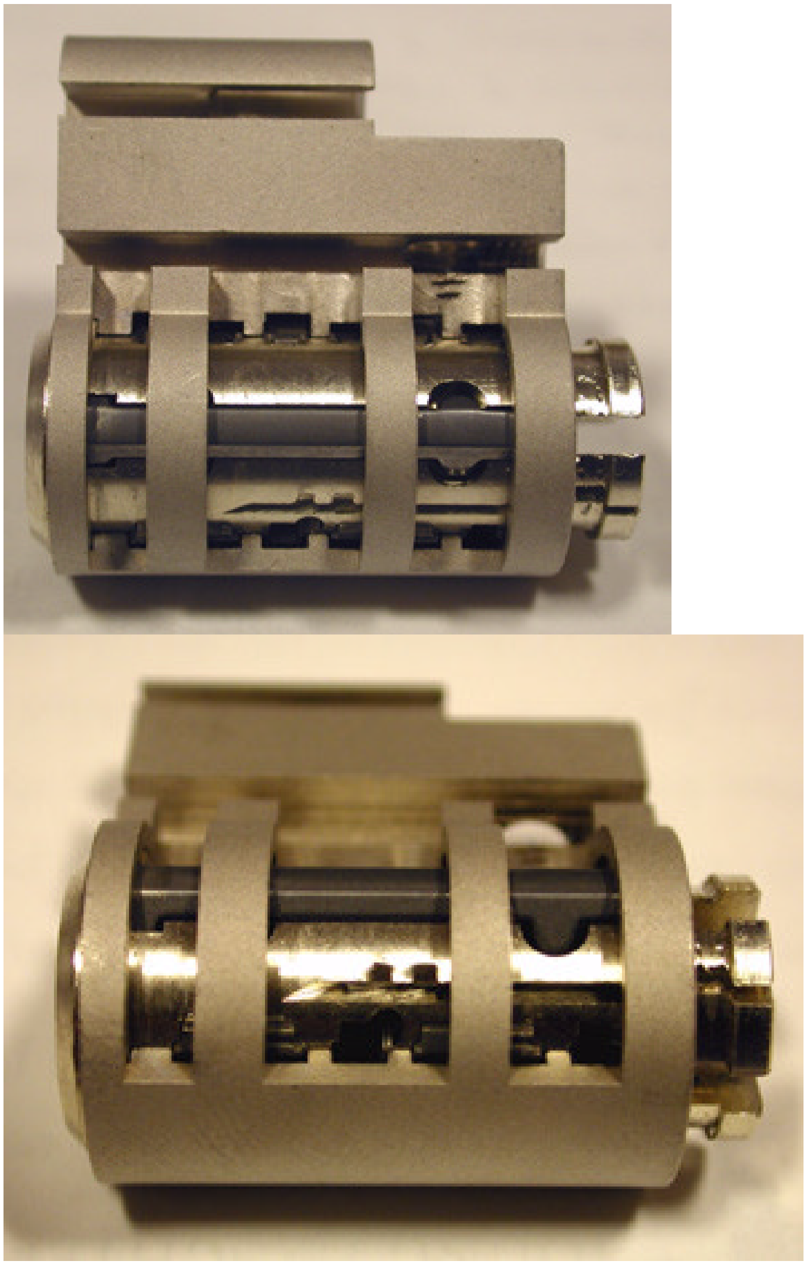


Figure LSS+1701 The Evva 3KS sidebar lock showing the sidebar in an unlocked and locked position.

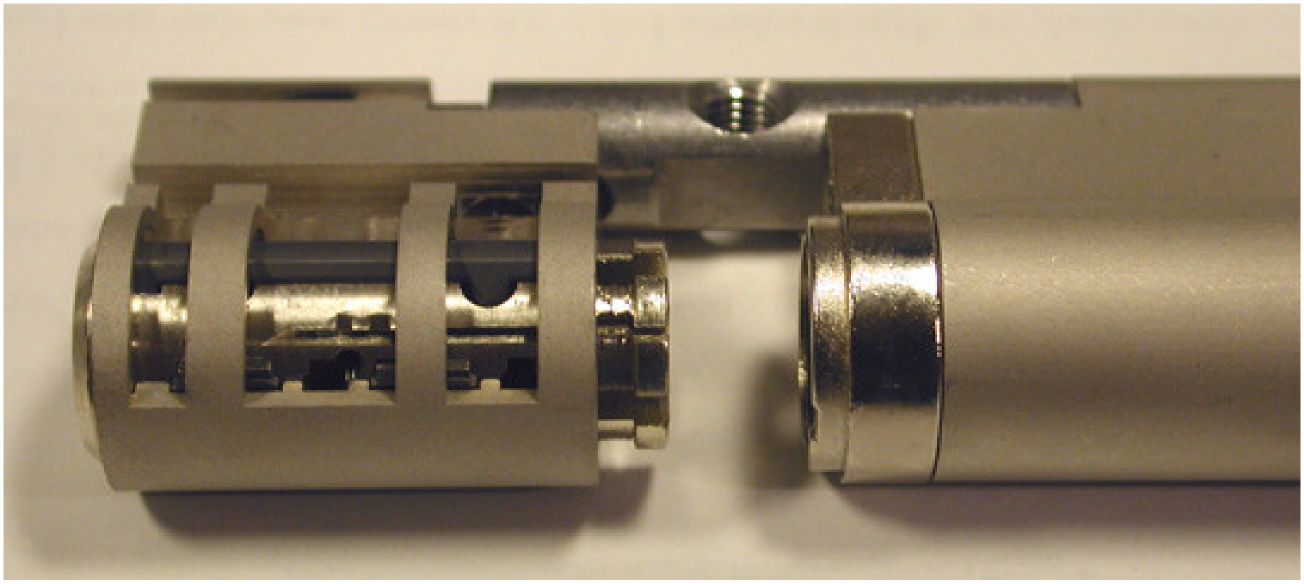

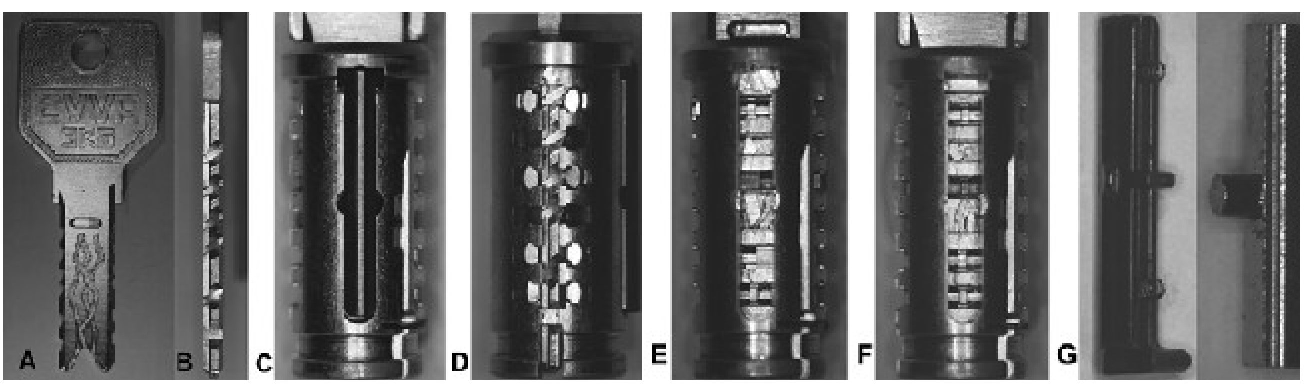

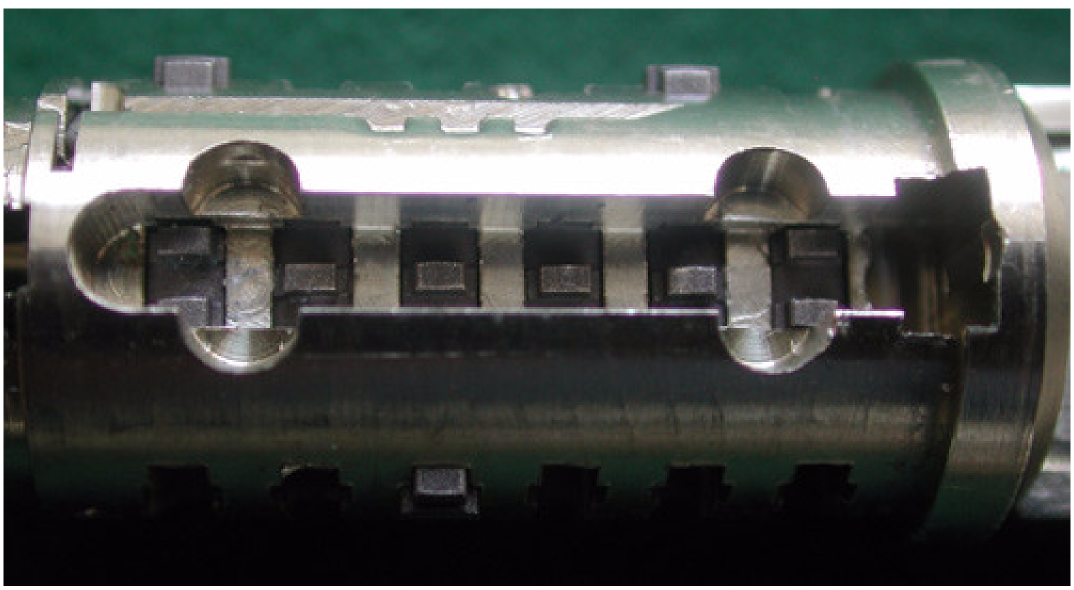

Figure LSS+1702 The Evva 3KS is a modular system. Shown is one cylinder in a locked position.

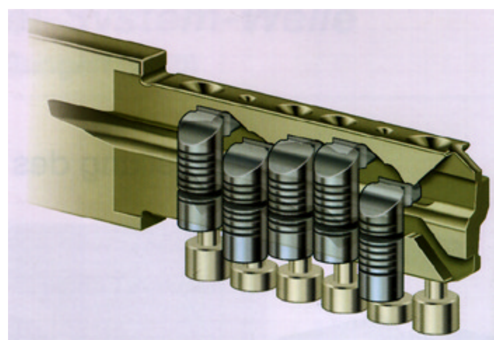
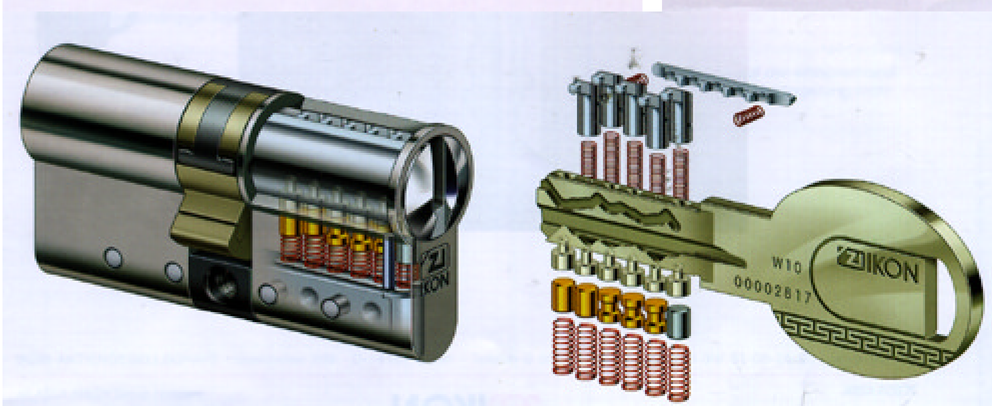
This lock utilizes the same general principle as other laser track systems but is more sophisticated because it also incorporates two separate sidebar mechanisms. In the photograph shown below, four of six sliders are properly aligned. The sliders on the ends, however, will not permit the sidebar to retract, thus preventing the lock from opening. Each of the sliders runs on the track, moving vertically into position. The lock incorporates two different slider designs. The sidebar fits on top of the dual indentation. Note the false gate below the true gates.



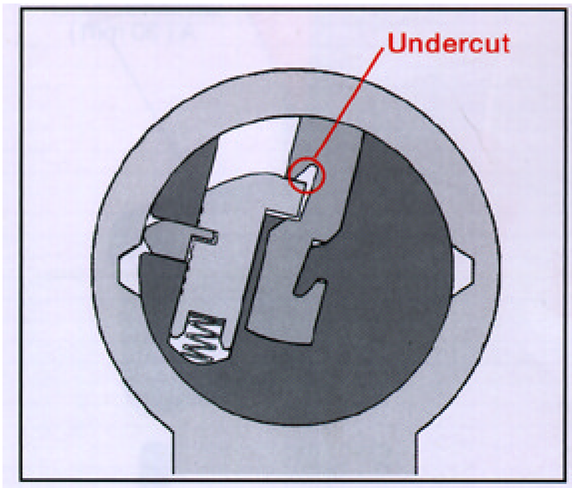
Patented in 1989 (**4977767(178)**), the lock features a unique flat key, having a blade formed with bittings along at least one of its edges. It has a pair of relatively shallow, open and parallel spaced grooves that extend across the longitudinal face in an irregular path. The sliding pins are shifted upon engagement with the grooves of the key. Two sidebars block rotation of the plug until all wafers are moved to the correct position to allow sidebar retraction. The pins are free-floating, providing high wear resistance and functional reliability. There are no springs.

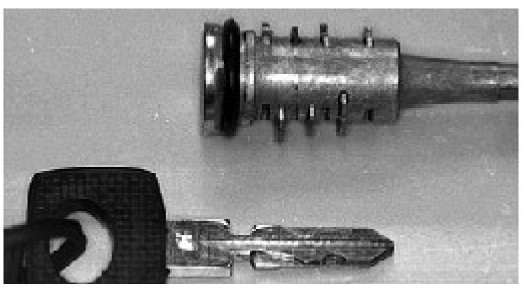


The manufacturer claims that there are a total of thirty trillion different combinations that allow master keying, construction keying, and instant rekeying. These cylinders also contain several internal security features including anti-drill pins, anti-torque, and plug pulling mechanisms.

17_2.5A IKON WSW System

The IKON WSW laser track sidebar system embraces a different design philosophy than the EVVA 3KS, and utilizes undercut finger pins that resemble the keyway technology introduced by Schlage in their Everest series of locks. The IKON mechanism is ideally suited to large master key systems. In such applications, reverse bitting surfaces on either side of the key are utilized. If high differing capability is not required, then only one sidebar is required, although the key is able to be inserted in either orientation. It will also be noted that the finger pins resemble those employed by ASSA, although the sidebar is a completely different design, as can be seen. Locking is accomplished by one or two sidebars and conventional pin tumbler bitting using dimples at the top of the key.





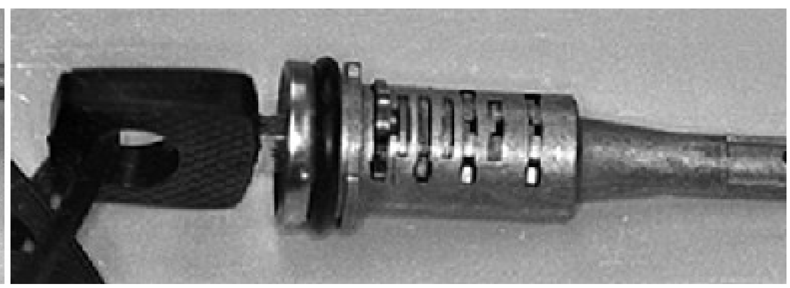


Figure LSS+1705 The IKON WSW Lock system

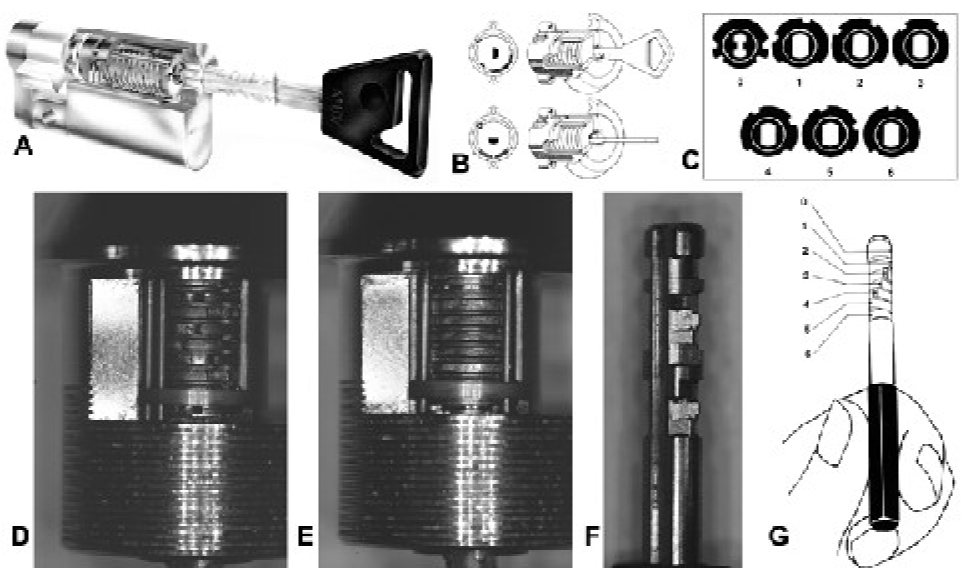
17_2.6 Laser Track Vehicle Locks

A number of automobile manufacturers, including Mercedes, utilize what has come to be known as laser track or laser cut locks to increase security. Mercedes utilizes four different track system locks in their vehicles, all manufactured by Huff of Germany. The first of these "track" locks was introduced in 1979, followed in 1980 and 1985 with different designs incorporating alarm features. The locks utilized both two and four-track mechanisms.

In the two-track systems, there is one track on each side of the blade; each key has two blade surfaces. Each lock has ten wafer tumblers having five depth positions. The two-track system is actually a modified double-bitted wafer lock in which the wafers ride on the side milling of the key rather than the traditional bitting.

17_2.7 Money Bag Locks

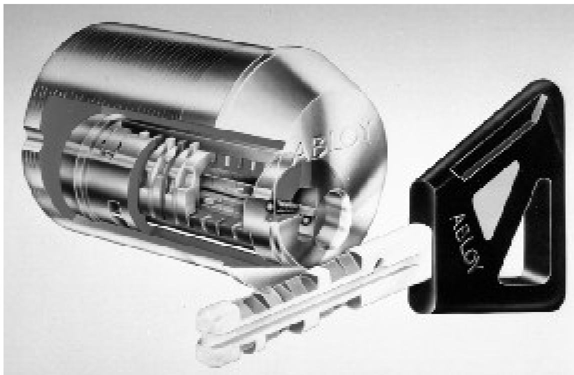
Courier bags used for carrying currency and gems utilize wafer



locks as described in **Chapter 15**. They are easy to pick and thus can be compromised without difficulty.

Section 3: Disc Tumbler Locks

ABLOY DISKLOCK



Disc wafer locks combine the attributes of traditional wafer designs with secondary locking systems, usually sidebar. Another distinction is that the wafers are **rotated** rather than moved in the normal vertical plane. These locks feature a key with different camming surfaces, having non-uniform radii from the central axis of the plug. As the key is rotated, it picks up different wafers based upon their internal spacing and structure. The operating theory of these devices resembles that of a combination lock to the extent that disks are rotated to align a sidebar. The sidebar can be likened to the fence that must enter all gates in order for the lock to open.

17_3.1 Abloy DiskLock

Abloy has developed a unique rotating disc sidebar locking system that distinguishes it from all other wafer locks (**3948065(179)**). The mechanism is comprised of rotating discs that resemble the wheel pack in a combination lock. Eleven discs provide up to 1.97 billion different combinations as well as complex master keying. The lock is somewhat similar in principle to the Olson

device that was patented in 1992 (**5086631(180)**). The position of the discs is automatically scrambled each time the key is removed in order to prevent visual decoding and impressioning. As an option, keys may be set to actuate a plug in one direction only or in both directions, allowing specific employees to lock or unlock certain areas.

Because there are no springs, the lock is impervious to dirt, water, freezing, poor weather conditions, and corrosion. Thus, it is suitable for use in difficult environments. Pick and decoding tools have been developed for certain series of this lock; however, picking can be quite difficult. See **Chapter 31** for information regarding the John Falle tools.

Forced entry of Abloy locks, and forensic indications, Courtesy of Hans Mejlshede.

17_3.1.1 Operating Principle

The operating principle of this lock is straightforward. Upon entering the keyway, the key meets no resistance because there are no springs. Discs initially remain in their locked position with their gate orientations scrambled. When the proper key is turned 90°, each disc is rotated a certain number of degrees corresponding to the radius of the cut. Each portion of the bitting will pickup its corresponding disc and rotate it until the key stops. The amount of travel of each wafer is dependent upon the angle of the cut. When all of the discs are aligned properly, a sidebar is retracted into the tumbler-pack and the plug is free to turn. As the key is turned in the opposite direction, the sidebar is lifted out of the gates into the locked position. The combination of the wafers is scrambled so that all of the gates are randomly placed. The key can then be removed.

The Abloy key is cut at varied angles, rather than traditional depths, which eliminates adjacent cut restrictions. There are seven different cut angles (identified as 0-6) and corresponding combination discs. Note that the discs are **not** reversible and are placed in the plug embossed side down. Discs 0-5 have two sidebar gates each; one for clockwise and counterclockwise turning. The number 6 disc only has one sidebar position and does not rotate. All Abloy locks have eleven discs and ten spacers sandwiched between the active discs; the spacers can be oriented in either direction. In addition, one-way spacers prevent discs from moving in both directions.

17_3.1.2 Master Keying

Master keying requires the use of discs with multiple gates (from 2-6 cuts on the side) resembling some early forms of lever locks. The same numbers of discs are utilized in all locks; just the gates are modified. A master keyed cylinder will have no more than four master discs loaded into the plug. The Abloy DiskLock is available in many configurations, including ANSI rim and mortise cylinder, high-security knob, European profile, cam, microswitch, furniture, and padlock.

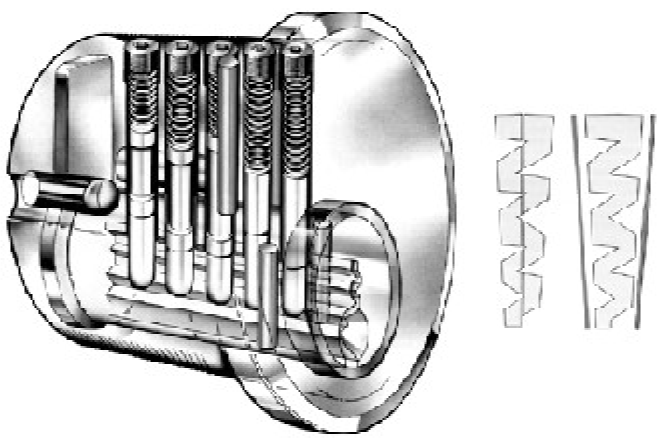
Section 4: Pin Tumbler Locks

EVVA GPI
MUL-T-LOCK
CORBIN-RUSSWIN EMHART
SARGENT KESO
DOM SPLIT KEY
IKON TK5S

17_4.1 The Basic Pin Tumbler Lock



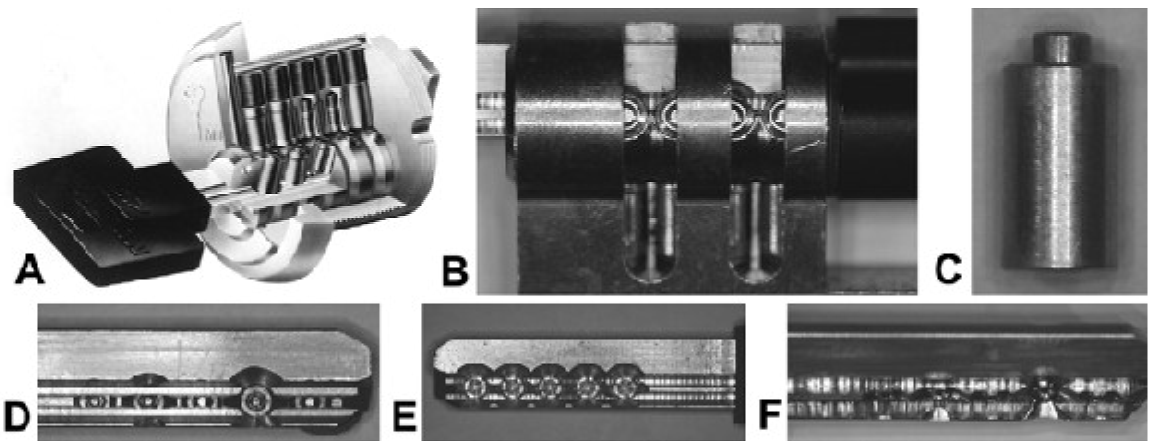
There are many unique variations of the basic pin tumbler lock discussed in **Chapter 16**. Several of these are described here because of their special application or unique modification to the basic pin tumbler concept. Not covered in this section are the family of tubular pin tumbler locks, hybrid designs, specialized industry locks, and those incorporating pin tumbler

"like" operation employing other technologies such as magnetics.

Several schemes rely upon the moveable pin tumbler as the basis for a locking mechanism. Many such locks have been omitted here due to space limitations. More importantly, the locks detailed in this section reflect the best and most significant mechanical designs. No inference should be drawn as to functionality, uniqueness, cleverness, or security just because they have been omitted.

17_4.2 Evva GPI Integrated Profile System

The EVVA **GPI** system integrates special design variations over the entire height of the keyway in order to increase the number of differs, security, and resistance to picking. The unique feature of this mechanism is the enhancement of the paracentric keyway function. Each profile rib overlaps the centerline and is distributed over the entire height of the keyway.



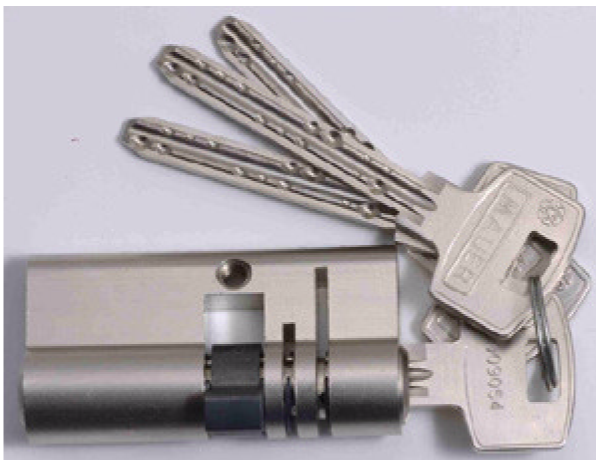
Both the key and the keyway are conical shaped. This virtually eliminates the generation of counterfeit keys, and more importantly, will make picking and probing of the lock difficult. The shape of the keyway and its sharp curves makes the insertion of any pick very difficult.

17_4.3 Mul-T-Lock

The Mul-T-Lock design was introduced in 1973 and has earned a reputation for mechanical excellence. The company, headquartered in Israel, is known for its quality assurance and innovation in

high-security products. The lock is manufactured to high tolerance and is recognized for its pin-within-a-pin telescoping tumbler concept (**4856309(181)**). The mechanism takes on characteristics of a dimple lock described below but more closely resembles conventional operation with a horizontal orientation of the keyway.

The primary locking concept is conventional, in that pin tumblers are utilized in a rotating plug. The addition of telescoping tumblers, requiring that both segments must be raised to shear line, provides a very high level of pick resistance.

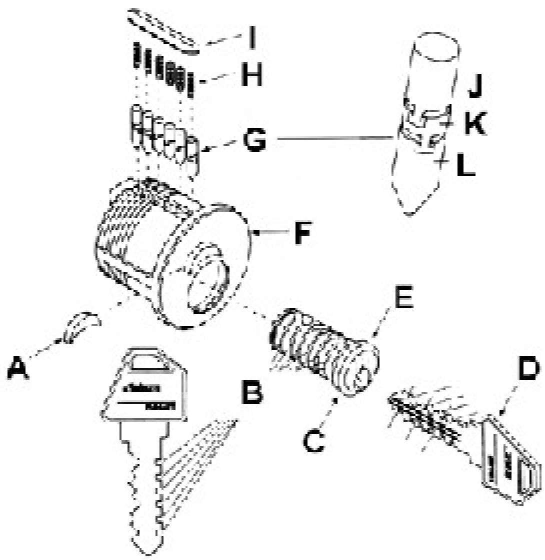


The company has received patents for the design, which provide for two independent pins within each chamber. Chicago Lock utilizes a similar concept in their high-security axial cam locks. However, Mul-T-Lock has engineered their telescoping pins to be a complete, self-contained assembly.

The plug is oriented horizontally within the shell. The four or five pin-sets are acted upon by the sides of the key, thereby reducing the space available for the action of a pick. Two types of pin assemblies are utilized: body pins, and plug pins. The Mul-T-Lock spherical plug is also different than other high-security locks. It is shaped so that a three dimensional shear line is created, engaging the entire contact surface between the pin and shell. This is called spherotation.

Pin surfaces are convex to precisely match the curvature of the plug with respect to the shell. The upper pins are concave. Thus, a three-dimensional shear line is attained and which provides very high tolerance. Keys are double-sided and may be inserted in either horizontal orientation. The double dimples that form the bitting are complex in their geometry. They have an

inner and outer ring to control the inner and outer telescoping pins. The locks are UL 437 listed and are available in a variety of configurations. John Falle has released, in 2004, a tool to decode these locks, based upon the pin and cam system design.

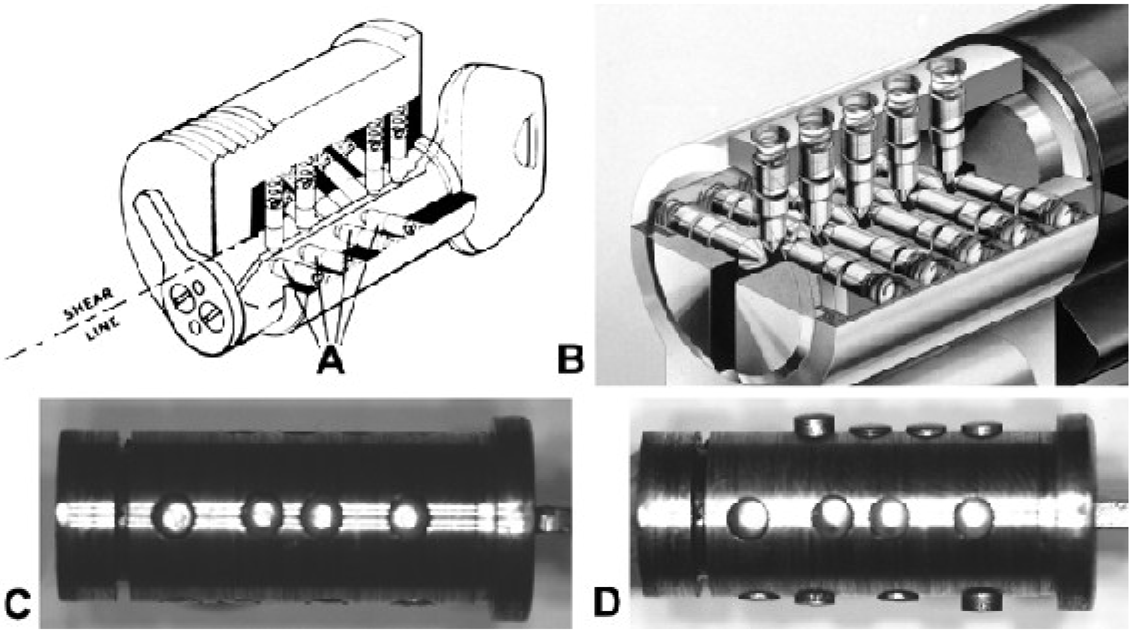


An interesting modification of the Mul-T-Lock was introduced by Mauer. Although this mechanism utilizes the European profile design, it employs one continuous set of bores and tumblers, rather than two separate plugs. The key is extremely long, and double-sided for insertion from either direction.

17_4.4 Corbin-Russwin Emhart High-Security

The Corbin-Russwin high-security cylinder is called the Emhart, first patented in 1978. The UL listed device was the first to allow integration of high-security cylinders into existing conventional system. All Emhart high-security cylinders use six pins and require keys with all cuts at one of two angles, or skews. The cuts are designated as left skew = 1, right skew = 2.

Security is attained through the use of interlocking pin tumblers. The end of each pin interlocks within the chamber and can only be released through the rotation action of the pin that is caused by the movement of the angled cuts on the key bitting surface.



If the proper key is not inserted, the pins will remain locked together, forming, in essence, one solid tumbler (driver, master pin, and lower pin). The proper angled cuts on the key will release the pins from each other at shear line. Cuts are 20° offset, and there are no cuts that are perpendicular to each other.

There are also slotted grooves in the bottom of the key. These increase the difficulty of duplication and allow the projecting "T" of the top or master pin pin to pass over the key when the plug is rotated more than 180°. There are six bottom pin lengths and three master pin lengths. Conventional Corbin-Russwin cylinders may be mixed with high-security cylinders, much the same as with the Schlage Primus system. Thus, older installations may be fitted with high-security locks to protect critical areas. If an Emhart lock is to be disassembled for forensic examination, a standard follower cannot be used. All high-security cylinders must be top-loaded and disassembled.

17_4.5 Sargent Keso

Sargent introduced the first "dimple" pin tumbler lock in about 1968 as a licensee of Keso of Switzerland. This lock, as described in the first edition of this text, offered high-security through the introduction of a key with three active surfaces and twelve pin tumblers. The lock provides improved pick resistance, key control, and several levels of complex master keying with no loss of security. The highest security version of

this design features telescoping pins for maximum pick resistance.

17_4.5.1 Principle of Operation

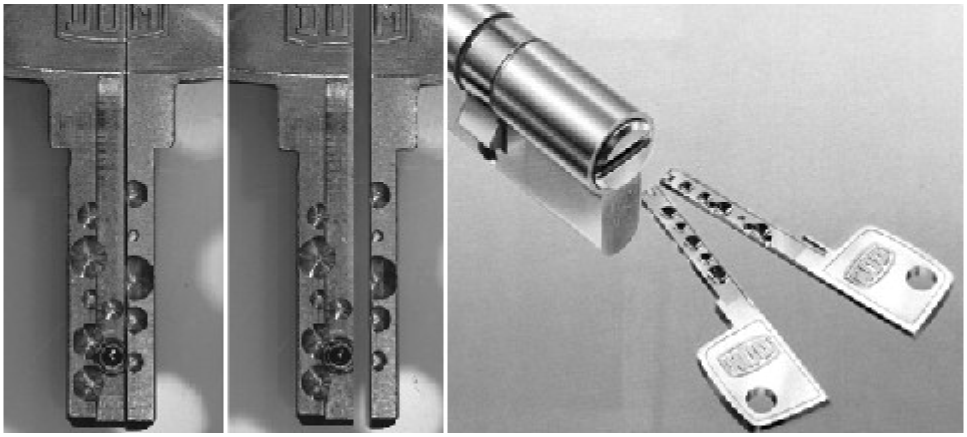
Most dimple locks are based upon the same operating theory and mimic the Keso. These devices can utilize conventional or telescoping pins.

The Keso resembles a conventional pin tumbler lock with regard to the double-detainer locking concept. However, instead of containing five, six, or seven pins, the Keso uses from nine to twelve tumblers. The pins are arranged in three interlocking rows spaced in approximately 90° increments around the core. While the design of Keso key is unique, its basic operating theory is similar to a conventional pin tumbler lock, except that is has more pins.

The key is six-sided and is cut on all surfaces. In use, only three of these surfaces come into contact with the active tumblers. This allows insertion without regard to vertical orientation. The depressions in the key, usually four per surface, are flat bottomed. These match the height and position of the bottom pins and form the bitting surface. The tumblers are pointed, in contrast to conventional pins that are rounded or flat bottomed. This maintains a higher tolerance.

17_4.5.2 Differs and Master Keying

The lock can contain at most twelve tumblers (four per active surface). Each has four depth variations, creating millions of differs. This results from the fact that pins can be placed in any of **ten positions** on each surface. This placement of pins in selected chambers is known as a **positional keying system** and is more fully described in **Chapter 11**. Although only four pins are used, ten tumblers could be placed on each active bitting surface. This would provide a total of thirty different tumbler positions in the lock.

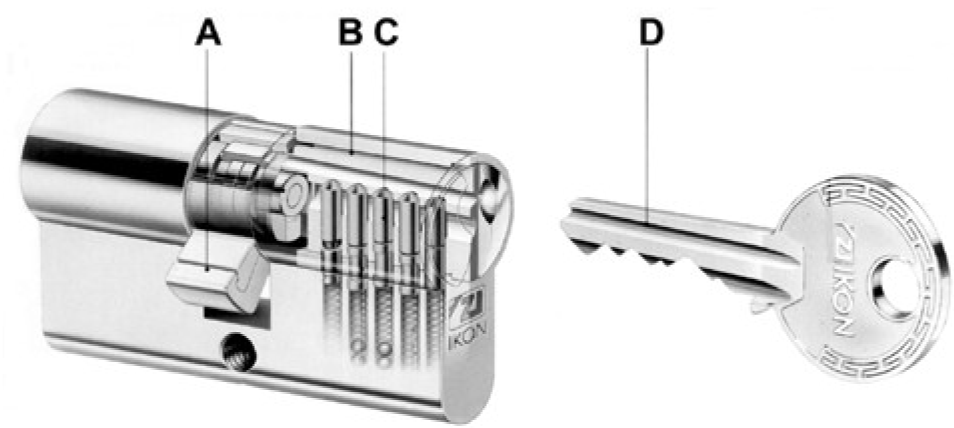


The combination for each cylinder is determined by the placement of pins in one or more chambers, for each of three surfaces. When group and master keying levels are established, identical patterns of chambers are selected. Whereas the **length** of a pin is determinative of the code for a key in the **conventional** lock, the **position** and **length** controls in the **positional** system. A matrix is established for each cylinder, defining the number of pins, chamber identification, and length. It can be seen that multiple keying levels are possible without the potential of cross-keying.

17_4.5.3 Security of the Lock

Dimple locks including Keso can be picked and impressioned. The success of such procedures depends upon tolerance, the use of security tumblers, and the number of pins.

17_4.6 Dom Split Key



DOM (a Black & Decker Company) produces a high-security pin tumbler lock utilizing a dimple key. The uniqueness of this mechanism lies in its ability to "split" the key in half, thus making it ideal for dual-control entry. Both sections must be simultaneously inserted for the lock to open. See **Section 7** below for a full description.

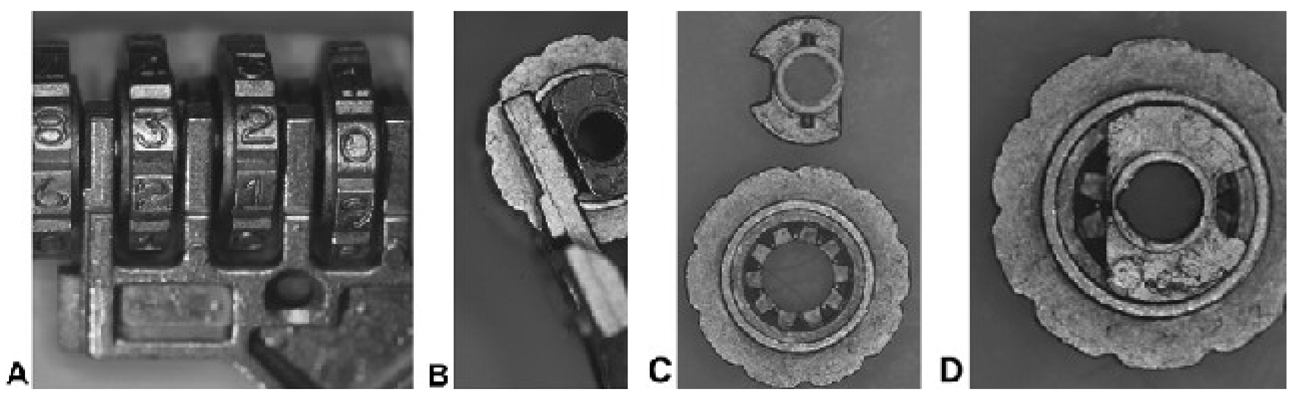
17_4.7 Ikon TK5/S

Ikon has developed a conventional pin tumbler lock with a tapered keyway and rotational control pins. This creates special restricted keyways and a system that can be configured to allow access to a limited group of locks. Individual keys can be cut to restrict rotation of the plug to either a locked or unlocked position. This is a similar option to that offered in the Abloy DiskLock.

The Ikon TK5/S is a five-tumbler lock with two side pins, used to control rotation. There are corresponding protruding tabs on the side of the key that is positioned at 90° from pin chambers one and three (from shoulder). Square depressions are cut into the side of the plug at these pin positions.

If the proper key is inserted, the tabs will cause the pins to be extended from within the plug to shear line. If the tabs are

not present, the key will be blocked from rotating more than 90° in either direction. This occurs because the driver pins will stop the plug when they encounter the depressions. Keys are difficult to duplicate, based upon the angled broaching of the keyway and bitting surfaces.



Section 5: Combination Locks

MASTER
S&G TIMBINATION
MAS-HAMILTON X-07

This section examines specialized mechanical and electronic combination locks. Conventional combination locks used in safes and vaults are more thoroughly described in **Chapter 34.**

17_5.1 Master Combination Lock

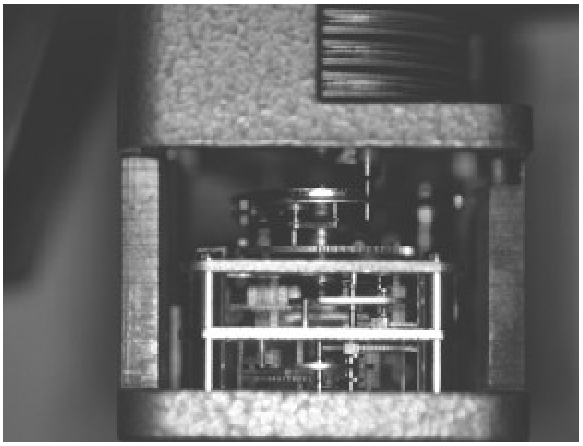
The Master four-wheel combination lock is extremely popular for padlocks and luggage. The Corbin Sessamee is of similar design (**4375159(182)**).

A traditional combination lock relies upon the rotation of a wheel pack to align individual gates. In this device, four discs are moved to the proper combination and may be instantly reprogrammed to a different number sequence.

The code may be changed by altering the relationship between the position of the disc, and the corresponding detent or flat-spot that forms the gate. Although there are 10,000 possible combinations, the lock may be very simply bypassed without the need to test every permutation. Each wheel may be rotated until

the detent is felt, while applying slight pressure to the shackle. The procedure is quite straightforward.

Another technique is to examine the individual wheels with an otoscope or borescope. There is a significant gap between the two halves of the lock casing, permitting a view of the discs. Simply rotate the wheels individually until a notch at the right of each wheel can be identified. Align all of the wheels so that each notch is visible, and note each displayed number.



A corrective digit is then added to determine the correct combination. For certain models, 7 is summed to each individual number, dropping the tens place digit result. When the wheels are moved to this new combination, the lock will open. For example, if 8614 is displayed upon viewing each detent, the actual combination would be 5381.

	8	***6***	***1***	***4***	***Decoded Combination***
+	***7***	***7***	***7***	***7***	***Correction***

	5	***3***	***8***	***1***	***Derived Combination***

17_5.2 S&G Timbination Lock

The S&G Timbination movement provides an integrated short-term time lock within a standard 6730. A timer is triggered whenever the combination is dialed, requiring a delay of up to fifteen minutes before the bolt can be retracted. The lock is used to frustrate daylight robberies.

17_5.3 Mas-Hamilton X-07 Electronic Combination

Lock

The Mas-Hamilton X-07 is more fully described in **Chapters 18** and **34**. It is the most sophisticated electromechanical combination lock ever devised and is certified by the General Services Administration for use on top secret security containers.

The lock is microprocessor controlled, self-contained, and does not require any power supply for operation. It offers advanced security features that make it completely secure against all known forms of electronic bypass. Shown above is the Auditcon, which utilizes the same technology as the X-07.

Although S&G, LaGard, and other manufactures produce computer-based locks to replace their mechanical counterparts, none has attained the sophistication in design and security of the X-07. In the opinion of the author, the X-07 will remain the world standard for many years, based upon the restrictions placed on the duplication of their unique technology by the claims in the Mas-Hamilton patent.

Section 6: Hybrid Locks

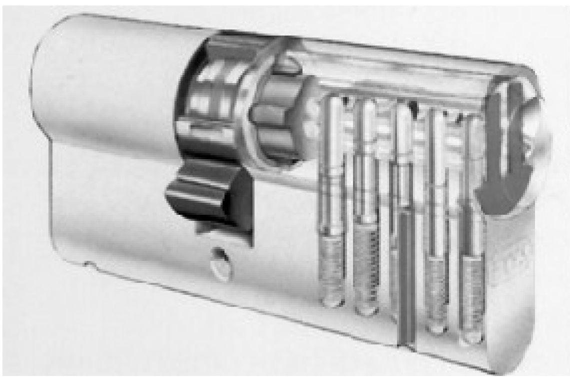
ABLOY DISK
EVVA DPX
MEDECO

Assa, Schlage, Medeco, Abloy, Dom, Ikon, Keso, Mul-T-Lock, Chubb, Evva, and many other vendors provide a rich array of sophisticated high-security locks that incorporate what the author refers to as "hybrid" locking technologies. Hybrid locks combine two or more separate and interrelated locking mechanisms to offer higher levels of security against covert and surreptitious entry. Although there are many mechanical configurations, the most popular secondary locking system utilizes the **sidebar.** This method can be used in conjunction with wafers, discs, pins, and magnets.

There are, however, other systems. Axial cylinders in combination with traditional pins are popular in public locker applications. A conventional pin tumbler, complemented by data transmission, is prevalent in the automobile industry and is described in **Chapter 20**. Microprocessors can add intelligence to wafer and pin tumbler designs (**Chapter 21**). The telescoping pin, used by Mul-T-Lock, has also become very popular as a secondary locking device. See Section 4.3.

17_6.1 Sidebar Designs

During the past ten years, several manufacturers have developed extremely clever modifications to the original Medeco sidebar design. The most unique of these will be described in this Section.



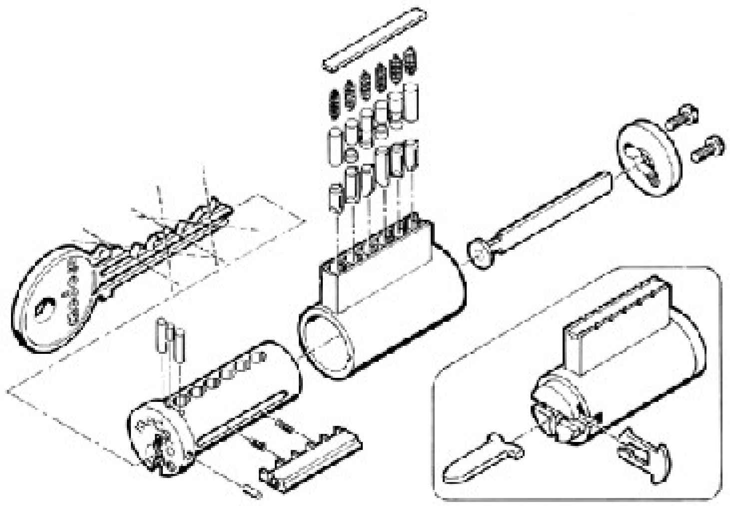
17_6.1.1 Abloy Disc

This lock incorporates a sidebar mechanism in conjunction with ten rotating discs, and resembles the wheel pack within a combination lock. The mechanism is fully described in Section

3.1.

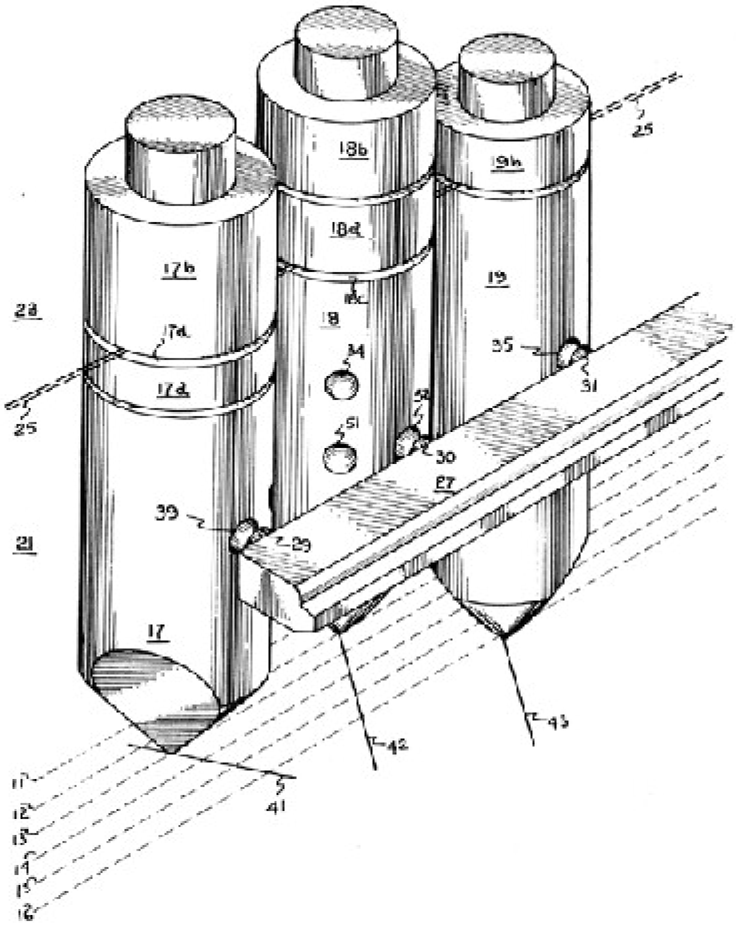
17_6.1.2 Evva DPX

This system integrates a conventional pin tumbler mechanism with an innovative approach to the use of sidebar technology. The lock utilizes five conventional pins and a sidebar with different profiles that mate with indentations on the side of the key. The approach to sidebar coding that Evva has adopted resembles that of Assa. This lock does not provide secondary locking, as with Medeco and other similar mechanisms. Rather, the sidebar simply adds security to the keyway.

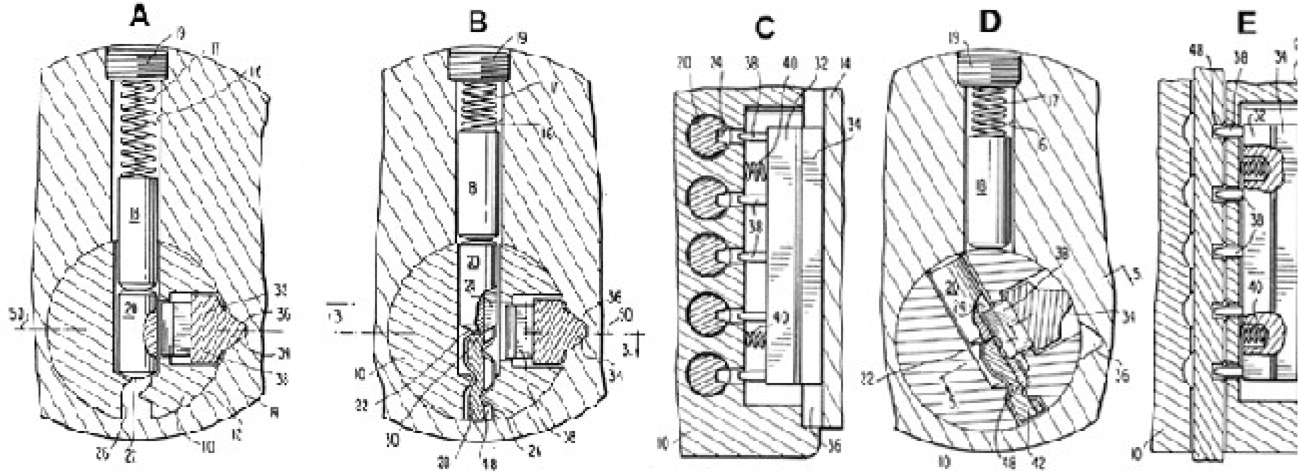


17_6.1.3 Medeco Twisting Tumbler Sidebar

Original Pin Tumbler
Biaxial Pin Tumbler
Cam Lock
BiLevel



Spain and Oliver invented the concept of the rotating tumbler lock. The Medeco Lock Company offers three distinct designs that employ this principle.



17_6.1.3.1 Original Pin Tumbler Design

The original Medeco rotating tumbler cylinder was introduced a short time before the first Edition of this text was published in 1970. The design was revolutionary and literally transformed the concept of high-security locks. The original patent, issued to Spain and Oliver, described a completely new and innovative locking technique (**3499302(183)**, **4723427(184)**, **3722240(185)**). It relied not only upon the traditional double-detainer principle first invented by the Egyptians and refined by Yale but introduced the theory of the **rotating** or **twisting** tumbler.

There have been many modifications to the concept described within the Spain patent since its first grant. Changes have been made both by the original inventors and by many others who altered the design in an effort to improve upon it, and to capitalize upon its uniqueness and ingenuity.

In the original patents, two distinct designs were claimed. Thirty years later, they have become the most successful high-security locks in use worldwide. In reality, it might be said that the invention was but a long awaited refinement of the Briggs and Stratton sidebar wafer lock first introduced in 1935 for the automotive industry.

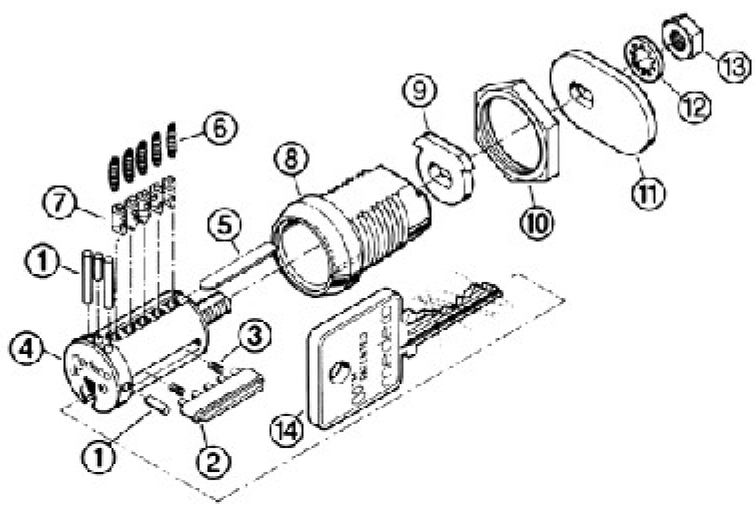
The Briggs and Stratton lock relied upon the use of wafer tumblers; the inventors of the Medeco used pin tumblers. The combination of pins and sidebar produced a high-security lock that would be extremely pick resistant.

There are two basic Medeco sidebar designs. The first is used primarily for vending, gaming, alarm, cash container, and in control applications requiring substantially higher security than can be obtained from a standard wafer cam lock. The other is a high-security pin tumbler cylinder design.

The first Spain patent was premised upon the standard pin tumbler lock that required that all conventional pins be raised to a shear line in order that the plug might turn. That is where all similarities to the original Yale design ended. The inventors integrated a sidebar mechanism into their lock that had to be retracted into the plug in order that rotation might occur.

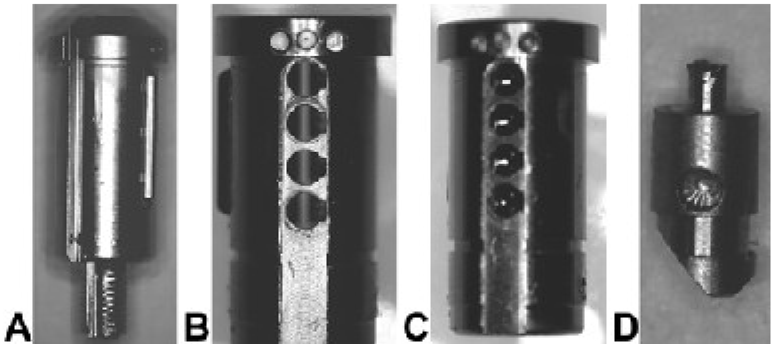
The sidebar is a spring-biased bar with protruding pegs corresponding to slots located in the side of each tumbler. **The security of the design is based upon the mating between sidebar pegs and tumblers, in order that retraction might occur.**

There is a small hole within each pin with a diameter that will just allow the sidebar peg to enter the slot within the tumbler. The tumbler must be raised to shear line **and also rotated** to the precise point that allows entry of the protruding pegs. Once this occurs, the sidebar will retract and the plug can be rotated. In the original design, each pin could be rotated to one of three positions: **right**, **center**, or **left**. If any tumbler is not raised to the shear line or is not perfectly aligned to allow

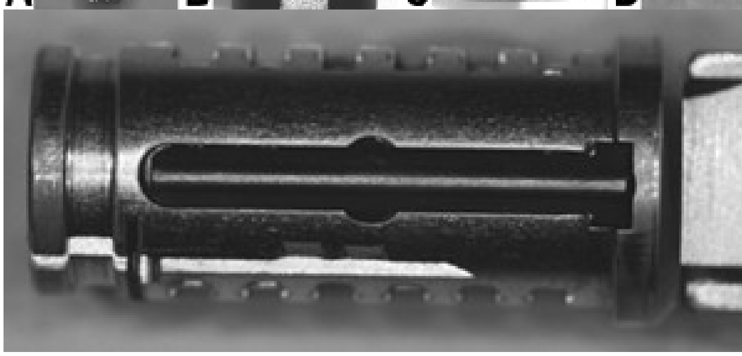


the pin from the sidebar to enter, then the lock cannot be opened. In 1994, Peter Field patented a design modification to the Medeco pin shape (**5289709(186)**) that provided for the interaction of the pin tip and key bitting in a unique fashion. This system provides additional differs and extremely high-security.

The Peter Field (Medeco) patent for a security tumbler. Courtesy of Hans Mejlshede.

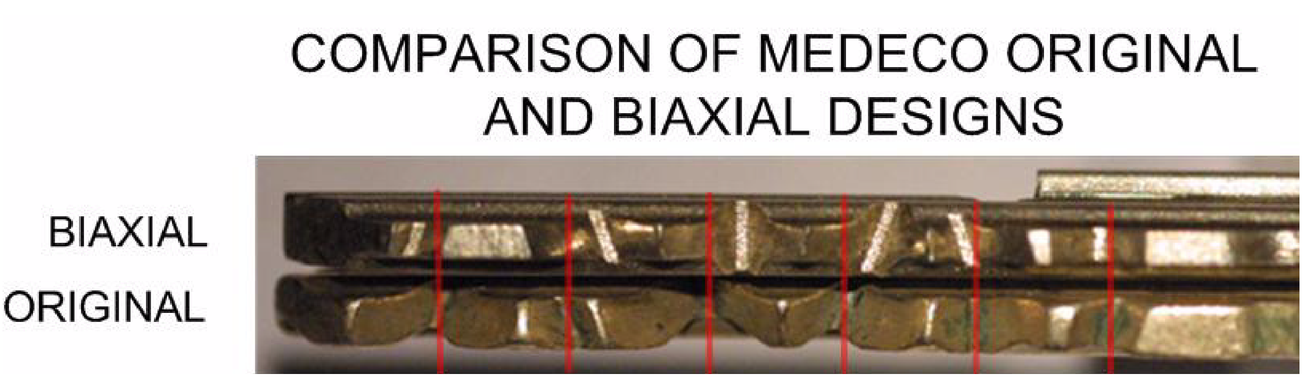


17_6.1.3.2 Cam Lock

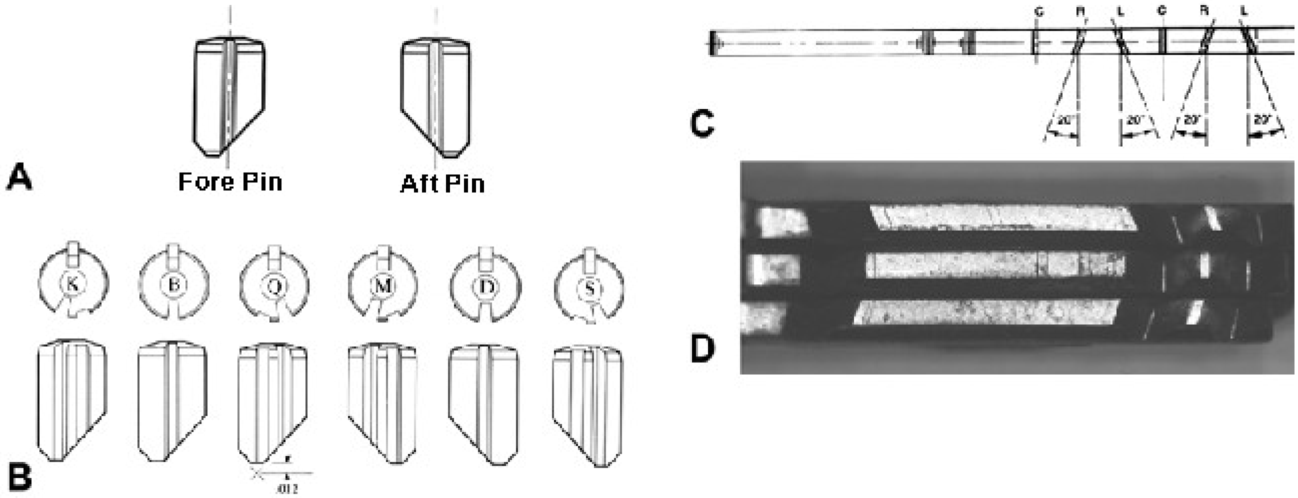


Forensic analysis of the Medeco cam lock. Courtesy of Hans Mejlshede.

The second patent provides for a modified pin tumbler design that is even closer in concept to the Briggs and Stratton lock. It relies upon the use of only **one** pin tumbler per pin chamber. The pins do not create a shear line but rather are the vehicle for the control of the sidebar.



Each pin has a precise hole in its side corresponding to a pin extending from the sidebar. Although each pin tumbler is lifted and rotated, there is no secondary shear line created by a top set of tumblers. The only function the pin tumbler performs is to be lifted and rotated for alignment of the sidebar.



17_6.1.3.3   Biaxial

In 1985, modifications of the original Spain pin tumbler configuration, referred to as the Biaxial was patented. This patent claimed an alteration of the original tumbler and key bitting design that affected the position where the chisel point of each lower tumbler came to rest on the key bitting surface. The photograph shows a comparison of conventional and Biaxial bittings. The red lines are referenced to the center of the root on the conventional key. It can be seen how all cuts on the Biaxial are either before or after centerline.

The new patent accomplished two primary functions: it kept the original patent alive for another seventeen years and it introduced a lock with complex keying abilities surpassing the original design.

Whereas the original chisel-points would rest in the root of each cut, the Biaxial was designed to cause each of the pins to rest at **different positions** along the bitting surface. This would allow for extremely complex master keying and a greater number of differs for a given keyway. The Biaxial pinning scheme incorporates three variables to increase the number of differs: depth of cut, rotation of tumbler, and position of tumbler-bitting interface. The Biaxial lock thus provides for six angles, taking into account rotation and tumbler position.

There are six possible depth cuts for Biaxial keys in .025” increments. Rotation of tumblers varies by 20^{o} from center (perpendicular to the blade of the key is considered as center). In addition, tumblers may be located **fore** (toward the bow of the key) or **aft** (toward the shoulder). Thus, the Biaxial provides for 36 different orientations for each bottom pin.

Biaxial pins and their chisel angles are identified by letter codes relating to whether the pin rotates left or right of center and whether the movement of the pin is based upon a fore or aft cut. The system can identify all six possible angles by single letter, extrapolated from **L** (left), **C** (center), or **R** right initial designation. The letter immediately before L, R, or C is used if the pin employs a "fore" cut; immediately after for an "aft" cut. Thus, K, B, and Q would indicate left, center, and

right "fore" cuts; M, D, and S, "aft" cuts.

The Biaxial bottom pin has a projection at the top called a locator tab that will limit pin rotation. There is also a vertical channel, cut into the side of each tumbler, which corresponds to the sidebar peg. The channels and tabs are correlated (K,B,Q,M,D,S) depending upon the coding of the tumbler so that rotation is always properly limited.

The slots or vertical channels have six positions, consistent with the orientation of the chisel points at the tip of the pin. Thus, channels are oriented to the left of, right of, or "on" the centerline of the pin. There may also be false channels cut around the pin for added pick-resistance. Top pins are made from brass or hardened steel, .135" in diameter, and are of varying lengths corresponding to the bottom pins. One or more mushroom tumblers will also be incorporated within each set of top pins.

17_6.1.3.4 Other Medeco Security Enhancements

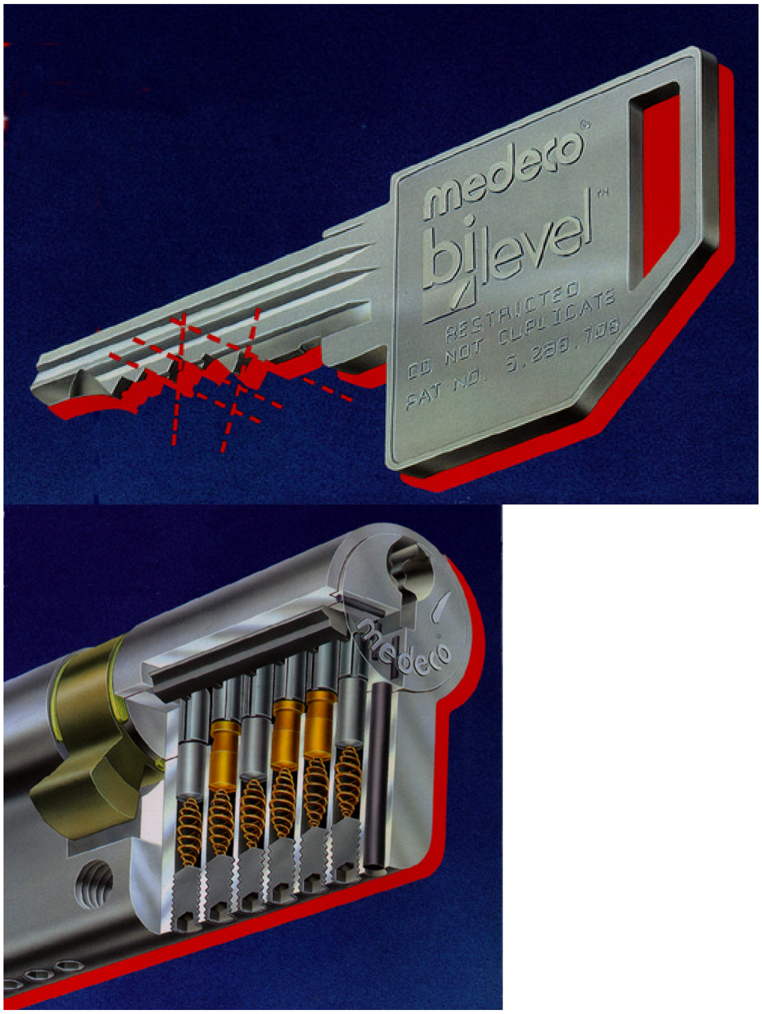
All Medeco locks incorporate hardened steel rods for added security. In the case of the pin tumbler cylinder, Medeco uses four hardened steel rods, two hardened steel crescents, hardened steel top pins, and a hardened steel ball bearing.

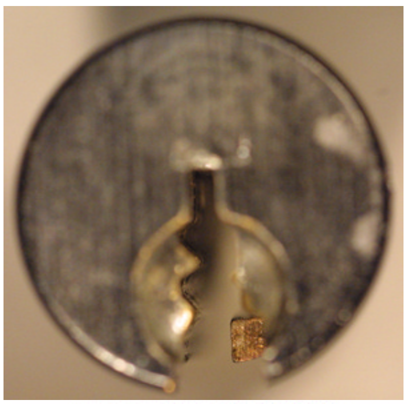
Medeco maintains strict key-blank control. There are at least four widely available commercial keyways (00, 60, S1, S6). There are also many restricted keyways exclusively designed for the use of one customer. Keys for all Medeco locks must be duplicated on special key machines, such as manufactured by Silca and HPC. They cannot be copied on conventional cutters because of the required angled cuts.

17_6.1.3.5 Medeco Bilevel

Medeco has introduced their Biaxial design in the European market under the name of Bilevel. It appears to be essentially the same design, and provides for a second rotational axis upon which the chisel-pointed tumblers operate. It will be remembered that in the conventional Medeco design, tumblers can have a left, center, or right twist. In this design, there are in effect two angled cuts that are available, thus increasing the differs. There is also an offset tip pin (OTP) in the last position, also with a new tab slow location. The design has received a European patent (EP 0651846). Medeco claims there are 75,582,720 (453,496,320 with sectional keyway) differs in their six pin locks, and

4,199,040 (25,194,240 with sectional keyways) in the five pin mechanism. There are 75,000 master keying combinations with sectional keyways for the six pin lock, and 15,000 for the five pin model.





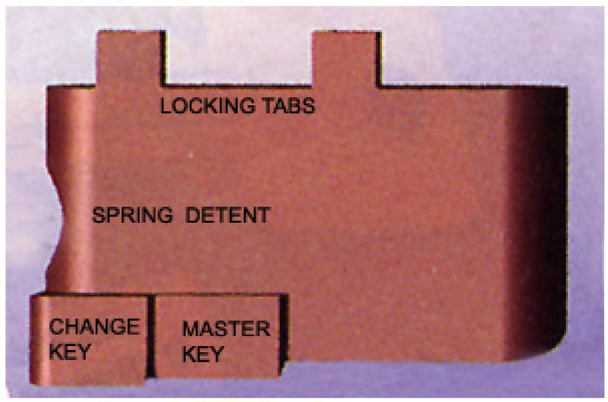


Figure LSS+1704 Medeco BiLevel key and internal sidebar design. Courtesy of Medeco.

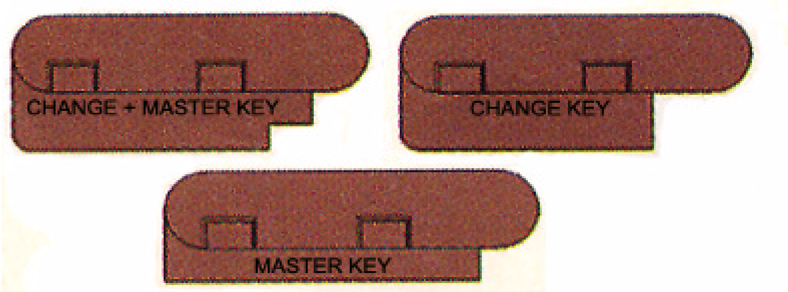
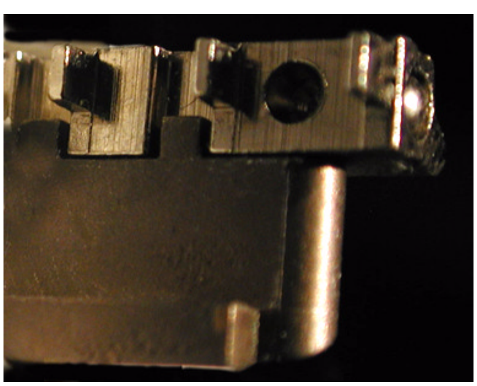


17_6.1.3.6 Medeco M3 System



The Medeco M3 slider system (U.S. Patent 6,477,875) was introduced in 2003 and adds another level of security to the Biaxial design. See the discussion in Chapter 31, regarding its enhanced security and integration within a master key system. A slider has been added to provide for complex keying requirements and to extend the patent protection of the Biaxial. The lock has

all of the attributes of the Biaxial, but a sliding component has been added to mate with the sidebar. Locks can be configured to operate with change keys only, master keys only, or change and master keys. The design can prevent the alteration of change keys for use on cylinders designated for master keys only. Likewise, locks that are set for change keys only cannot be operated by any master key. Cylinders can also be defined for either change key or master key. This coding is accomplished by two levels of steps or protrusions within the design of the keyway. There are six slider variations for each level, and a total of 27 permutations of slider step positions. The slider makes contact with the side millings on the key as it enters the keyway.

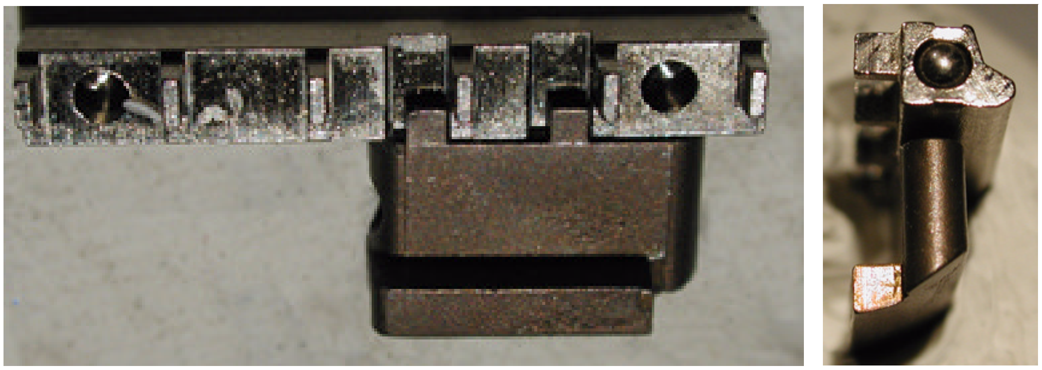


Figure LSS+1706 shows the critical component of the M3 system. The slider is actuated by side milling protrusions, as shown. There are a total of 27 sliders available. The steps on the slider correspond with the side milling on the key, which cause the slider to be moved in the proper position so that its two tabs precisely mate with the gates in the sidebar. Shown in the photographs (top left) is the face (step) of the slider that makes contact with the key in the keyway; (top center) a slider with both steps; and (top right) the three different slider combinations. If the slider is not moved to the correct position, then the sidebar is prevented from retracting into the plug. The bottom photographs show how the slider tabs mesh with the gates in the sidebar. It can be seen that if the slider is not moved into the correct position, the sidebar is blocked. In these photographs, the plug is oriented so that the keyway is on the right. The slider is spring biased toward the face of the lock. The photograph (bottom right) shows the slider properly aligned with the sidebar gates, as it would appear within the plug. The side millings on the key would make contact with the front step of the slider.

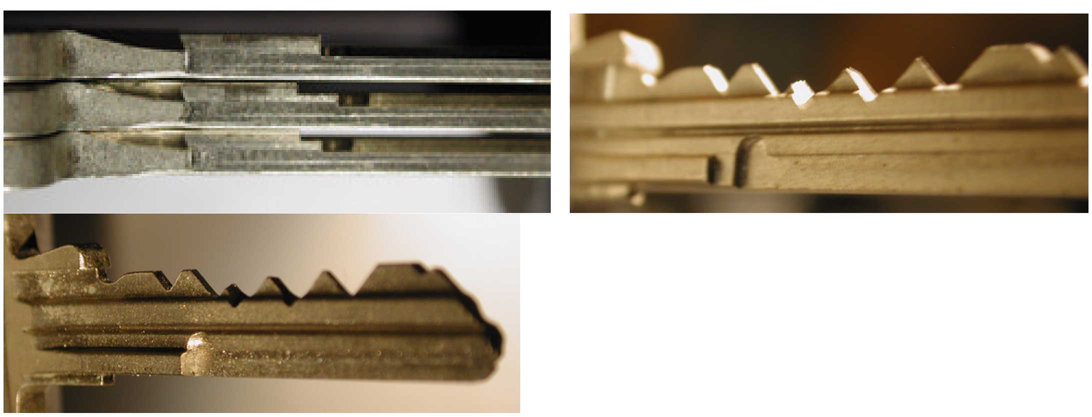

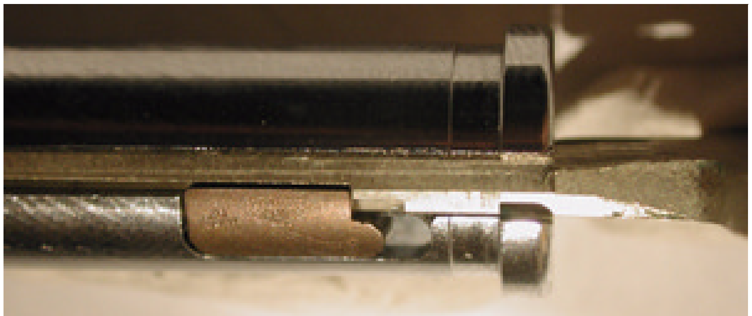

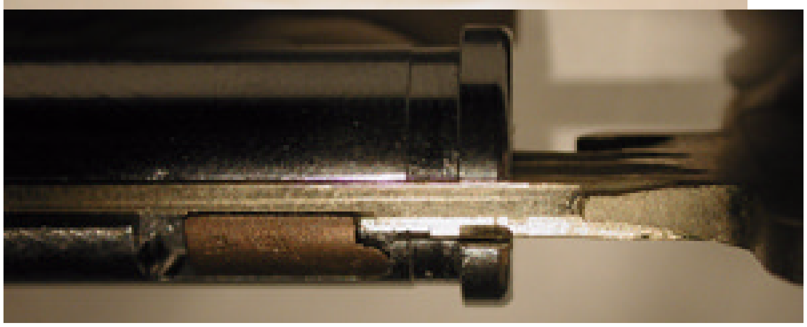

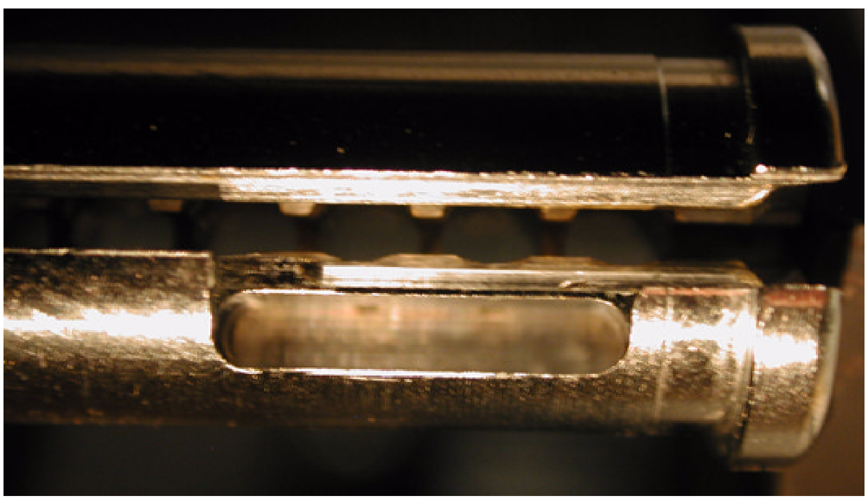

Figure LSS+1707 shows a comparison of the side millings for three different keys. The top key (left photograph) is a master key, the two other keys are change only. Note that the first side milling toward the shoulder is for the master key step on the slider. The center photograph shows a change key side milling, and the right photograph shows a master key milling.

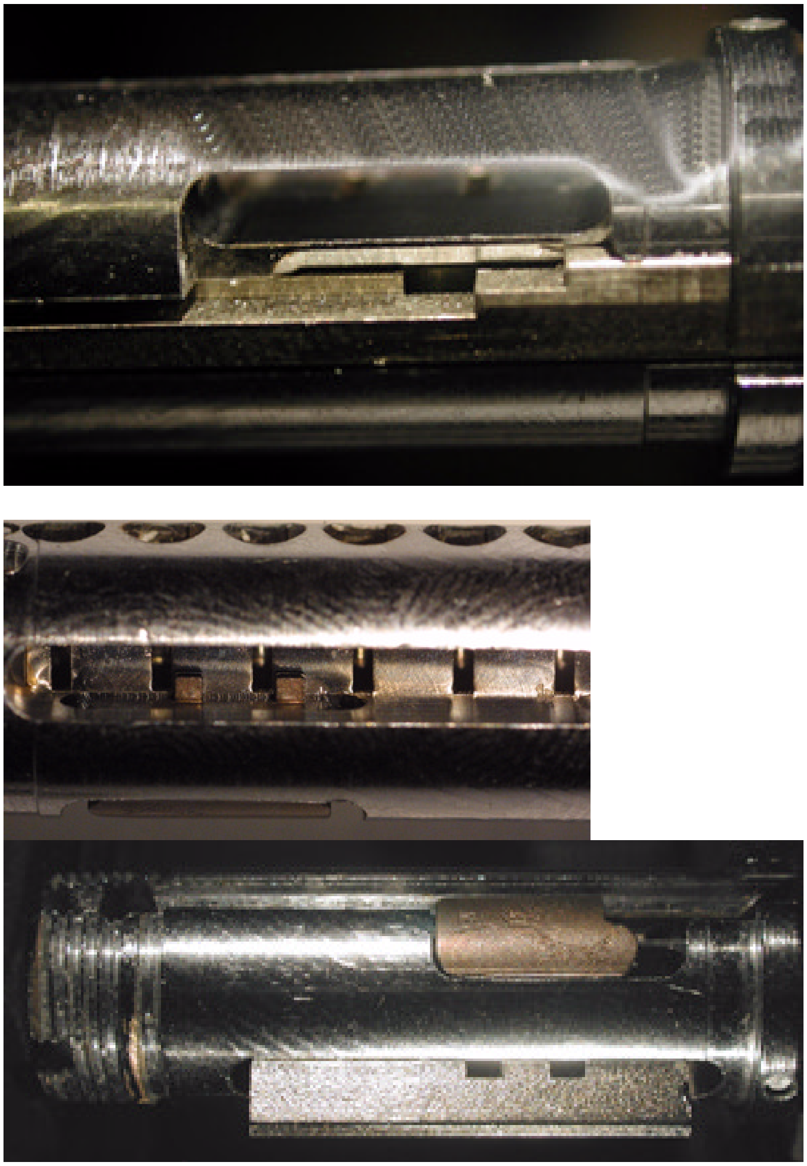

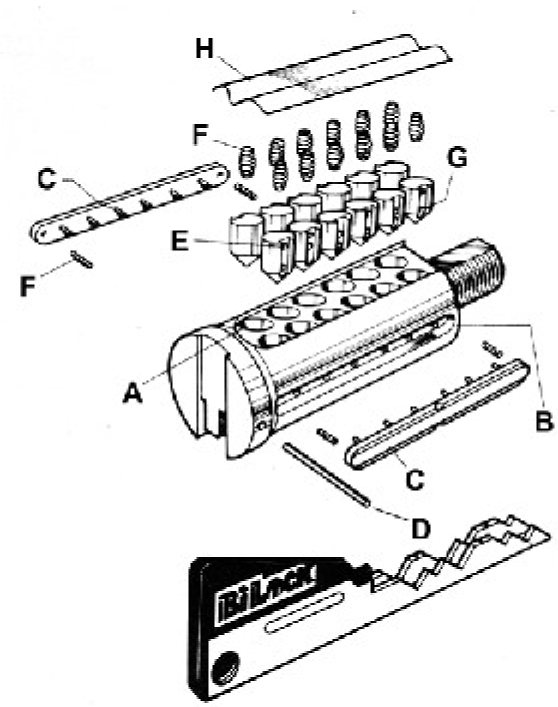

Figure LSS+1708 shows the plug, slider, and sidebar. In the photographs (top) the action of the key upon the slider step is shown. As the key is inserted into the keyway, the slider is forced backwards until its tabs align with the gates in the sidebar. In the photographs (center) the plug is shown without the slider inserted. It can be seen that the front step of the slider is designed to make contact with the side millings on the key, as shown (right center). The photograph (bottom left) shows the slider tabs protruding into the area where the sidebar resides. The photograph (bottom right) shows the sidebar partially inserted into the plug and how its gates integrates with the slider. The gates must mate with the sidebar tabs in order for the sidebar to retract.

17_6.1.4 BiLock Pin Tumbler Sidebar Lock

Figure LSS+1703 A BiLock key is distinctive in its dual bitting configuration.

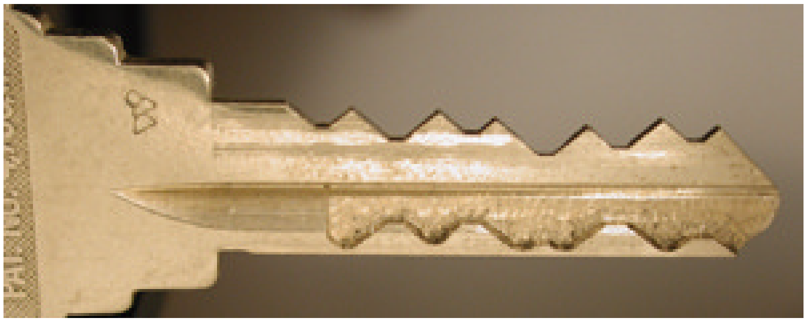
The BiLock was first patented in Australia and has been available in that country since 1981. Its inventor designed both an eight and twelve-pin tumbler lock with dual sidebars that resembles both the Briggs and Stratton and Medeco mechanisms in certain respects.

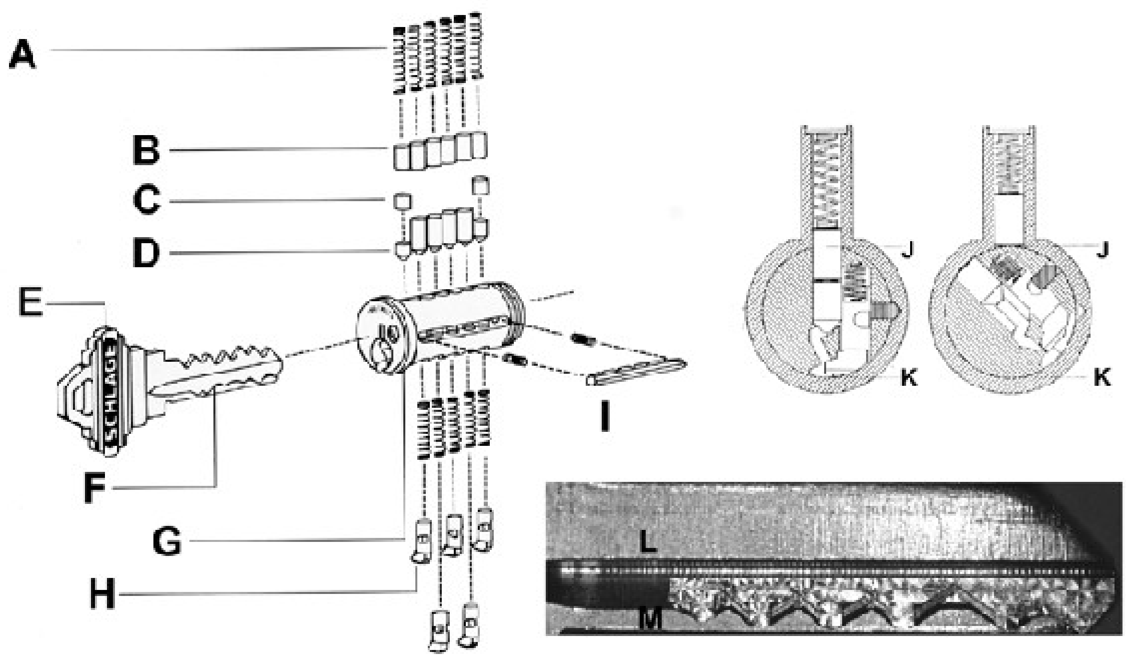
Exploded view.

The plug contains two parallel rows, each with six (or four) pin chambers, and slots for sidebars at the 9 O'clock and 3 O'clock position. Each of the rows of pins act independently of each other. A "U" shaped keyway allows the insertion of a uniquely shaped dual-bladed key. Keyways can be altered with the introduction of a special profile pin through the center.

Much like the Medeco cam lock, there is only one set of tumblers in each pin-stack: the shear line is created by the sidebar interacting with each pin. A hole is drilled in the side of each tumbler, vertically positioned to correspond with the depth-cut of the key. When raised to the proper height, a projecting pin from the sidebar will enter a corresponding recess. When all pins are aligned properly, the sidebar is allowed to retract into the plug. In the Medeco cam lock, the pins are raised and rotated; the BiLock only requires that the tumblers be raised to the proper height. All BiLock pins are of identical length.

17_6.1.5 Schlage Primus and Assa





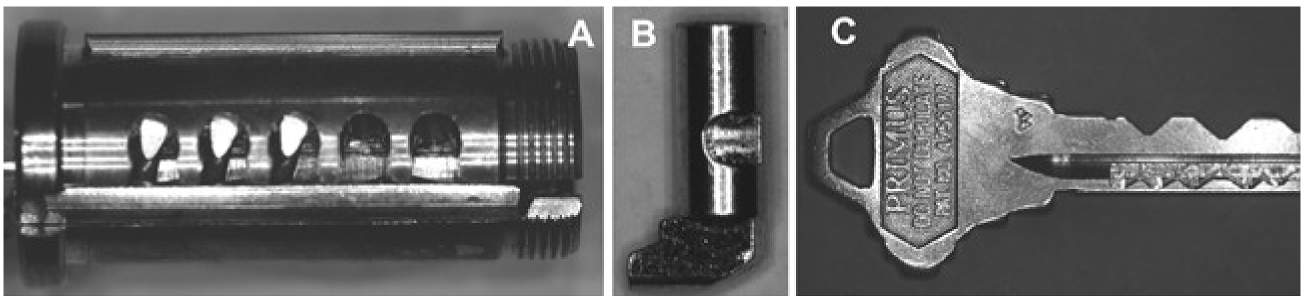


Figure LSS+1709 A schlage Primus key, showing sidebar millings with a code of 23624. There are three rotations and four actual depth increments that are available with Primus.

Schlage introduced the Primus series in 1989 as a high-security lock that could be easily integrated into conventional Schlage systems. The cylinder was primarily designed to facilitate key control, and it utilizes both conventional pin tumblers and a sidebar. Special **side bit milling (SBM)** is employed to control the "fingers" which determine the position of the sidebar.

The same inventor who conceived of the Assa mechanism, Bo Widen, designed the Schlage Primus lock. Assa has been in business in Sweden since the early 1800s. The **Assa 6000** series is the counterpart to the Schlage Primus.

The Primus is a pin tumbler lock with a second line of five finger-pins that allow the operation of a sidebar. These secondary tumblers are located to the side of the keyway and toward the bottom of the plug. The pins must be raised to their own shear line, thereby allowing the sidebar to retract. Millings into the keyway to various levels are produced at the factory. Thus, the locksmith must only cut the standard bitting with a precision key machine. The factory maintains close control of the secondary key differs. A unique pattern is assigned to each locksmith or distributor of the product, or to specific customers.

Primus keys will work with conventional Schlage plugs; however, the converse is not true. This allows high-security locks to be integrated within a conventional system without disruption. Conventional keys cannot be cut to fit Primus cylinders. In the view of the author, the Schlage Primus and the Assa lock offer excellent **key control**. They do not afford the level of security of other competing **high-security** locks, such as Medeco, Ikon, and EVVA, with respect to unauthorized key duplication and generation, or extrapolation of the TMK within a master key system. See **chapter 31**. Pick resistance, however, is excellent.

There are two versions of the Primus: the model 20-500 series which is UL 437 listed, and the unlisted model, 20-700 series. The listed version contains hardened anti-drill rods.

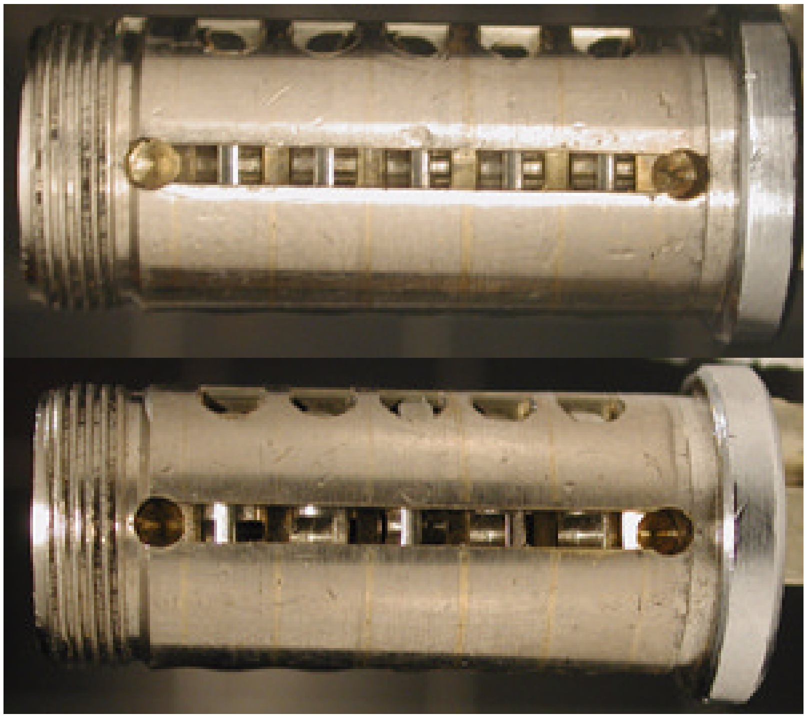

Figure LSS+1710 The sidebar has a vertical gate that must precisely align with the protrusions on each finger pin, as shown on the left. The pins on the right are not elevated and rotated to the correct position, preventing the sidebar from retracting into the plug.

A modification of the Primus concept was introduced by Schlage, based upon the Bo Widen patents (**4715717, 4756177, 4815307 and 5809816(187)**) in 1998. The key is unique in this system, having an undercut profile groove at one side surface and a corresponding profile tongue with a downward projecting end, which fills up the undercut portion of the key profile groove upon insertion into the keyway. See the discussion regarding the Everest cylinder in Chapters 6, 8, and 29.

17_6.1.5.1 Security of the Primus

The security of the Primus and Assa locks is premised upon the high-tolerance pin tumbler set, coupled with the second locking mechanism provided by the sidebar. Schlage and Assa chose a different approach to their sidebar designs than other manufacturers. They opted to split the action of the traditional pins and the sidebar to provide for a double independent locking system. Medeco, in contrast, linked the action of raising the conventional pin tumbler and its rotation in one mechanical

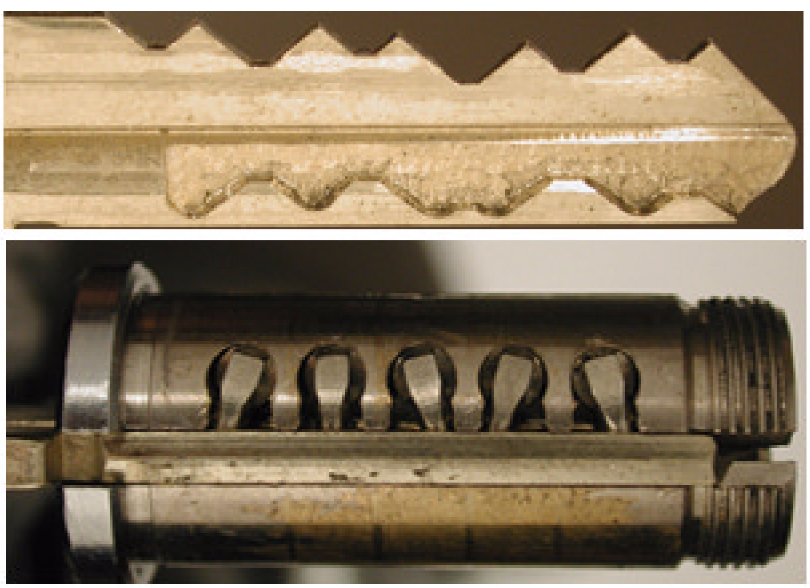
movement.

Schlage and Assa offer an excellent approach to key control, but security suffers for two fundamental reasons. The side millings for the sidebar pins can be duplicated on a precision-milling machine, and entire systems can potentially be compromised by obtaining the sidebar codes that are utilized within that geographic area or by the same locksmith.

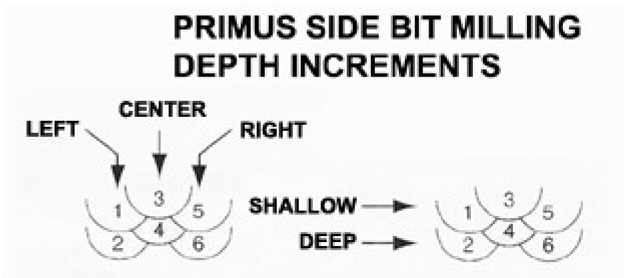
17_6.1.5.1.1 Sidebar Codes

Generally, each locksmith or major distributor is given a unique sidebar combination for all locks delivered for resale. Although Assa and Schlage carefully monitor these codes to assure that no reuse occurs within a given geographic area, the problem of security is inherent in the overall scheme. Both Schlage and Assa has established five levels of security to control distribution of blank keys. The lowest level of security as defined by Schlage is Level One. This allows for Primus to be stocked locally, with standard side bit millings. Keys can also be generated at the local level. The highest level, Level Four, the factory maints control of all Primus key systems. SBM are assigned by one of two methods: either the side bit milling (SBM) will be assigned to a customer by time zone, or nationally. The end user or the factory can control keys and keying. If needed, all keys can be zero bitted and combinated locally.

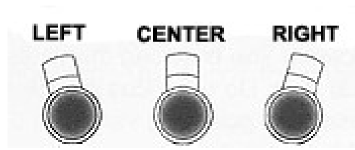
Assa defined levels of security are:



- **Gamma: Regionally shared, locksmith restricted, controlled and serviced;**
- **Beta: Statewide exclusive, locksmith restricted, controlled, and serviced;**
- **Delta: Nationally exclusive, distributor restricted and controlled. Serviced by distributor or locksmith;**
- **Alpha: Regional or national exclusive, end-user controlled and serviced;**
- **Factory: Controlled and serviced by Assa.**



In Gamma and Delta levels, all customers of a given locksmith will have the same sidebar codes. The locksmith will be issued blank keys, all precut with identical sidebar millings. A customer could potentially order locks with specific codes, or keys could inadvertently be cut for one customer which could be



modified or re-cut to codes for a different customer. If the keyways are the same, then no increase in security has been attained using the sidebar insofar as unauthorized key duplication is concerned.

Primus utilizes five finger-pins with three different orientations (left, center, right).
As shown in the diagram, there are six defined depths, but only four actual variations.
The depths are denoted as 1,2,3,4,5,6. Left rotation is pointing toward the bow; right toward the tip of the key (from the bottom of the plug). The deep cuts are 2 (left) and 6 (right), shallow cuts 1 (left) and 5 (right), and center cuts 4 (deep) and 3 (shallow). All side bit millings must be read in reference to the **primary bittings** and their center points. Remember that for each angle, there are only two depths: deep and shallow. Bittings can be visually read with practice. Note also that center cuts are shallower than left or right cuts, and their depth is one half increment between equivalent left and right cuts.

There are restrictions as to the level of finger-pins that can be utilized with different depth cuts in the primary bitting of the key. The photograph shows the relationship between rotation angle and side millings. In this lock, the difference between left, center, and right angles are quite pronounced.

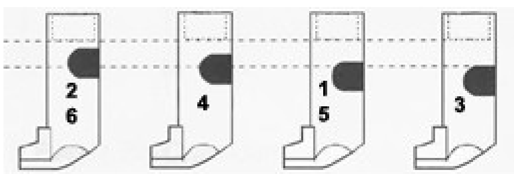


Figure LSS+1711 The code for the above key is 23624. There are a total of four actual depth increments, as shown in the representation of finger pins. Reading of the position of the finger pins is from their base.

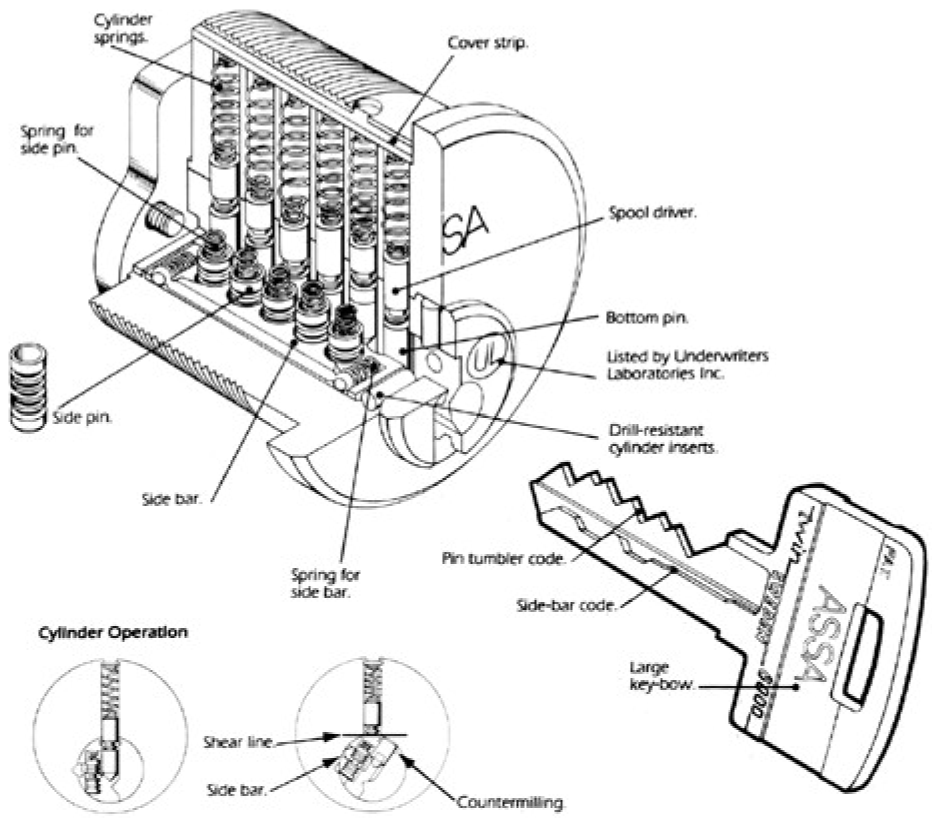
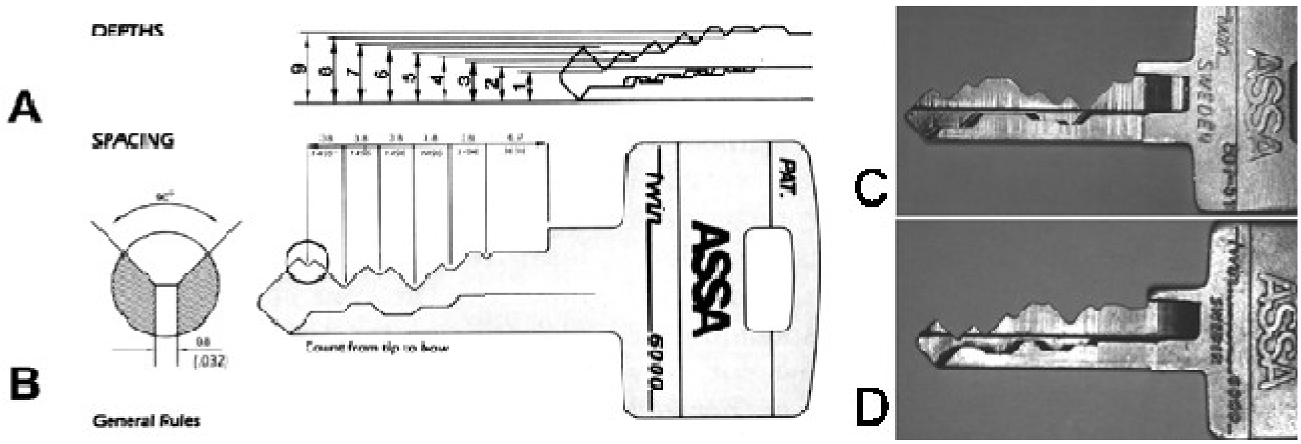
17_6.1.5.1.2 Picking

Another security issue raised by the Assa and Primus approach involves resistance to picking and impressioning. A cursory analysis of these designs would lead one to believe that the locks are highly resistant to forms of surreptitious attack. This is true if one **only** considers penetration by an intruder walking up to the lock without prior intelligence gathering. Attempting to bypass the lock by picking or impressioning without added assistance in the form of precut keys having the same sidebar code and keyway will present significant difficulty.

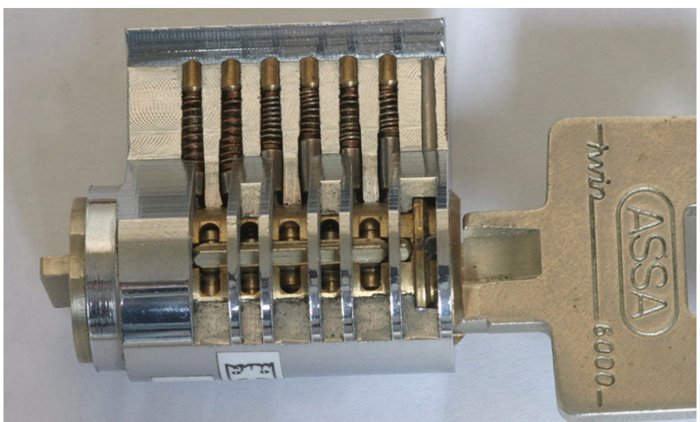


However, if one has obtained keys with the identical sidebar code and primary keyway in advance, then the lock can become substantially easier to pick or impression. The precut key is made into a torque wrench by cutting away the top bitting area. This will remove the sidebar as a security device. Then, we are left with a standard high-tolerance pin tumbler lock.

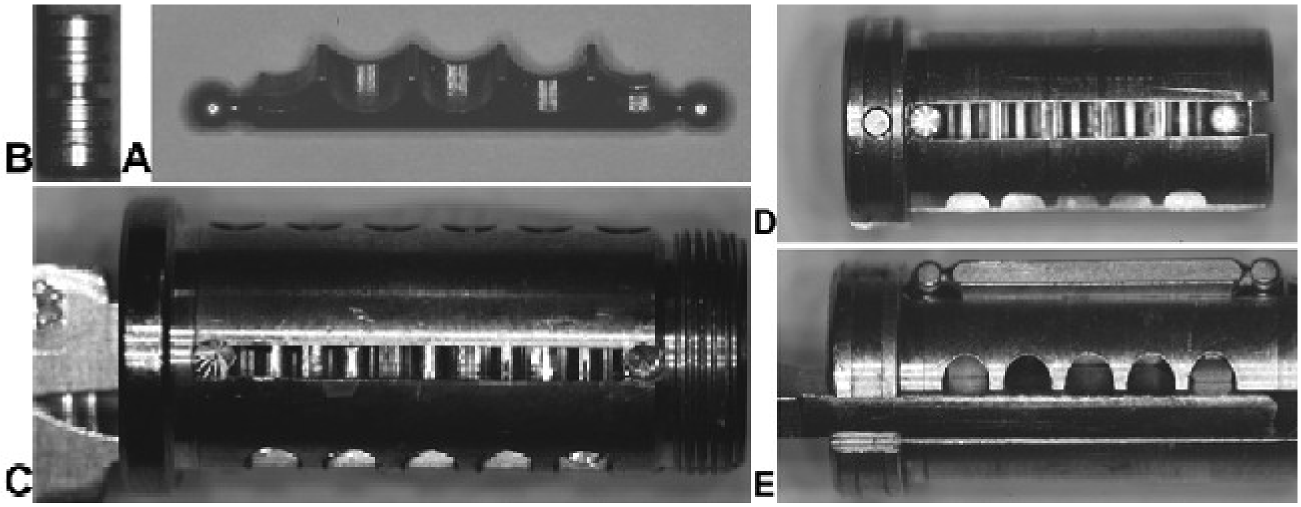
The operation of both the Primus and Assa requires raising the conventional tumblers to shear line and the five finger-pins to align in order that the sidebar may retract. Each set of pins operates independently. The plug will only turn when both sets of pins are set properly.



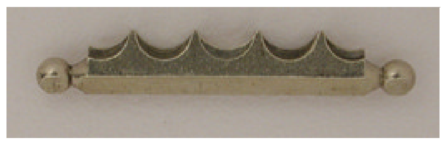
17_6.1.5.2   Assa Sidebar Design



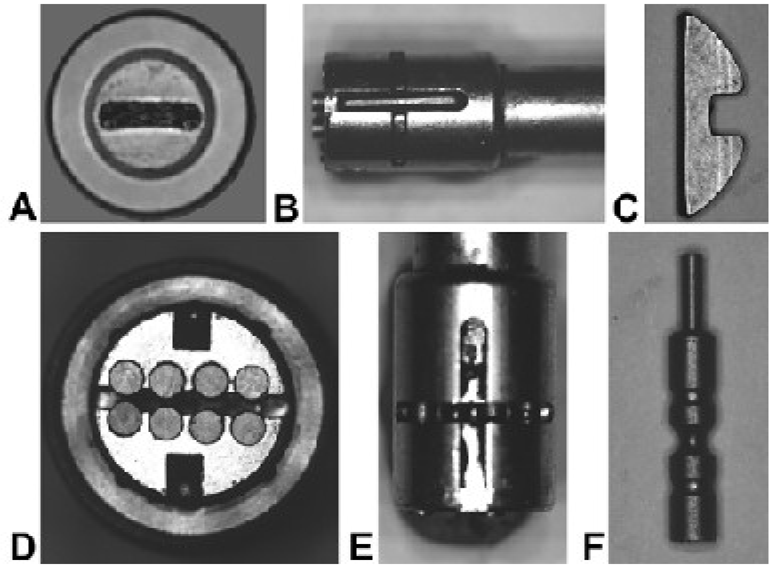
Assa has taken a different design approach to that of Primus. Whereas the contour of the Primus sidebar is uniform among all locks, the Assa sidebar **matches** a particular milling pattern on the key. All of the sidebar tumblers or fingers are identical in the Assa.



Schlage requires that the different finger-pins be raised to the proper level and rotated in order to allow the sidebar to clear. Assa mills a unique sidebar, with projections in different vertical positions to correspond with detents in the middle of the sidebar tumblers. Each tumbler is raised according to the millings on the side of the key, to align the detent with the sidebar projection. If the correct sidebar-milling pattern is present on the key, the tumblers will be raised to proper alignment. There is a detent or slot to receive each of the individual sidebar projections.

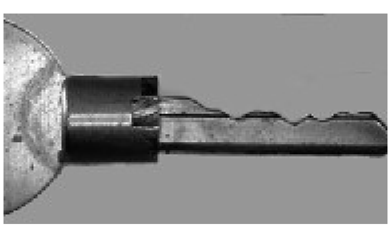


There are five side pins, each with five different depths, for a theoretical 3,125 combinations. Not all finger-pin positions are available for all depth cuts, and there are actually 1402 useable pins per sidebar side (the sidebar can be reversed within a cylinder for another 1402 codes). See the discussion in chapter 31 regarding the Assa V10 7000 cylinder utilized in high security master key systems.



17_6.1.6 Chicago Tubar

The **Tubar**, manufactured by Chicago Lock, is a modified axial mechanism incorporating two sidebars. Utilized primarily on vending machines, it features eight pins (two rows of four) which must be aligned for the sidebars to retract. A notch in each of the tumblers provides a gate. An examination of the keyway, using an otoscope, will reveal grooves on the side of each pin. There are usually three false gates per pin. Four depth increments are available for each pin.



Exploded views 1, 2, 3.

17_6.1.7 Briggs and Stratton Sidebar

The Briggs and Stratton sidebar design was invented in 1935. It utilizes a wafer mechanism with a secondary locking sidebar. The lock is fully described in **Chapter 23**.

17_6.2 Storage Locker

The American Locker Company has produced a hybrid pin tumbler lock that has been extremely popular for use in storage containers during the past forty years. It combines a conventional pin tumbler mechanism with a seven-pin axial design. This combination offers high pick resistance and makes keys almost impossible to duplicate.

Section 7: High-Security

17_7.1 DOM IX Series

The DOM series IX is a dimple pin tumbler high-security lock that features a split key for dual control. The key has bittings on both lateral sides, so insertion may be in either vertical orientation. This lock is ideal for safe-deposit, vault, and other applications where two keys are required to be simultaneously inserted to actuate the bolt. A single key, which is simply a composite of the two halves, may also be utilized. This is a rather novel approach to dual-key control and warrants consideration in such applications.

Although the mechanism resembles other dimple locks in some respects, a number of sophisticated and unique features have been incorporated. The lock is essentially a nine-pin tumbler device; there are two rows of tumblers that interact with the lateral surface of the key. In addition, there are added side-pins for increased security.

The lock achieves extremely precise shear line tolerance by incorporating an oblong-shaped pin set. The tumblers are keyed so that they fit into the chambers with a precise orientation. This is required because each tumbler surface is cut at an angle, which equals the radius angle of the plug. The top surfaces of the lower pins (those making actual contact with the bitting of the key) are convex in shape, to follow the rotational curve of the plug. The bottom surface of each top pin is concave and matches exactly the corresponding convex lower pin. Lower pin tumblers are uniquely shaped, with angular ramps making contact with the bitting. The dimension of the ramp determines the depth of cut.

A floating steel ball bearing is pressed into the surface of the key in the last tumbler position toward the tip. This bearing

actually is free to move up or down, depending upon the way in which the key is inserted. The bearing will make picking extremely difficult. As the key is inserted, a protruding pin permanently pressed into the bottom side of the plug will force the bearing upward within the key. A corresponding small floating security pin in the tenth chamber is located precisely above the bearing that is lifted to shear line with the proper key. A special top pin with a pointed tip will enter this security pin chamber if the bearing is not present. The driver will block any rotation of the plug.

This technique for immobilizing the plug is extremely clever. In order to pick this lock, the security pin must always be raised above shear line. Normal picking procedures will not accomplish this. Several specially designed mushroom and spool tumblers are also utilized to further frustrate bypass.

CHAPTER EIGHTEEN: CONVENTIONAL DESIGNS

Electromechanical Locks

Master Exhibit Summary

EMHART
MAS-HAMILTON X-07

18_1.0 Introduction

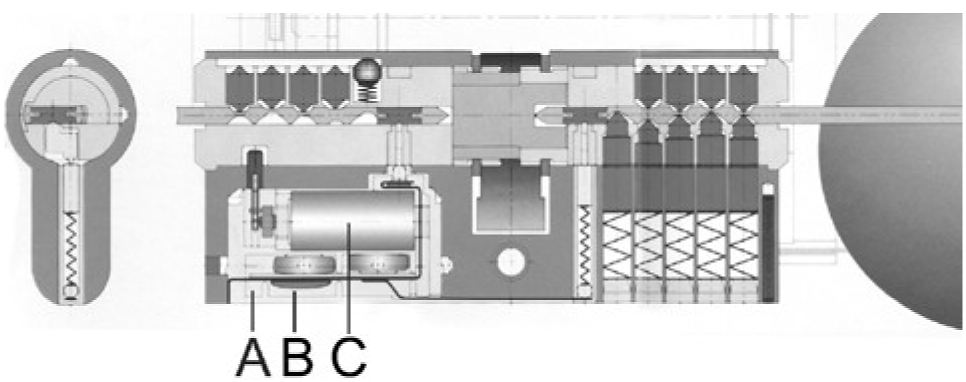
Electromechanical locks incorporate electronic circuitry into traditional mechanical locking devices for enhanced security and access control. This chapter will examine some of the systems that utilize this hybrid technology. There have been many examples of locking devices operated by an integration of electronic and mechanical means. They are predominantly used in safes and vaults (4901545, **5061923(188)**, **4745784(189)**), access control applications (4866962, 4891636, **4868559(190)**, 5094093,

4684945, **4712398(191)**, 4766433), and in the lodging industry (4887445, 5020345, **GB 2174452A(192)**, **GB 2158870A(193)**, 4802353). See also (5092148), for a pry-proof computerized mechanical lock.

Within the past five years, many companies have introduced mechanical locks with integrated microprocessor logic. These combine the action of a conventional or hybrid locking mechanism with intelligence and memory provided by computer control. See Chapter 21 for a discussion of smart keys and locks.

18_1.1 Survey of Electromechanical Locks

Abloy, Medeco, LaGard, Sargent & Greenleaf, TrioVing, Ilco-Unican, DOM, Evva, Chubb, Union, and many other manufacturers have introduced electromechanical locking systems. Many vendors provide direct replacement of conventional locks with the more sophisticated systems. This practice is especially prevalent in the hotel industry and for safes.

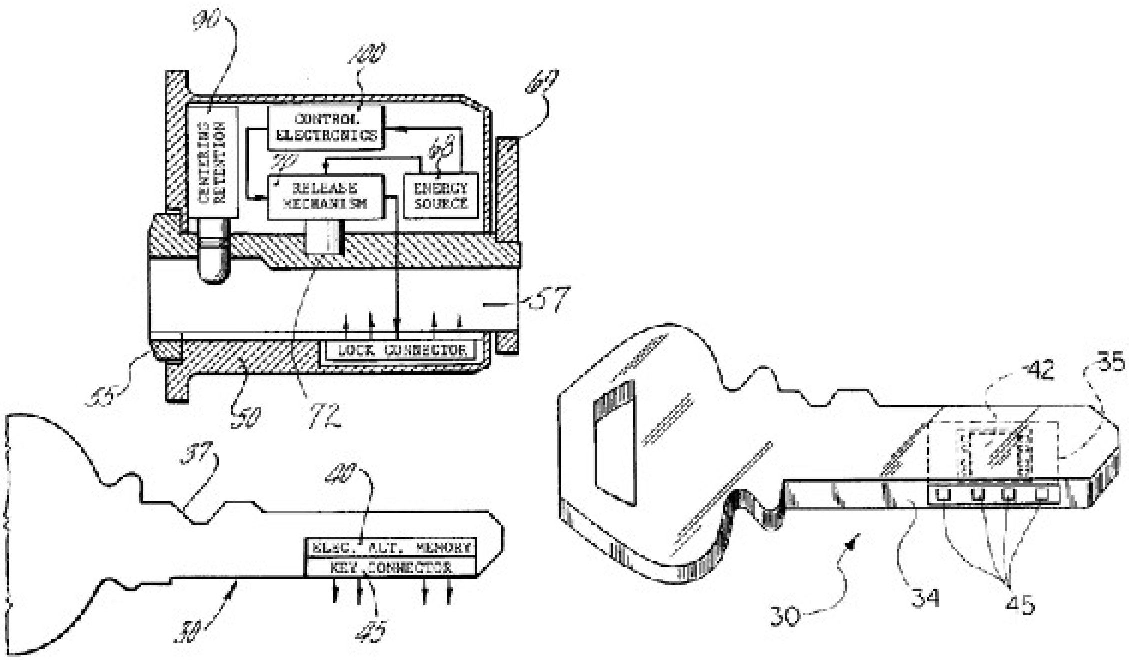


Several patents had been granted for locks that incorporated some form of electronics prior to the introduction of the X-07. All of these can be distinguished from the Mas-Hamilton design.

In 1988, Gartner (LaGard) patented a conventional combination lock with a means to sense when the correct combination was entered in order to release a solenoid (**4745784(194)**). Several other related inventions disclosed similar prior art sensing technology (3968667, 3758734, 3702070, and 4038846). Bacon, in 1990, was granted a patent (4901545) for an electromechanical locking device completely contained within a doorknob. This invention integrated an access code device with a traditional cylinder. When the correct sequence of numbers is input, a solenoid would release a locking pin, allowing the conventional mechanism to actuate the bolt.

Other similar electronic systems have been integrated into conventional locking devices, by Ben-Asher in 1990 (5094093), Clarkson in 1987 (**4712398(195)**), by Pinnow in 1989 (**4868559(196)**), and Rieker in 1990 (4891636). The Rieker invention (4891636) described an electronic keylock system comprised of a key with a precision resistance and a receiver for decoding the key. An analog-to-digital converter provided information for comparison with a programmable array logic to verify the insertion of the correct key. This system was designed for use on point-of-sale terminals and other commercial applications.

In 1989, Pinnow received a patent (**4868559(197)**) for a security system which employed an optical key-shaped reader to photoelectrically derive an electrical signal from a shape characteristic of a key. The system provided heightened security over standard key- operated devices and was designed for use in automobiles. The technique can offer higher security than the VATS resistor pellet sensing system used by vehicle manufacturers. See **Chapter 23** for a discussion of the VATS system.



Yale Security Products patented an electronic keylock in 1989 (4866962) that provided for a mechanically actuated reading device. Two separate reading elements within the lock could determine key coding based upon grooves or notches in the blade of the bitting surface.

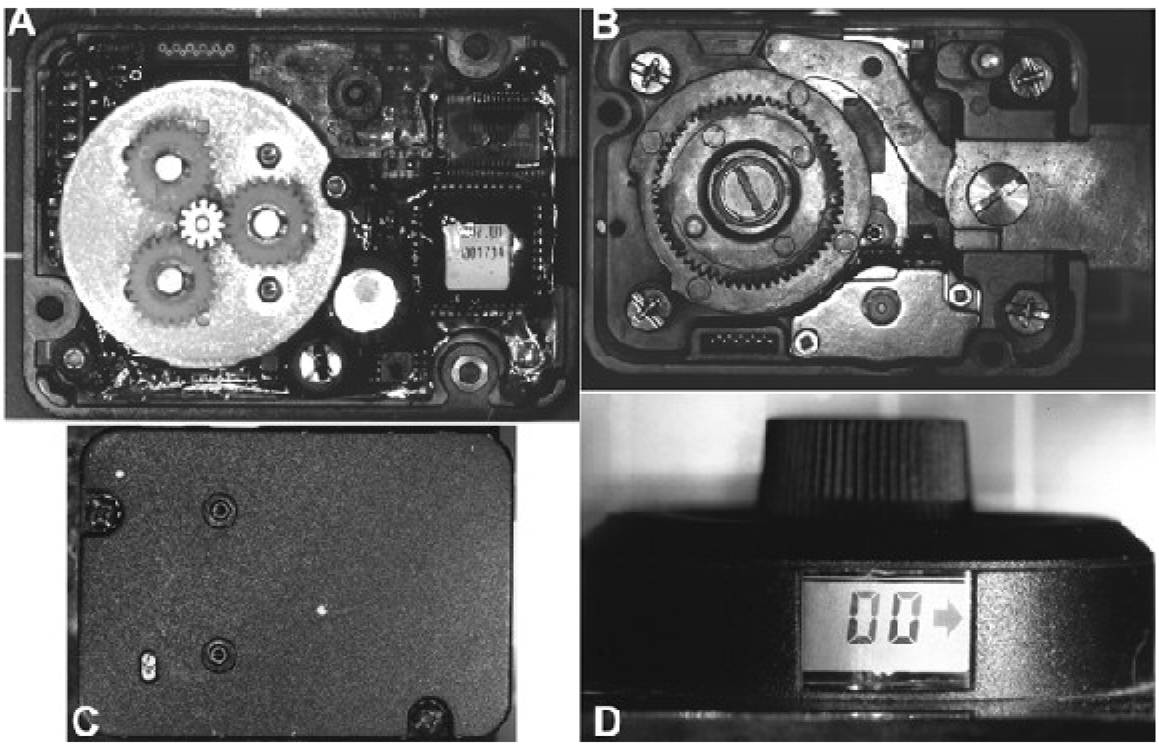
18_1.2 Emhart Electronic Locking System

Clarkson patented an integrated locking system in 1987 (**4712398(198)**) that was comprised of a pin tumbler cylinder containing an EEPROM memory device for storing codes. A matching

programmable memory chip was contained within the bitting of the key. Upon insertion of the key and a verification of the codes, an electrically controlled release pin would allow the plug to rotate. This lock is somewhat different to those described in **Chapter 20**, relating to induced fields for the transfer of information from the key. The Clarkson device relied upon physical contact points on the bottom of the key for the exchange of information.

Exploded views 1, 2.

18_2.0 Access Control



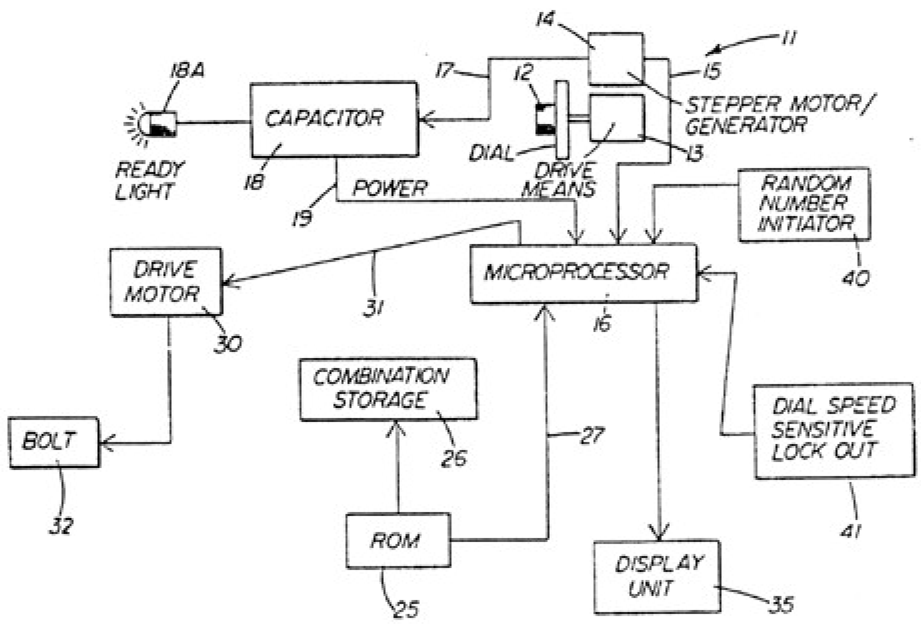
Many locks combine mechanical and electronic systems for use in access control. They are especially popular in hotels. Typically, these devices utilize keypads, magnetically coded cards, smart cards, and proximity sensors in combination with conventional cylinders or lock sets. The units can be self-contained battery operated or connected to a central computer system for enhanced audit and control functions.

Intelock Corporation (4802353), Ilco-Unican, and many other manufacturers produce an access control system for use in the lodging industry. These provide for sophisticated security and auditing functions and are essential due to issues of liability inherent in the hotel environment. The Ilco system, for example,

will provide detailed information regarding each time the lock is accessed. Automatic lockout can be accomplished so that access rights “expire” upon checkout date and time. The lock can be interrogated by security staff for a complete transaction summary. It can be reprogrammed upon demand or automatically by the next guest to insert a card having a different code.

18_3.0 Mas-Hamilton X-07 Electronic Combination Lock

The Mas Hamilton X-07 was the first self-powered fully computerized high-security electronic combination lock (**5061923(199)**) for a safe or vault. It was introduced in 1992 and was the result of intensive research and development by some of the foremost lock experts in the United States. The design integrates advanced electronic features with sophisticated mechanics to provide the highest level of security in a true 1,000,000 permutation keyless lock.



The stepper motor also provides input signals in the form of code sequences to a microprocessor. It processes the signals to initiate the operation of a drive motor to release a lock bolt once the proper combination has been entered. A read-only memory

(ROM) determines the correct combination and provides the data for a comparison with that entered by the user. As each dialing sequence is begun, a random code generator provides a different starting position in the sequence, so that surveillance techniques cannot be employed to derive the combination.

A speed-sensitive lockout device that also controls the microprocessor thwarts robot dialing. This effectively prevents any attempt at auto-manipulation. An on-board generator and stepper motor, actuated by the turning motion of the dial, powers the microprocessor, solenoid, and liquid crystal display. Energy is stored in super capacitors contained within the lock. The system can theoretically remain idle for many years without concern for the status of batteries found in other similar designs.

Once the dial is initially turned, the LCD will display the dial position and direction. To open the lock to the factory combination (50-25-50), the dial is rotated to the left, stopping at 50; then rotated to the right, stopping at 25; then again rotated to the left, stopping at 50. The dial is then turned to the right, until OP (open) is displayed, causing the bolt to be retracted. The lock is extremely user friendly. In contrast to conventional combination locks, the user need not be concerned about counting the number of turns between numbers.

The lock offers many sophisticated features, including audit trail, invalid attempt logging and lockout, dual control, supervisory control, and high-security against manipulation and surreptitious entry. The lock was the first to be accepted by the GSA for government security containers. See **Chapter 34** for a detailed discussion of security options incorporated within the X-07.

CHAPTER NINETEEN: MAGNETISM

Magnetic Locks

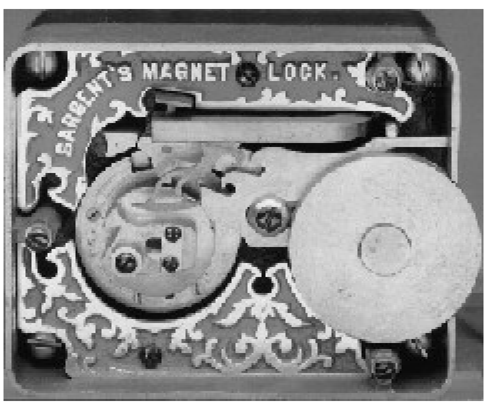
GIBRALTER

Master Exhibit Summary



magnetic lock
Figure 19-12 Gibralter magnetic lock

19_1.1 Introduction

This chapter provides information about locks that employ magnetic fields for actuating, setting, rotating, or moving tumblers in order to create a shear line. Included are cylinder locks that replicate the action of conventional pin tumblers, and magnetic card locks that use barium ferrite or other materials to allow the placement of magnetic spots throughout the surface. In some cases, high-security, versatility, and reliability have been attained using magnetic pins, discs, and wafers. In others, manufacturers have represented levels of security that simply do not exist.

19_1.2 Magnetism and Locks

Lock manufacturers have relied upon many mechanical design approaches in utilizing magnetic fields to control internal mechanisms. The theory of magnetism, however, is relatively simple when applied to locks and their construction.

Essentially, all mechanical locks that utilize magnetics will function based upon two fundamental laws of physics: **opposite fields attract and like fields repel**. Every design will incorporate one or both of these principles. These basic concepts have spawned extremely clever designs.

19_1.3 Bypass of Magnetic Locks

The author has conducted forensic examinations, evaluated many magnetic locks throughout the world, and found that some devices

are extremely easy to compromise. Certain magnetic locks can be rapidly and surreptitiously decoded through a variety of techniques. For that reason, the author cautions the reader that many systems are simply access control devices that provide no significant measure of security.

In some cases, it has been possible to surreptitiously produce, duplicate, and decode change keys. In others, it was possible to decode locks and then derive and produce master keys for entire systems. The result was the total compromise of major commercial facilities. The problem with many magnetic locks is the ability to decode and compromise both individual and master key codes quickly, silently, and without taking the lock apart.

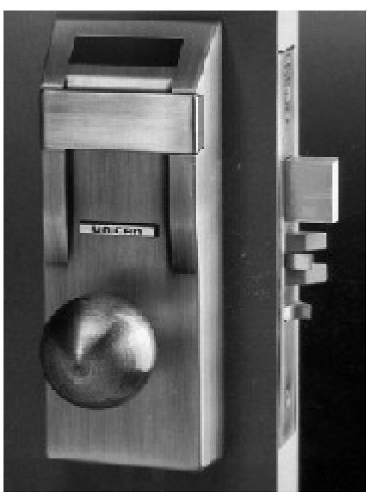
The author has developed extremely effective methods of surreptitiously reading magnetic key codes in seconds, from many locks, without fear of detection and without trace. This information can then be rapidly translated to produce keys for individual locks and for all locks in a system. Some magnetic locks, especially those used in the hotel industry, are particularly vulnerable to surreptitious bypass. Certain magnetic-based locks, particularly those manufactured by Chubb for use by the Home Secretary in the prison system in England, and the EVVA (Austrian) lock (also manufactured by Ikon of Germany and Ankerslot of Holland), are extremely secure. While others may **represent** high levels of security, they are, in the opinion of the author, merely access control devices offering very low protection against surreptitious attack.

19_1.3.1 Materials for Decoding Magnetic Locks

Several technologies can be utilized for decoding active locking components within a magnetic lock. These include:

- **Special films for observing the location of domains on BFV cards;**
- **Spray powder for viewing the position of magnetic spots and for reading magnetic stripes embedded within plastic cards;**
- **Recording medium for directly capturing and decoding the placement of magnetic pins within a lock, so that a key can be generated based upon such information;**
- **Gauss meter and Hall-effect probe, for sensing the position and polarity of magnetic fields;**

- **Field disturbance generators for reorienting magnetic pins;**
- **Probe and audio sensing for testing the polarity of each magnetic domains.**

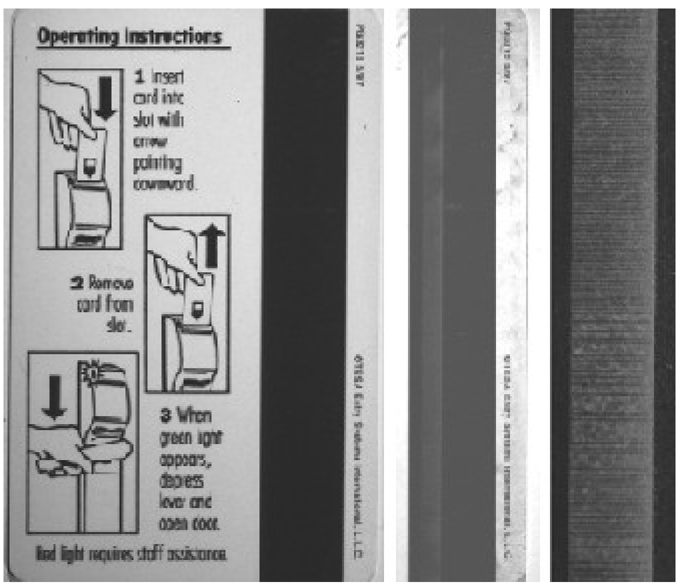


Chapter 31 provides additional information regarding decoding techniques.

19_1.4 Magnetic Card Locks

Magnetic card locks fall into two primary design categories and are based upon whether **physical position** (barium ferrite vinyl based cards) or the sensing of **data** (magnetic stripe cards) is utilized as the security technology.

19_1.4.1 Magnetic Stripes



The first classification utilizes plastic cards with magnetic stripes that are used for the storage and transmission of information in the form of binary data. Magnetic stripe cards resemble credit cards. They have a strip of magnetic material embedded within the plastic that is equivalent to bonding a piece of audio recording tape to the surface. The stripes are electronically encoded with a number of binary data bits contained within tracks. While most credit cards have three separate tracks that hold different card holder information, cards encoded for locks generally have only one readable track.

The data, created by magnetic flux reversals, can be observed under the microscope as a series of very small parallel lines

having changes in spacing and polarity. Each line is a bit. As the card is moved across a read head, a coil detects changes in polarity. This creates a tiny voltage that is amplified, squared (turned into a square wave), and processed. The series (or stream) of bits combine to form bytes of information that can be read and compared to data stored within the non-volatile memory of the lock.

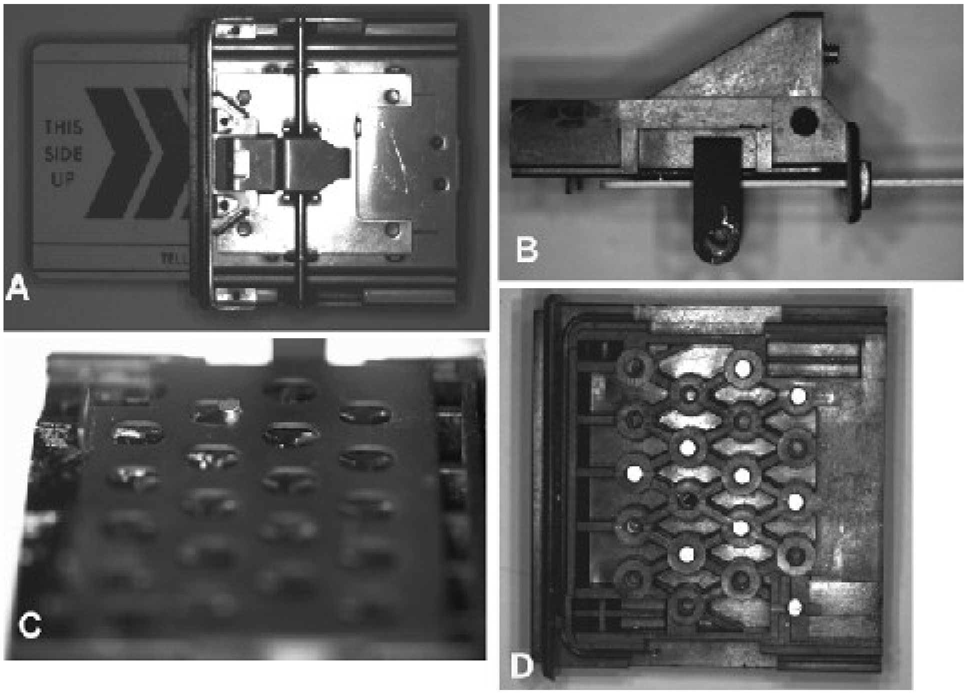
Some cards are encoded following the International Standards Organization (ISO) standards for magnetic information. Data may be placed on the cards in low or high-density formats. Other lock companies have developed their own secure, encrypted formats that may be difficult to compromise.

Card encoders/decoders that will read both low and high-density formats for all three tracks are available commercially or can be easily constructed. One industry leader in the production of readers is **American Magnetics** in Los Angeles, California.

19_1.4.2 Barium Ferrite Vinyl Cards

BFV is a relatively hard material in comparison with soft ferrite that is used as antenna cores or forms and easily magnetized. Barium ferrite cards have magnetized spots or **domains** located in various positions across the surface. They will coincide with the location of magnetic pins within a lock. Generally, all magnetic card locks that employ floating pins utilize this technology.

BFV is a material that is capable of being magnetized and retaining the information over long periods of time. Barium carbonate and iron oxide are mixed to produce the magnetic medium. The material must have a high **coercivity.** This means the ability to resist attempts to change or demagnify unless high Orsted levels are attained (up to 9,000). It is important that average strength magnets will have no effect on data encoded on BFV cards.



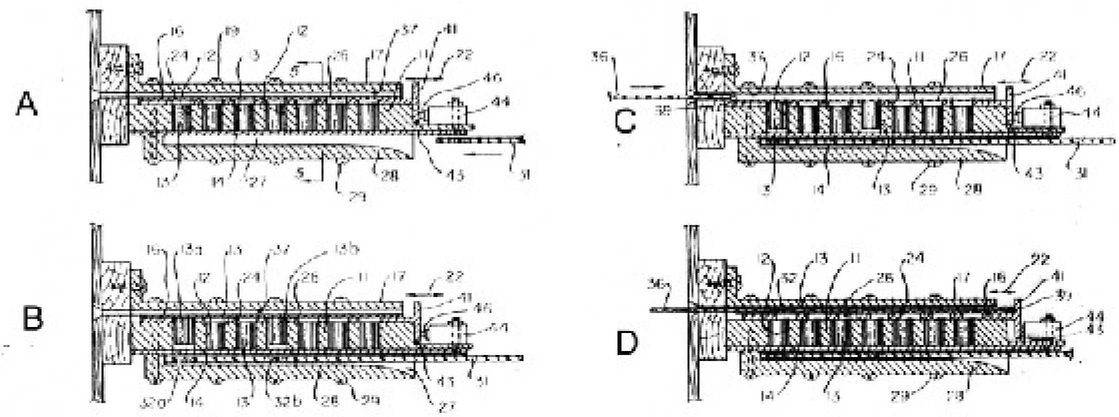
Characteristics of BFV material have significantly changed during the last twenty years. 3M Magnetic Products has done a great deal of research and development with flexible magnetic materials including BFV. When they began examining the technology, they found that rubber-based materials were common, with a magnetic sensitivity of about ½ gauss.

A BFV-based lock requires that the magnetic card material have fields of sufficient strength to be capable of repelling internal magnetic pins so that they can be moved above the shear line.

All BFV-based cards can be decoded using a variety of techniques. The result is the ability to easily decode the information contained on the card as to the number of magnetic positions and their polarity. Once that data is known, virtually any locking system using this technology can be compromised.

19_1.5 Showa Magnetic Card Lock

Showa Lock Company (Japan) produces a card lock similar in principle to the Corkey system (Hong Kong) and Schulte-Schlagbaum(Germany) but with several distinct differences. The Showa system creates a shear line as in a conventional pin tumbler lock, with free-floating magnetic pins. These are allowed to vertically travel between a moveable platen and the body of the lock.



An encoded barium ferrite card is inserted into the platen, with magnetized domains placed to correspond to the pins. The proper card will cause all pins to be repelled or lifted upwards, so that the platen is free to move. As with the Corkey system, the security of this lock rests in the number of pins, their location, and individual polarity.

This lock can be easily compromised due to its construction, number of pins, strength of the magnetic field required in the barium ferrite card, and spacing between pins.

19_1.6 Corkey and Schulte-Schlagbaum Lock

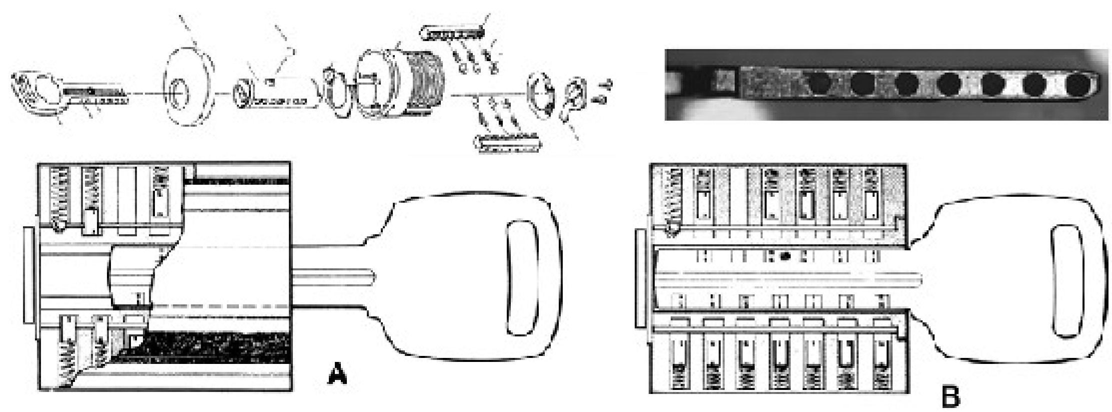
Corkey (Hong Kong) and Schulte-Schlagbaum (Germany) produce a series of patented magnetic card locks for the hotel industry that can be easily programmed in the field (**3611763(200)**, **3834197(201)**, **4133194(202)**, **4676083(203)**, and German patent 0-276-444-A1). Corkey has developed a system based upon the random placement of small cylindrical magnets in any of 45 chambers, within each lock.

These free-floating pins perform the same function as conventional pin tumblers. The magnetic field of corresponding magnetized domains on a removable barium ferrite card, rather than the bitting of a key, control the movement of pins.

As with the Showa devices, this lock contains a sliding card platen. It is linked to the strike mechanism within the door and cannot be moved to a locked or unlocked position unless all magnetic pins are raised above shear line. The shear line physically separates the platen from the body of the lock. When the correct magnetic card is inserted, the pins are repulsed and forced upward so that the platen is free to move. Corkey has incorporated certain anti-decoding features to frustrate compromise. However, these measures are not totally effective. The security of the Corkey system relies upon knowing how many magnetic pins are contained within any given lock, their position, and the polarity of each.

19_1.7 Magnetic Pin Tumbler Locks

Several manufacturers produce cylinder locks utilizing moveable rotating or sliding magnetic pins. Some designs emulate traditional pin tumbler mechanisms, while others combine sidebar technology for high-security. In all cases, magnets are attracted or repelled in order to control the rotation of a plug.



19_1.7.1 Miwa and Ankerslot (Netherlands)

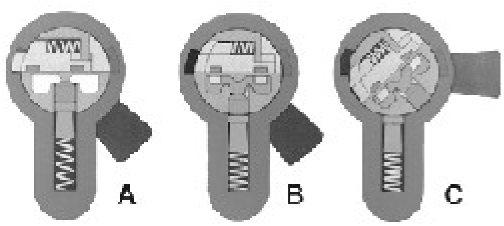
The Miwa Lock Company (Japan) and Ankerslot (Netherlands) manufacture two primary series of magnetically based locks. Although they are not well known or recognized in the United

States, the company has been in business since 1935 and is one of the largest lock manufacturers in Japan.

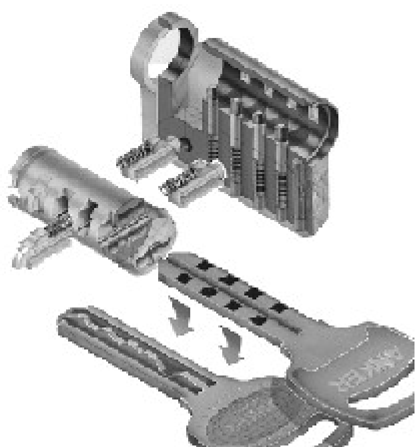
19_1.7.1.1 Series EC

The **Miwa EC** is a magnetic cylinder that can be bypassed with limited technical ability and technology. The security of this lock as well as the Corkey, Showa, and others, is based upon two criteria: **the polarity and location of each magnetic pin or spot.** In the Miwa EC and to a lesser extent in the Corkey, if one knows these two pieces of information, the lock can be decoded and opened.

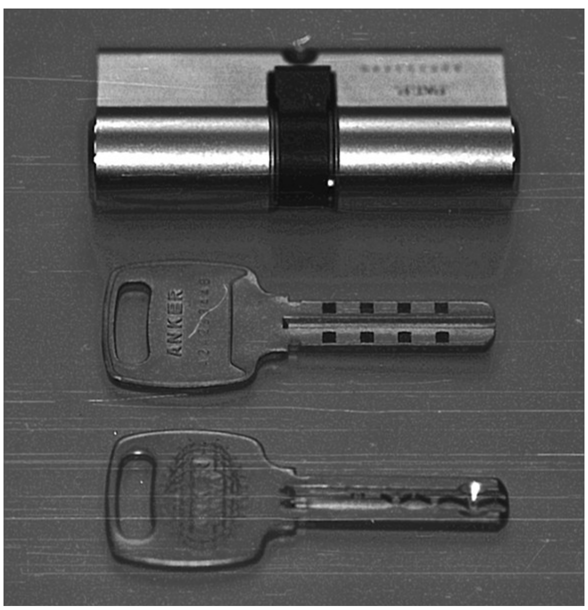
19_1.7.1.1.1 The Key



There are seven magnetic pins impressed on each side of the blade where the bitting would normally appear in a conventional key. They will interact with corresponding magnetic tumblers within the lock. There is a lateral channel and corresponding ridge running along both sides of the key to simulate a keyway. The key is not reversible and can only be inserted in one orientation. There is also a dimple on one side of the key as part of the keyway configuration. The dimple mates with an internal ball bearing that retains the key within the keyway once the plug is rotated. The position of this bearing can be altered during manufacture to create different keyway series.



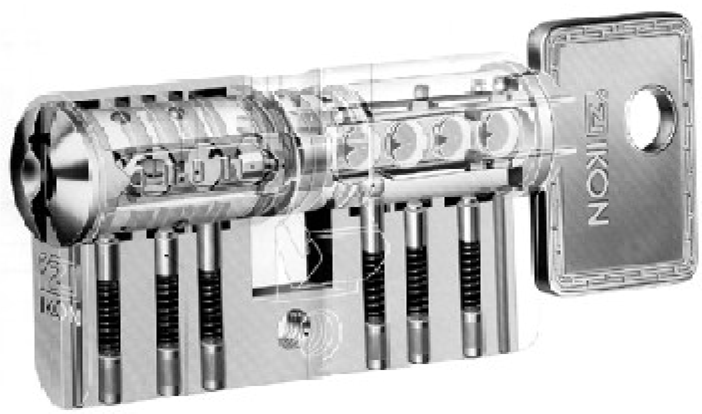
Although there are fourteen chambers within the lock, only seven of these positions are usually filled. A magnetic tumbler with either polarity may be utilized in any position. Corresponding magnets are placed in holes in the blank key. The unused holes are filled with neutral pins so that the position of magnets

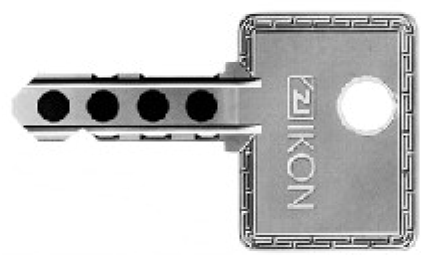


cannot be readily determined. Keys are assembled by the locksmith by placing magnets in the proper pin locations and blank pins in the remaining holes. The key is then crimped to retain all inserts.

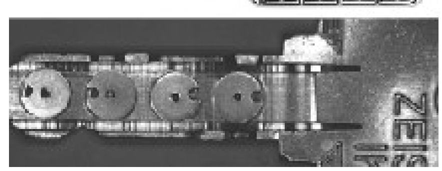
19_1.7.1.2 Miwa High-Security Lock (3800)

The Miwa high-security lock (also manufactured by Ankerslot, Holland) is the competing product with the EVVA and Chubb magnetic designs. It operates on a slightly different principle than does their EC series, although it still relies upon attraction and repulsion between magnets within the key and the tumblers within the lock.





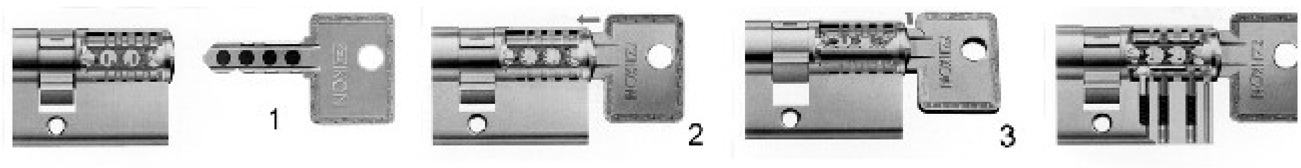
The 3800 is more complex than the EC in its operation. There are eight magnets placed in two rows of four on each side of the key. These inset magnets are magnetized in quadrants, so only a portion of the magnet acts in concert with the four pairs of sliding magnetic tumblers. The action of the field is a great deal more precise than encountered with the EC version. Four conventional pin tumblers ride in the center channel of the reverse side of the key for added security. Thus, the inner cylinder is double locked: vertically with pin tumblers and horizontally with sliding magnets.



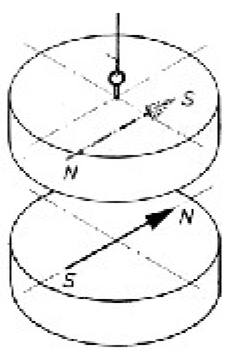
19_1.7.2 Evva Magnetic Code System (MCS)

Evva (Austria) and Ikon (Germany) make a high-security dual-sidebar magnetic lock incorporating eight rotating discs that is essentially pickproof. Evva uses rare earth Samarium Cobalt (SmCo) magnets that have a high coercivity requiring over 6,000 gauss to reorient their domains. A Swiss company owns the process that is used to produce the material, known as UGIMAG.

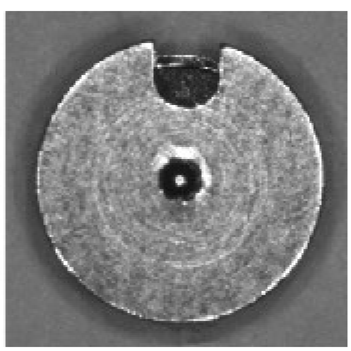
The Evva MCS lock features three independent locking systems, presenting an extremely high resistance to surreptitious attack. The mechanism offers 2.9 times 10^{26} differs, making it ideal for large installations requiring complex master keying.



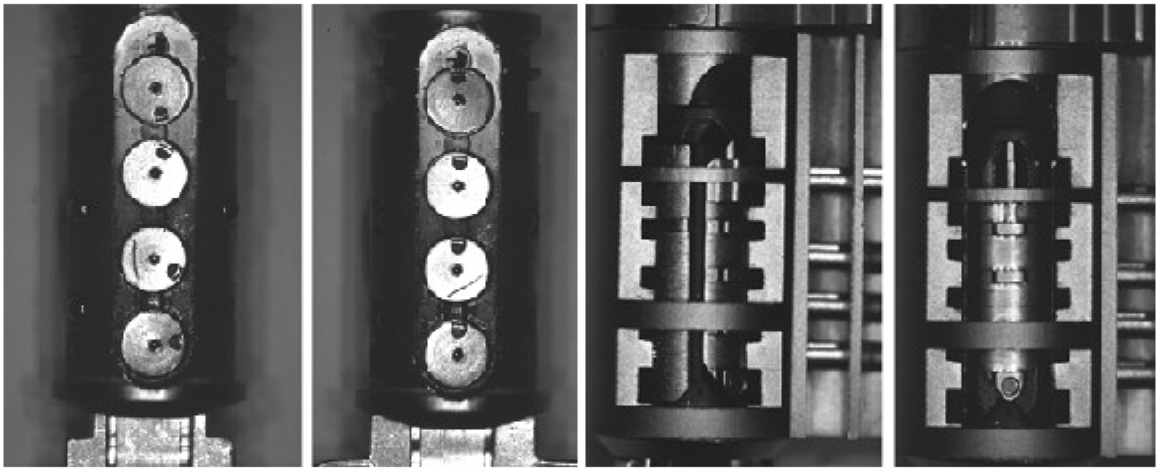
There are eight rotating magnetic discs within the plug- four on each side of the keyway. They correspond with magnets embedded into the bitting surface of the key. This will allow eight different field orientations per magnet, or 8^8 permutations. There are also side-wards in the keyway that provide another 768 permutations.



Evva and Ikon use a process that allows them to magnetize each of

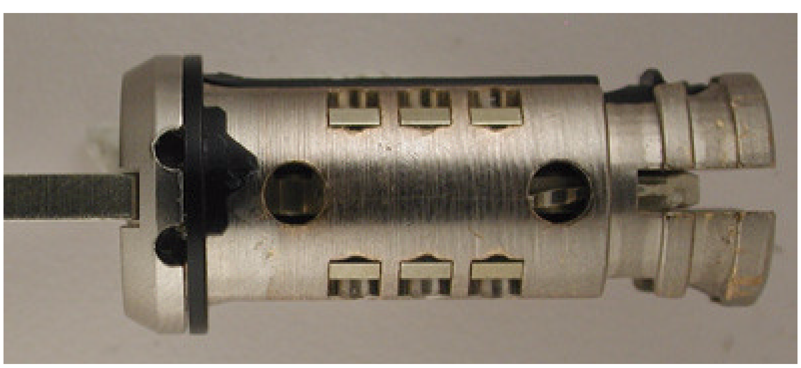


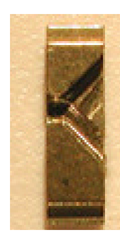
the discs with eight distinct orientations, much like a piece of pie sliced into eight sections. Thus, each magnet is polarity-coded at a different rotational position in 45º increments.



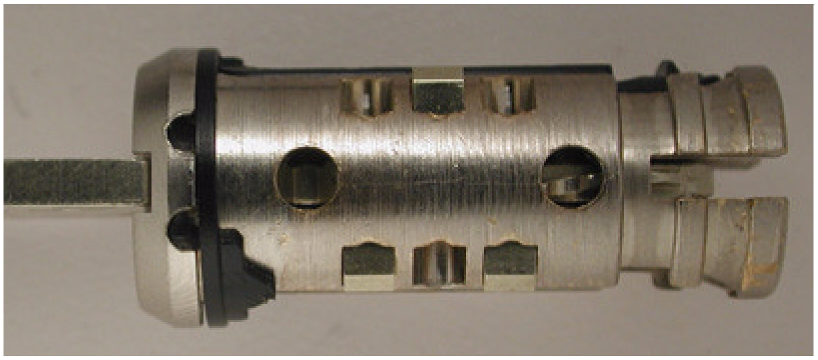
Extremely precise rotation can be achieved to allow for very close tolerances between each fence and gate. The magnetic discs can only be moved to their correct gate positions upon insertion of the proper key.

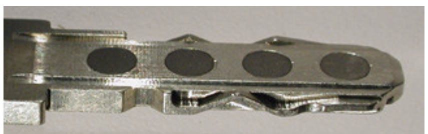
The rotors contained within the plug resemble individual wheels in a combination lock wheel- pack. Each of these discs has a gate that must be aligned with a fence in order that sliding sidebars may retract. The corresponding magnets embedded within the key cause each rotor to spin to the proper position, based upon the attraction and repulsion of fields.





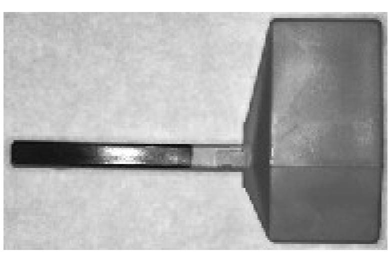
Sidebars on each side of the plug can retract only if all of the gates are properly aligned on the rotors. When the key is withdrawn, the magnets are moved to random positions to prevent decoding. For added security, a secondary ball bearing locking system must also be activated by indentations on the edges of the key.





Exploded view of magnetic disk orientation.

The Evva and Ikon design, in the view of the author, is a great deal more sophisticated than many other magnetic devices. This is because of the rotating gate concept and the precise magnetic fields required to properly orient the discs. Decoding of the lock will not provide any information as to the relative positions of each gate. Evva has implemented a revision to their original design, and incorporates three separate locking systems to secure the plug. In addition to two sidebars, there are seven sliders (three on top and four on the bottom of the plug) that are controled by variable ridges at the top and bottom of the key that interact with sliders, as shown. Two additional pins at the top front and rear of the plug prevent rotation until lifted and depressed by the key. In the photograph (top left) a key is inserted with the proper combination for the three top sliders. In the (top right) photograph, the sliders protrude from the plug, preventing rotation. The bottom photographs show the ridging on the top and bottom of the key that interacts with the sliders.



19_1.7.3 Gibralter Magnetic Lock

A lock was developed for use in the hotel industry that employed a magnetic stripe as a replacement for the conventional bitting surface of a key (**4616491(204)**). Information encoded on the stripe is read upon insertion, similar to that of a credit card. The system never attained a significant market penetration. It is, however, an interesting adaptation of magnetic stripe technology to simulate a conventional key.

19_1.7.4 Other Design Approaches

Inventors and manufacturers have tried many design approaches to exploit the magnetic properties of materials for use in locks. Chubb spent five years developing a magnetic- based locking system for the Home Secretary for use in prisons throughout England. It closely resembled the Evva and Ikon technology (GB **2151295A(205)**). DOM produced and patented (**5010750(206)**) a

mechanical lock that contained both conventional and magnetic tumblers. A coil mounted within the lock body senses an embedded magnetic code in the key. If the proper code is not present, the plug is prevented from turning. Bo Widen obtained a patent (**4507944(207)**) in 1985 for a cylinder lock that utilized pin tumblers, and a decoding system to read information in the form of regions of mutually different magnetic permeability. As the key moves in the lock, these regions cause variations in a magnetic flux that are decoded and evaluated.

Technology similar to that developed by Evva, involving rotating magnetic tumblers, was disclosed in British and American patents (GB **2214226A(208)**, **3633393(209)**).

CHAPTER TWENTY: WIRELESS

Wireless Exchange of Coded Information

Master Exhibit Summary

20_1.1 Wireless Technology

This chapter describes several relatively new wireless technologies that employ invisible infrared light beams, radio frequency energy (RF) and inductive fields to transmit coded information between keys and locks. **Infrared technology** (**IR**) relies upon the same basic scheme that is used in television, VCR remote controls, and alarm systems. The IR is utilized as a carrier to convey information passively between a key and electronic decoder.

Three infrared schemes are examined in this chapter. The VingCard utilizes a punched card that is popular in the hotel industry. Marlok resembles a conventional cylinder that employs a unique key with holes placed laterally through which infrared beams pass during the insertion process. Abloy combines IR with their

rotating disc lock for high-security access control.

Radio Frequency (RF) has been utilized for many years in access control devices such as garage door and gate openers. These systems rely upon low-power transmitters that are digitally encoded with a specific address. They communicate with a local receiver that controls relays, locks, or other devices. These systems are also utilized for motor vehicle access.

More sophisticated RF systems rely upon passive devices. These utilize circuitry embedded in identification cards. They may also employ special material that senses RF fields and in effect reradiates altered or processed signals, RF, or data back to a receiver. Examples of the use of RF can be found in access control applications. In such cases, the user possesses a badge or ID card that will receive and radiate signals that are recognizable by a device located at the entry point. Ranges of up to twelve feet can be achieved by such systems.

In the simplest of these schemes, small pieces of wire or etched printed circuits are placed in books or on merchandise to deter theft. If the encoder is not disabled, an alarm will sound upon exit.

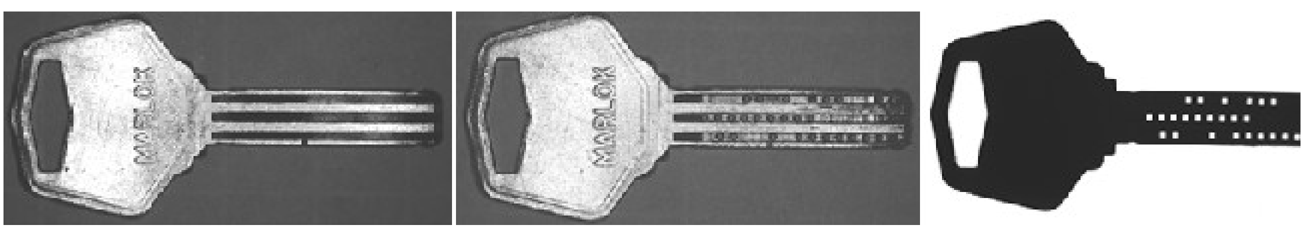
20_1.2 Infrared Systems

Infrared systems have found wide acceptance throughout the world. In most instances, they are reliable, are not prone to failure, and cannot be easily bypassed or compromised.

20_1.2.1 VingCard Electronic Lock Model 3000

See Chapter 23 for a discussion of the VingCard mechanical version of this device. VingCard utilizes a plastic key with a matrix of holes to control the transmission of infrared light between the card and receiver. There are seven **IR LED** transmitter and receiver pairs located on either side of the card entry slot. A microprocessor reads the holes in the card through the transmission of IR. It then compares the unique bit stream created by the holes with data stored within non-volatile memory in the lock.

Unlike its sister product (mechanical version models 1040-1050-1060), the 3000 is quite secure against surreptitious entry involving bypass of the processor and memory system. The lock incorporates an essentially non-repeating algorithm for code

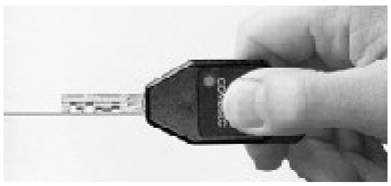


combinations. Each time a new hotel guest utilizes a key, the lock resets to the updated code. There is no predictability to the matrix of holes in each key, and therefore the lock offers millions of useable permutations. It is impossible to decode the present combination contained within the software. This is because Ving has utilized proprietary processor and memory chips that cannot be read by external devices connected to the circuitry.

Although the mechanical versions of this lock are not secure against bypass techniques (**5355701(210)**), the models that utilize IR present an excellent defense against decoding.

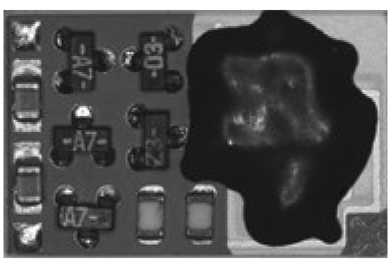
20_1.2.2 Marlok

The Marlok is a programmable lock that uses infrared as the transmission medium for the exchange of digital information between the key and internal microprocessor. The system allows the integration of retrofit cylinders into existing installations. Either stand-alone or remote reporting locks can be utilized.



The key is shaped like its conventional counterpart. However, rather than traditional bitting, it contains three data tracks embedded across its lateral surface. A unique pattern of holes creates a stream of infrared pulses that are transmitted through the key as it is inserted. These are decoded and matched with the code for a given lock.

Keys are activated or deactivated by programming individual locks for their specific code, thereby allowing them to be reused within the system. The manufacturer claims 14.5 million differs are available. Keys can be photographed, decoded, and simulated without difficulty. The process is somewhat more involved than copying an ordinary bitting surface, however. The Marlok system also provides for remote reporting of transactional information for security and audit functions.



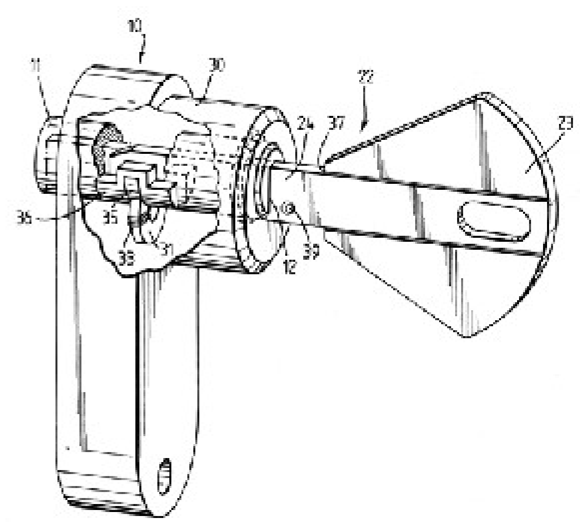
20_1.2.3 Abloy Combisec

The Abloy Combisec is a microprocessor-controlled electronic locking system that utilizes IR embedded within the head of the key. A 40-bit code is transmitted to the lock from up to four feet away. Up to 200 different codes can be stored in each lock. Each lock has several programming options to allow key enable, disable, time of day/week usage, audit trail and other functions.

20_1.3 Induced Fields

Many patents have been granted in the U.S., England and Europe for locks that utilize an induced field for the transmission and exchange of coded information between the key and lock. Some of these devices appear in this text under the category of Instant Keying (**Chapter 22**) and Intelligent Locks and Keys (**Chapter 21**). The technology is currently in use in a variety of applications, ranging from automobile locks to access control. A passive integrated circuit is embedded within the body of a key that communicates with a transmitter and receiver within the lock.

An exchange of information occurs to validate the code that has been programmed into the memory of both the lock and key. If the code is correct, then the lock is allowed to operate normally.



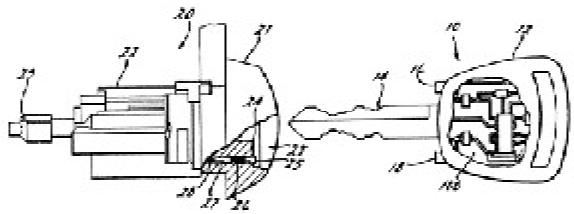
These devices require the generation of an alternating magnetic field in a region through which the key passes. The key has circuits that control an inductive transmission element in order to modulate or alter the field. This enables detection of a code that has been programmed into the key. The power for the circuit within the key is derived by rectification of the induced voltage from the alternating field without requiring direct connection to

the key.

20_1.3.1 Chubb Inductive Code Transmission System

In 1992, Chubb was granted a series of patents for an inductive code transmission system (GB **2252356A(211)**, **2273128A(212)**). It was distinguished from prior art in the United States Denmark, the EU, and England (DE 2634303, EP-0115747, **WO-88/03594(213)**, GB 2158870, GB-2174452, GB 2174452, US **4549176(214)**, **4602253(215)**, WO 88/03594).

The Chubb device emulates a conventional cylinder in function and appearance. An inductive decoder within the lock can read the code from the key when inserted into the keyway. Chubb sought to maximize the linkage of magnetic flux between the key and lock for optimum performance and stability.



Within the bitting of the key lies an inductive code transmission element in the form of a coil wound about an axis that allows maximum energy transfer. The key is comprised of a Nickel Silver metal blank, having an aperture at the tip wherein the integrated circuit is mounted between two ferrite pads and sealed in epoxy. The IC includes a memory programmed with an authentication code that is read by the receiver.

20_1.3.2 Ford Motor Company

Ford Motor Company has been granted patents for directly connected and induced field systems that are used in conjunction with ignition locks in their automobiles. In the original system

(**5003801(216)**), an electronically coded circuit was embedded in the bow of a conventional key. It had electrical terminals extending forward that contacted with the lock body when fully inserted. The invention was distinguished from cited prior art (4200227, 4298792, 4366466, (GB **2174452A(217)**).

This device functioned similarly to those utilizing induced fields. A programmed code within the circuitry of the key would be transmitted to the decoder incorporated within the lock. If the data was validated and the bitting pattern was correct on the key, then the conventional portion of the lock could be actuated. The vehicle could be started based upon the exchange of information between the lock and the electronic ignition system.

Ford later introduced an inductive system on certain model vehicles that parallels the operation of the Chubb device described in Section 1.3.1. These locks will also allow the instant programming of blank keys by the vehicle owner.

20_1.3.3 Abloy Electronic Lock

Abloy has developed an electronic lock utilizing inductive coupling for the transmission of power and code information (GB2158870A). This mechanism utilizes a traditional Abloy rotating-disc cylinder which is operated by use of a key, accompanied by an electronic system. Within the bow of the key is a processor and memory, together with an inductive pickup coil.

The circuitry is designed to receive activating power from an external unit that is mounted in the door or door frame. The programmable circuit in the key will transmit a code to the receiving unit by the inductive circuit. One feature provides for the ability to change codes on a designated schedule, including every time the key is used.

The Abloy system allows for the programming of both the lock and key to be changed to fit any system requirements, based upon time of day, location, and usage. The device provides for either

conventional mechanical operation or combined usage with the electronic portion, thereby offering higher security as well as the verification and registration of keys.

When the key comes within range of the transmission system, a carrier is transmitted that conveys power to the integrated circuit embedded in the bow of the key. This radio frequency energy can be set to a frequency of up to 27 MHz depending upon range requirements. A unique code is stored within the internal memory. When activated by a carrier frequency, the code modulates a return carrier that is sent back to the receiving unit for validation.

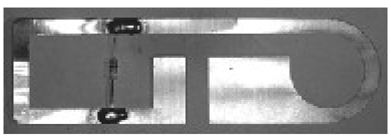
20_1.4 Radio Frequency (RF) Transmission

The use of RF as a transmission medium for locks and keys is widespread. Digitally encoded systems can be found in alarm sensors, keyless vehicle entry, access control devices for gates, parking ramps, garages and buildings, and for product security tags. The technique is also utilized for proximity detectors and house arrest systems.

20_1.4.1 Digitally Encoded Transmitters

Digitally encoded transmitters have been integrated into alarm sensors, access control devices, and vehicle entry systems. Many of these units operate within a standard frequency allocation of 305 MHz. A coded signal, with 40 data bits or more, is transmitted to a receiver within the lock or control system. Upon receipt of a validated code, a microprocessor, relay, or other actuating circuit is enabled. The transmitters emit extremely low power with a useable maximum range of 50 feet. Signals can be intercepted, decoded, and regenerated without difficulty within a short distance of the source.

20_1.4.2 Proximity Detectors



Proximity detection is the latest form of access control device. They are becoming extremely popular and will find wide acceptance within the lodging industry within a short time. Most systems operate in similar fashion to that of a security tag but have a greater sensing range and provide addressable keys.

An encoder is located at an access point. In operation, it will transmit a bitstream of data, together with sufficient energy to power a passive circuit within the key card. When an authorized

device is brought within the proximity of the encoder, a validated return signal will be transmitted and the lock can be opened. Each card or device can be programmed with a unique electronic serial number that can be distinguished by the host. These systems are ideal for applications requiring authentication of the user, without the necessity of the insertion of a physical key into a lock.

20_1.4.3 Security Tags

Although they cannot be considered as a lock in the strict sense of the word, a security tag performs a similar function to an electronic padlock. Most retail establishments affix security tags to high-value items in order to prevent theft by shoplifters. The devices are physically attached to clothing and other goods and cannot be removed without a special tool or magnetic field. Libraries embed similar devices in books, and manufacturers can "mark" goods during production.

If tags are permanently attached to an article, then they must be disabled prior to the customer leaving the store. If not, security staff will be notified at an exit location.

Electronic security tag manufacturers utilize many technologies, including radio frequency energy, magnetics, acoustics, and embedded integrated circuits. Some tags can now be encoded with serial number information and may be turned on and off electronically. "Smart tags" closely resemble access control devices that utilize proximity detection circuitry.

Certain devices utilize RF and a modified form of induced field for their operation. In order to function properly, a carrier frequency is transmitted within a limited radiating area or housing. A checkpoint is usually placed at an exit location through which the customer must pass. If a security tag is brought within close proximity of the RF, magnetic, or sonic radiating source, the active element will become excited. It will emit harmonics, resonate at a certain frequency, or change characteristics from which an alarm can be triggered. The RF modulated tag is actually a short antenna and tuned circuit having a specific wavelength. A diode forms part of the "antenna" and causes energy to be retransmitted. The harmonic or

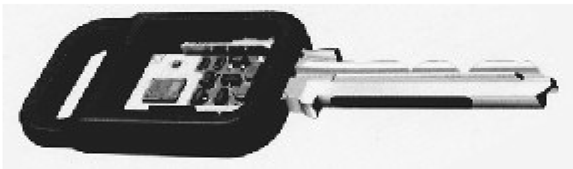
difference in frequency is received at the sensing point, processed, and used to initiate an alarm.

20_1.5 House Arrest Systems

House arrest systems have become extremely popular within the past five years. They are used to restrict a criminal defendant to a specified location as part of a court-ordered sentence. They consist of a personal transmitter and base station receiver that is connected to a central monitoring facility by telephone line. The transmitting device periodically sends a digitally coded signal to the base station to provide physical verification that the defendant is within 100 feet of the receiver. In older units, the transmitters utilized encoding technologies similar to alarm and access control devices. In the third generation systems, spread-spectrum transmission is employed for security against interference and tampering.

CHAPTER TWENTY-ONE: SMART DEVICES

Intelligent Keys and Locks



UNION-CHUBB
MEDECO IN-SITE

Master Exhibit Summary

21_1.1 Introduction

This chapter surveys innovative mechanical and electronic locks that incorporate "intelligence" into their design. These systems allow planners and administrators to closely match individual access restrictions and requirements with the location, its personnel, and security. Sophisticated microprocessor control circuitry is integrated in both the lock and key to provide many functions that are unavailable in conventional hardware. The "intelligent keys and locks" allow for a precise record of entry,

together with instant authentication of users, based upon security level, time of day, location, ingress and egress, and many other parameters. These locks are finding wide acceptance because of the versatility they bring to access control.

Due to the overlap in technologies, certain locks have been included in other chapters that may just as well fall into the category of "intelligent keys and locks." In **Chapter 23**, intelligent card locks that are used in hotels are described.

21_1.2 Union/Chubb

In 1991 and 1994, Union Works, a part of the Chubb Group in England, received patents for an extremely sophisticated intelligent lock that is instantly reprogrammable. The Union **Electro** described in **Chapter 20** has a processor and sensor system built into the lock housing. A small read-only chip is impregnated into the bitting. Each key has a unique factory-encoded electronic signature. Only if the lock recognizes the data from the key can an opening occur. Any one or more locks can be programmed to accept or reject one or more signatures (keys) within seconds.

21_1.3 Medeco Security Electronic *InSite*

Medeco was the first to introduce an integrated high-security encrypted access device. The system consists of a smart key that

works in conjunction with an intelligent door controller, hard-wired to a central processor. The DES encryption algorithm is utilized for all communications within the host network.

Smart keys utilize dual technology for optimum security. The rotating tumbler mechanical design, coupled with a read/write memory device and processor within the bow, allow unparalleled resistance to bypass.

The system provides customized access control to meet the requirements of any installation. Internal circuitry within the key can store a significant amount of data to clearly indicate the identity, authenticity, and access authority of the bearer. Additional data fields can be programmed into the key to include:

- **Key Holder Name;**
- **Key ID Number;**
- **Unique Facility Security Code;**
- **PIN Number;**
- **Key Class Field;**
- **Key Valid Date;**
- **Key Expiration Date Field;**
- **Number of Uses;**
- **Extra Time Allowance.**

The Medeco InSite system was introduced in 1991. It provided the model for subsequent intelligent access products that would be introduced by different manufacturers. Today, many vendors offer intelligent locks and keys that provide extremely high-security and functionality.

21_1.4 Ikon CLIQ

The Ikon CLIQ (**Cy**linder **IQ, or smart cylinder**) is one of the third generation intelligent systems to be released in 2002. Other manufacturers, such as EVVA, KABA, BKS, Medeco, and KESO have also introduced sophisticated systems that integrate traditional mechanical sidebar security with microprocessor control. All of these systems perform essentially the same functions with respect to central monitoring, programmability of keys, access, egress and ingress, timing, logging, system integration with older locks, and audit functions. Although each vendor has adopted different power, processor, and transponder technology, all of the locks perform the same functions.

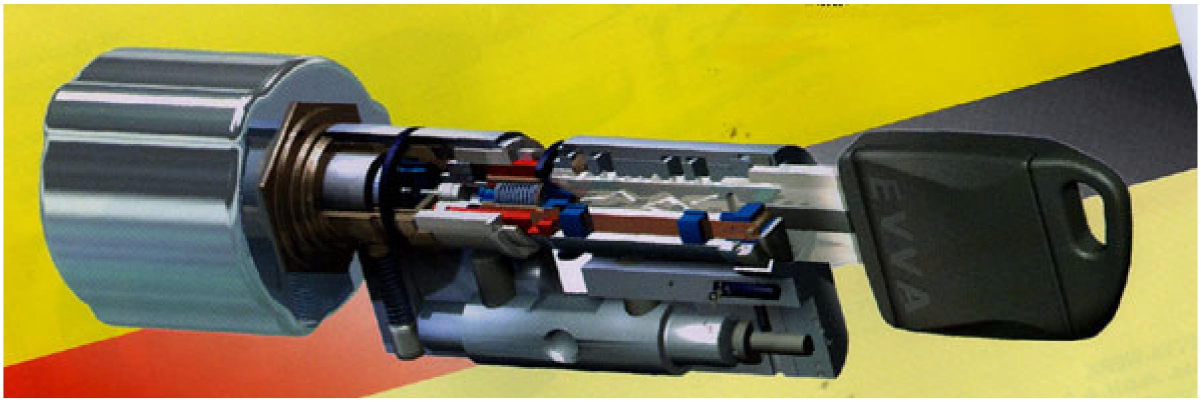


Figure LSS+2101 The EVVA Electronic Modular Cylinder is another intelligent lock. Note the same power and transport technology as the IKON shown below, through the use of contacts on the key.

With respect to security, all of the intelligent systems are virtually impossible to bypass, either with traditional means, or electronically. This is assured by the required coincidence of a very secure mechanical lock with transponder data exchange between specified keys and the lock, or central processor.

Some of the locking systems utilize passive circuitry within the key head; others power a processor within the key by small internal button cells. Some of these systems communicate by RF energy interchange between key and lock, while certain manufacturers, such as EVVA and IKON, hardwire link the key to the processor within the lock each time the key is inserted, via two contacts, as shown below. The IKON key head also has a LCD to indicate battery status.

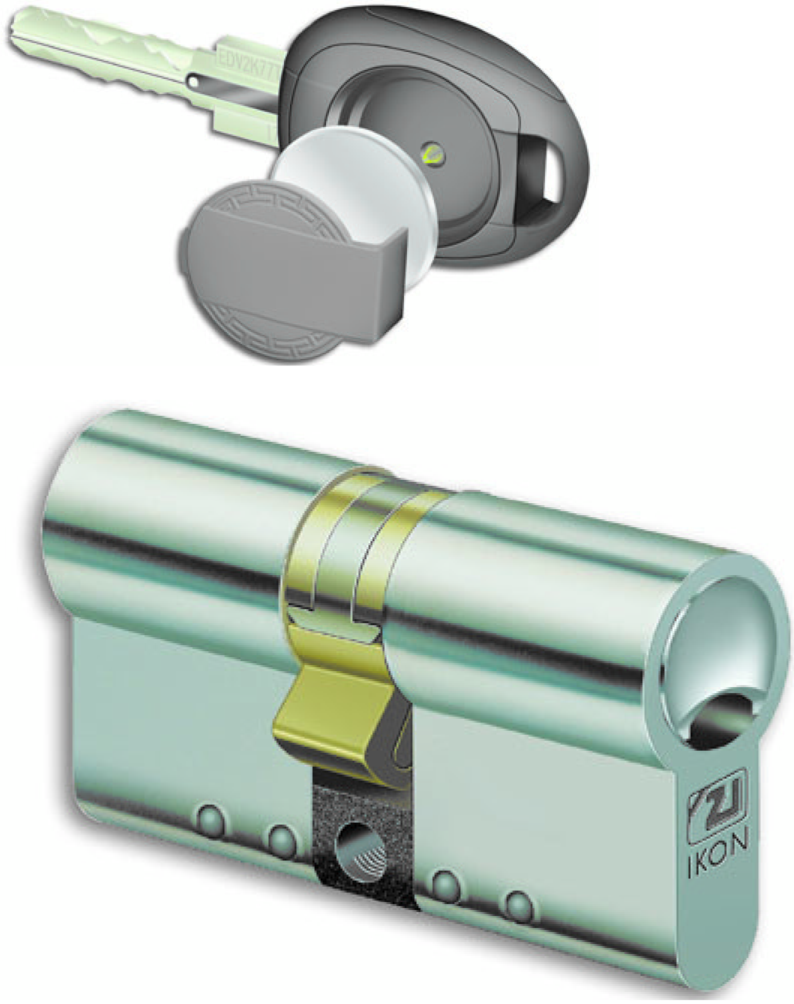

Figure LSS+2102. Details of the IKON CLIQ system are shown, including the programmer.

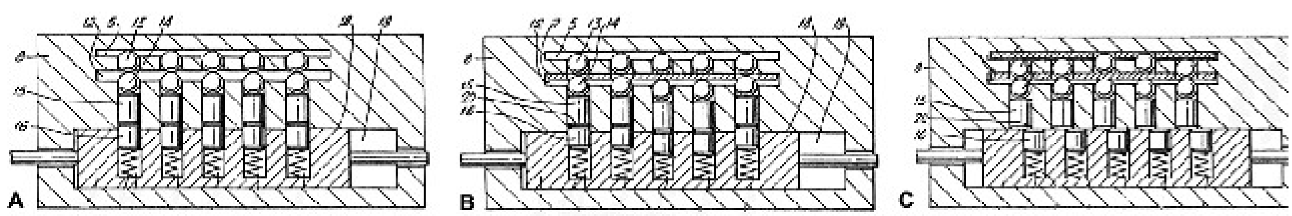
Master Exhibit Summary

22_1.1 Introduction

Manufacturers of safe and vault locks have produced changeable wheel pack and lever mechanisms for many years. In combination locks, several techniques are available to alter the relationship between spindle and gate position in order to change the combination. Levers and their corresponding gates can be moved to fit any key. See **Chapter 34** for a discussion of these mechanisms.

The ability to quickly reprogram locks and keys first became important in the lodging industry in the 1970s. This was a result of the failure of guests to return keys and the resultant losses of property and personal injury claims. Today, most large hotels as well as many businesses and government agencies utilize electronic or mechanical locking systems that provide the ability to instantly alter the key bitting or access code.



This chapter provides information about systems that can be programmed by a control key, change key, card, or code, at the lock or from a remote location. There are, of course, many similarities between these locks and other "smart" devices described in earlier chapters. Our discussion will focus on locks that have been specifically designed to allow a change to be made in the code or key that opens them. Other devices, such as those that utilize induced fields for example, may ultimately accomplish the same result but with different technology.

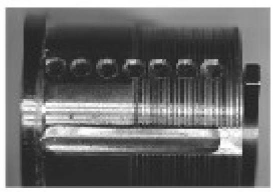
22_1.2 VingCard 1040-Series Card lock

Ving manufacturers a series of mechanical and electronic card locks for use in the hotel industry. The infrared system is described in **Chapter 20**. A bypass cylinder, present in most installations, is provided for hotel security and maintenance staff.

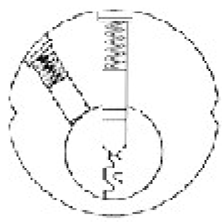
The 1040 mechanical card lock introduced an extremely innovative and clever design that provided for instant card change capability (**4149394(218)**). Unfortunately, the system can be bypassed with few implements and little skill. The author was granted a patent (**5355701(219)**) for the tools and techniques needed to decode and open these locks.

The mechanical version consists of a 32-pin tumbler lock, oriented in a matrix of 7 x 5 chambers along a horizontal plane. A programming card is placed into the rear of the lock that sets the pin code for the change key. A shear line is created between the fixed portion of the lock and the moving platen that holds the card during insertion.

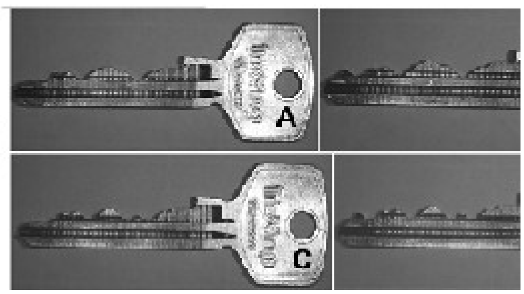
Exploded view.



When the key card is inserted from the front, it must **block** or allow to **pass** specific tumblers, based upon the matrix of holes in the **program** card. If all positions are correctly programmed, then the platen is free to move and actuate the bolt. If there are any holes or spaces present in the key card that do not match

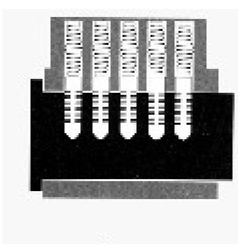


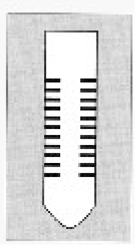
the program card, then the tumblers are lifted above shear line and the lock will not open. There are normally from seven to ten active holes within any key card out of a possible thirty-two useable positions. The security of this lock is based upon the random placement of these holes.



22_1.2.1 Instant Rekey Cylinder Lock

Bypass cylinders are installed for use in case of mechanical failure of the primary lock. They are manufactured to high tolerance and have a paracentric keyway to frustrate picking. The design features two sets of chambers within the shell, permitting master pins to be "parked" in the second location. This allows an instant combination alteration to be made for the change key.





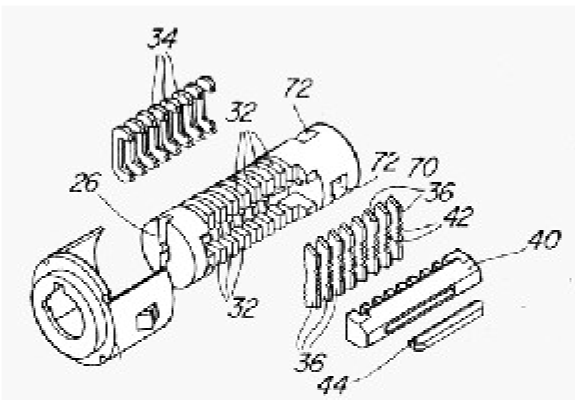
The plug contains seven lower pins. The upper chamber, aligned vertically when the keyway is set at the 12 O'clock position, has seven drivers and springs. In this orientation, the lock functions in the standard fashion. Offset approximately 30° clockwise is a second set of bores in the shell containing **six** drivers and springs. The last pin of the key (cut nearest the tip) is not present in the "control" chamber. Thus, only a specially cut master key can be inserted and removed when the plug is rotated to the control position. The first position on these keys is cut lower than the deepest depth.

In operation, a master key is inserted, the plug rotated to the control position, and the key withdrawn. A new master key is inserted, the plug rotated back to the normal vertical orientation, and the key removed. The new change key, having the same combination as the most recently inserted master key, will now operate the lock. No other change key will function. When the plug is rotated to a control position and a different master key inserted, master pins are parked in the offset group of chambers. These wafers are no longer part of the pin-stack, and thus, a different combination is set.

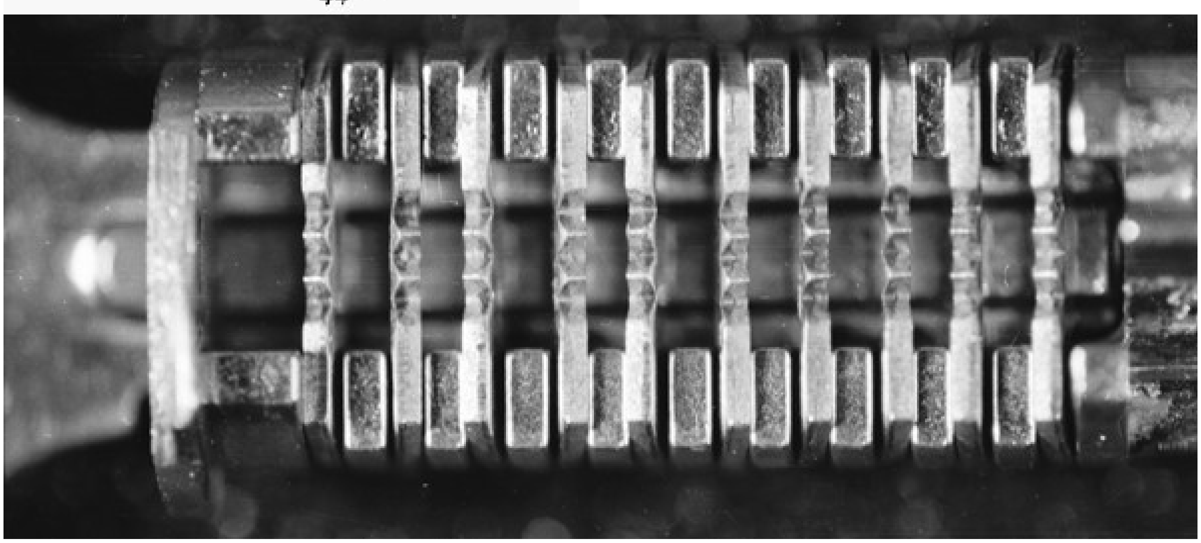
22_1.3 Master Lock Company Universal Pin Keying System

Master Lock, in 1994, introduced a fast, convenient, and easy method to combinate most of the major residential keyways without disassembly. The system relies upon the use of a special serrated pin in each chamber. The serration points correspond with each manufacturer's depth segments. For example, a pin for a Schlage **C** keyway would have serrations every .015". A Kwikset pin would have serrations every .023". The pins have sufficient serration density to accommodate most depth coding systems. In practice, the specific change key is inserted into a cylinder that has been loaded with the special pins. The lock is then placed in a pinning fixture. Using the wrench provided, a bolt at the rear of the fixture is turned. This causes the plug to be forced forward slightly, thereby breaking the pins at shear line. By this action, the lock is set to the desired combination.

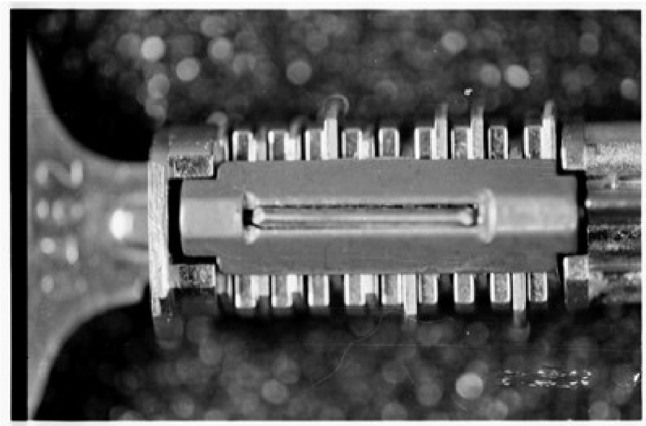
The system is not designed to be used with cylinders of standard construction. It requires a change in metal content by the manufacturer, so that internal deformity does not result from the stress induced during the shearing process. Master keying is not recommended. Sufficient testing has not been performed to determine the impact upon the security, pick resistance, or impressioning of the cylinder. This system is useful in allowing the locksmith to rapidly rekey standard cylinders at the change key level.



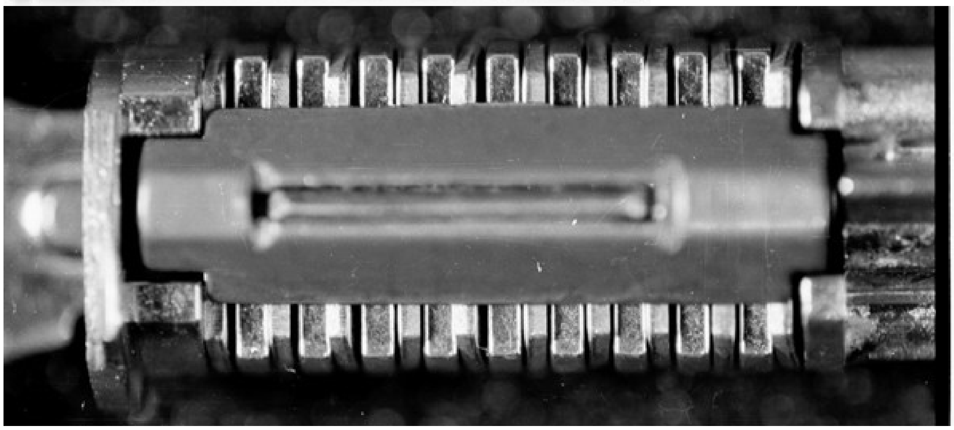
22_1.4 Vanlock Axial Pin Tumbler



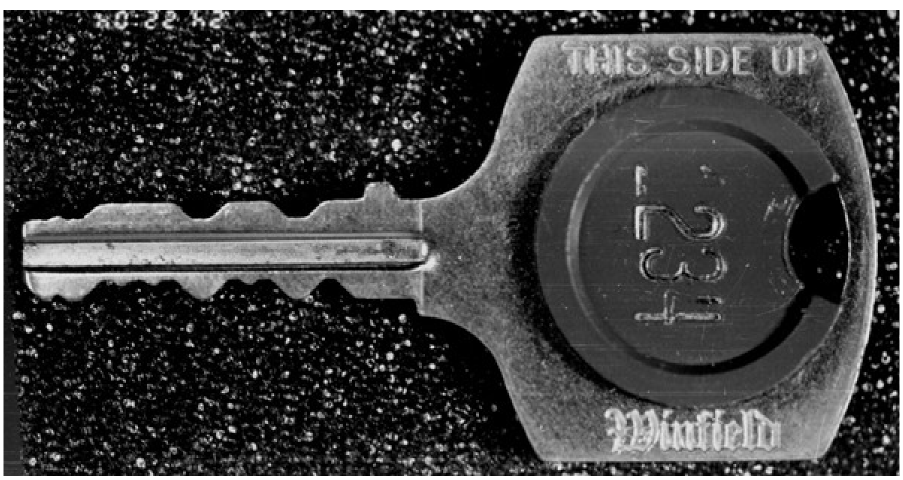
This lock is popular in the vending industry. It utilizes a special seven-pin tumbler key having removable pegs that correspond to axial pin tumblers. The lock can be reprogrammed by first altering the pin-stack in each chamber, then inserting the corresponding pins into the key. When mated together, the pegs will force the first set of tumblers to shear line. See **Chapter**



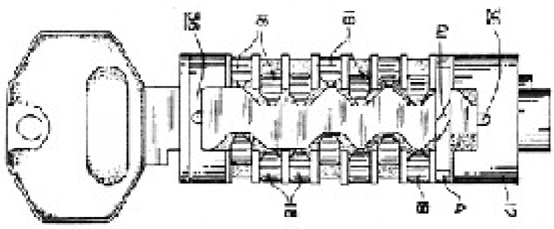
23 for a full description.

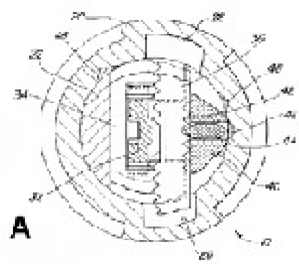


22_1.5 Winfield

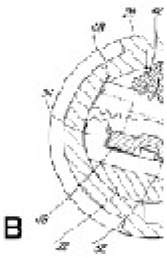


The Winfield Lock Company developed one of the first instant rekey locks and received patents for the design in 1978 (**4069694(220), 4966021(221), 4376382(222)**). The mechanism is extremely innovative and has found immense popularity in the hotel industry worldwide. The cylinder features two keyways: one for the change key and one for maintenance, programming, and emergency access. A view of the wafer pack is shown by use of a **borescope**. This enlarged photograph shows the precise position of each of the moveable wafers. The lock can be decoded through this process.





The design utilizes ten wafers to secure the plug within the shell. The unique feature of this lock is that each wafer is programmable to two different depth codes (full cut or no cut). There are 2^{10} or 1,024 possible combinations for any given lock. Only one keyway is available. The photographs above show the wafers in a aligned (proper key inserted) and misaligned state.



The tumblers are a split-wafer design. The **relative** internal spacing can be changed to match a particular bitting depth by use of the control key. When inserted into the second plug, it causes the two halves of the wafers to be separated and reoriented.

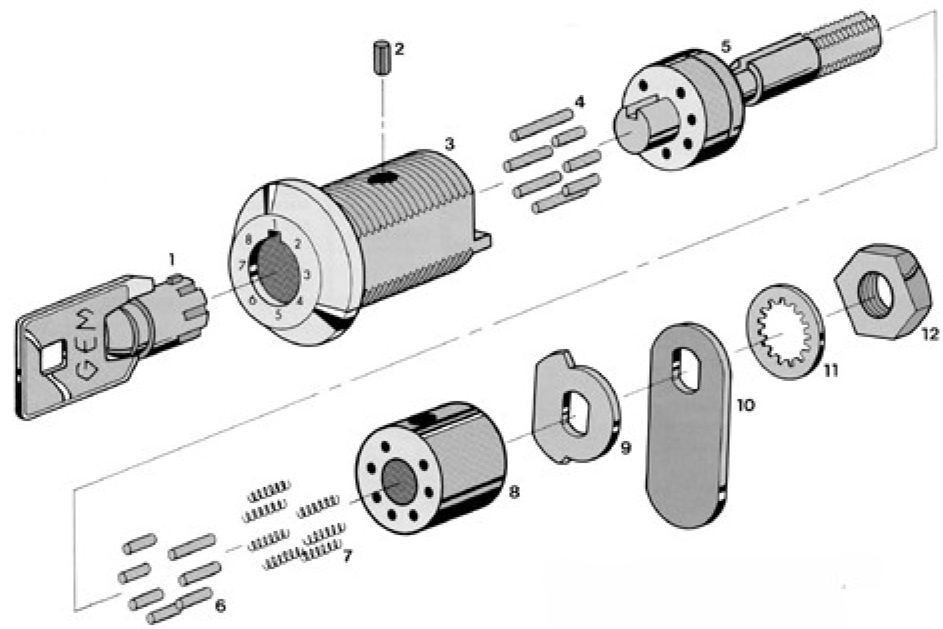
A

B

A master key operates the second control keyway and will open every lock in the system. A maintenance key, when inserted into the control keyway, allows instant reprogramming of this lock to any change key or master key combination.

Although found in hotels everywhere, this lock does not provide any real measure of security and can be picked and otherwise compromised. The lock does offer ease in reprogramming, however, and can provide immediate entry into a room, even when the mechanism is double-locked from the inside.   The original inventors set the standard for instant rekey in the hotel industry. T

22_1.6 Union Electro



The Union Electro, more fully described in **Chapter 20**, provides for instant programming by the insertion and removal of a control key. The lock receives coded information from an integrated circuit memory chip embedded in the tip of the bitting. This integrated circuit is powered through energy transmitted by induction, from the lock housing. An internal microprocessor within the lock verifies the unique code in the key and actuates a mechanical release.

22_1.7 Fort Gematic Tubular Lock

The Fort Gematic series of locks is instantly programmable to any one of eight preset combinations. Although the Gematic resembles the Chicago Lock changeable system, it is somewhat simpler to operate and only requires two keys. It is used primarily in the

vending industry and in merchandise display cases where keys may be lost or compromised. The Gematic looks like most other tubular locks from the exterior. It has seven radially positioned active pins, although there are actually eight lower tumblers. The eighth pin is non-active and is required to fill the void left in one of the chambers as rotation of the control plug occurs.

The lock is constructed to create two distinct shear lines: one for the individual change key and the other for combination control. Two discs, each with eight chambers, are stacked above the core to form the individual shear lines. These discs are equivalent to two concentric plugs in a conventional pin tumbler lock.

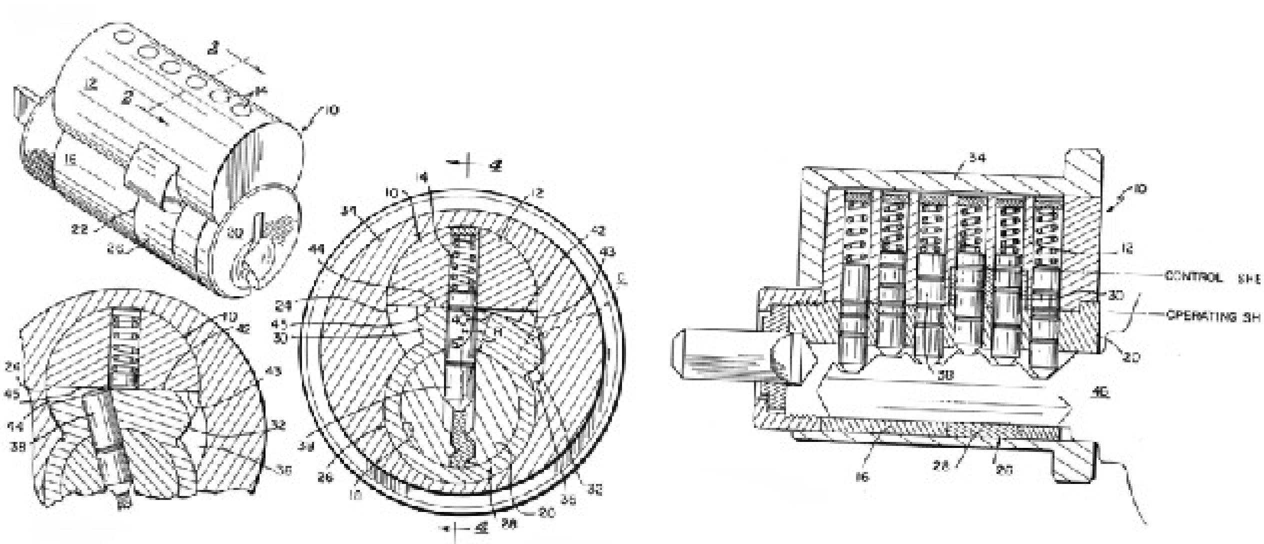
In theory, the system closely resembles the Corbin master ring, or the Best removable core lock, except that the second shear line controls the orientation of the lower set of pins with respect to the change key position.

In the normal axial pin tumbler lock, the key is inserted and all lower tumblers are brought to shear line. The cam may then be rotated. In the Gematic, the relative position of the lower tumblers, with respect to the fixed combination of one or more change keys, can be altered. Thus, the entire set of lower tumblers is rotated in one of eight positions, much like the hands of a clock. The correct key reflects the same tumbler pattern and orientation.

In operation, the change key will cause the first and second moveable discs to rotate in concert; the second disc forming the active shear line. When the correct key is inserted, the spindle may be turned because all pins are aligned to the second disc. The change key can only be inserted where the vertical index guides correspond on the cam and shell. Thus, the key will only make contact with the pins when it is inserted properly. It cannot work in any other radial position, because the key is blocked from entry.

A separate control key will bring all lower tumblers to the first shear line. The combination of this key will be different than any of the change keys because of the creation of a **control** shear line. The control key allows the plug with lower pins to be rotated to any one of eight radial positions. The control disc is not linked to the spindle and thus can be rotated freely once all tumblers are aligned.

The control key may be derived from any of the change keys by adding the precise difference between the operating and control shear lines to the combination of a change key for each tumbler. In other words, if the base combination of the lock is 1234123 and the thickness of the operating shear line equals two depth cuts, then the control key would be 3456345.



The ability to change combinations is based upon the orientation of the lower pin-stack with reference to the index guide. The control key sets a different combination by varying the relative position of the pin-stack, with respect to the index of the change key. There are eight such positions. To change combination, the control key is inserted to the current relative position (1-8). The entire plug is then rotated and the control key withdrawn at any of the eight permutations. The **apparent** combination is now changed, and only the corresponding change key with the correct cut pattern, as referenced **to the index**, will operate the lock.

The control key has been specially milled so that the top and bottom index has been removed. This allows the key to be inserted in any of eight positions. The control key will not rotate the spindle; it will only allow turning of the control plug containing the bottom pins.

22_1.8 Best Removable Core

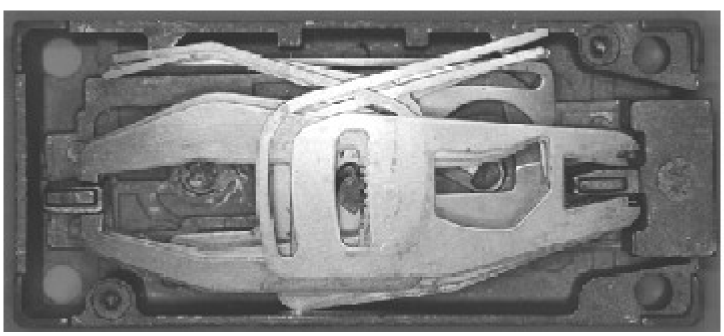
The Best Lock Company produces a series of interchangeable core locks (**A2, A3, A4(223)**) that are used in large complexes where immediate on-site key change ability is desired. The locks are available in mortise cylinder, key-in-knob, and padlock. All cores are interchangeable between hardware designs.

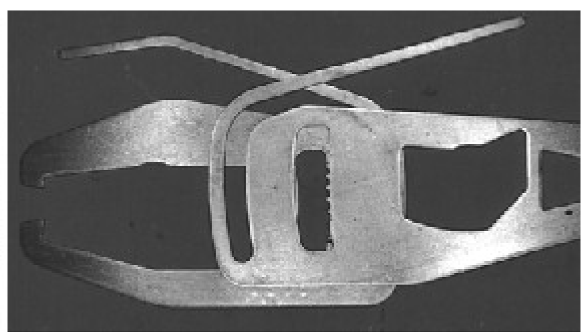
In normal operation, the lock functions the same as any other pin tumbler device. When, however, it becomes necessary to change the core, a special control key is used. This key is inserted and turned 15° to the right. The entire core is then withdrawn from the shell and a new one inserted. With the new core inserted, the old key is useless.

22_1.8.1 The Key

The Best key has no shoulder. Instead, the tip is flat-faced to act as a stop. A high tolerance is maintained between tumbler and root, because both are flat as opposed to the curved valleys and tumblers found in most locks.

22_1.8.2 Security Issues





Removable or interchangeable core systems are especially vulnerable to compromise and sabotage if the code for the control key is improperly obtained. This is because in most systems the control key will work on many if not all of the locks. Convenience and necessity can pose serious security risks. If the control key is lost or falls into unauthorized hands, the entire system can be compromised. Accordingly, the control key should be

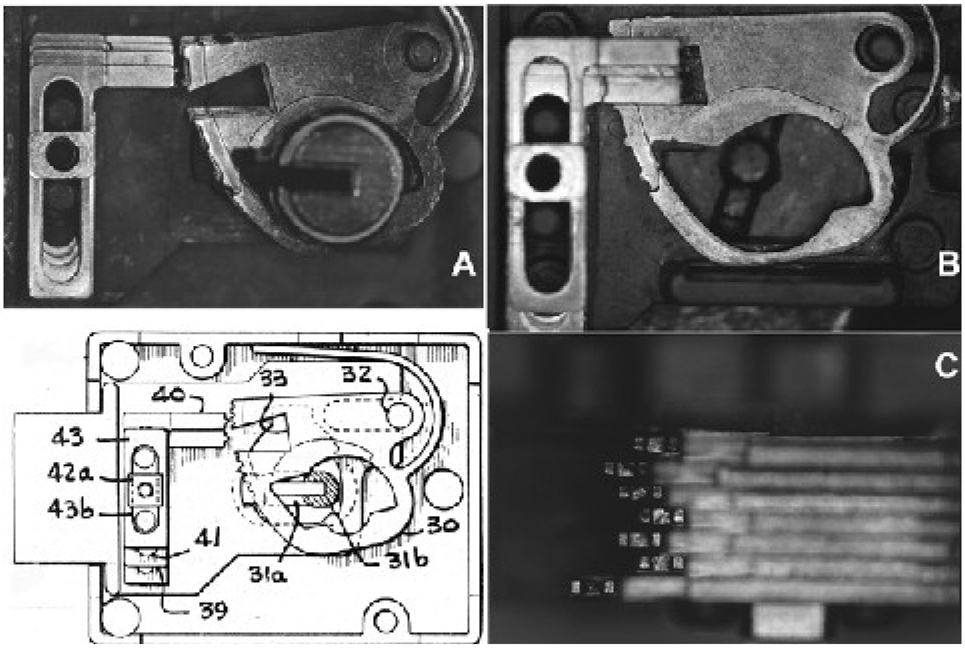
considered as a great grand master. With its possession, one can simply remove any core and open the lock.

Sabotage is another significant threat. Possession of a control key allows an exchange of cores, resulting in a lockout condition. In high-security installations, groups of locks should have their own control keys so that system compromise can be localized.

22_1.9 LeFebure Lever Locks and Decoder

The LeFebure seven-lever dual-control lock is utilized in safe-deposit vaults. The bitting combination for both the renter's key and guard key can be changed without disassembling the mechanism. A decoding/impressioning tool for the 7700 series lock was introduced in 1997 by Lock Defeat Technology. The system allows almost instant bypass of the renter's lever pack, and will produce an impression on a brass blank that can be decoded. Individual levers in each lever pack are identical in design with regard to the spatial relationship between gate and belly. Differs are created by physically placing a lever in a different position as to its gate.

Decoding and impressioning this lock is extremely simple, because the location of each gate directly correlates with the position of the lever and its belly. In many respects, the design of this lock is identical to a conventional wafer mechanism. In both instances, the active locking components are offset by the precise distance to the gate or shear line.



The impressioning and decoding process resembles the use of plasticine and yields almost identical results. In practice, a special brass strip is inserted into the lock alongside a guide that is used to actuate the bolt. The strip is forced against the lever pack until stopped, resulting in a precise impression

of the **relative** position of each lever. A guide key, in concert with the impressioned brass strip, is turned until the levers are raised to clear the fence. Because the strip mirrors the relative height of each lever at the drop in point, all that is required is that the strip be rotated to the correct position. The impression strip can then be decoded, if the amount of rotation required to bring all gates to the fence can be ascertained.

22_1.10 S&G 4110 and 6805 Changeable Lever Locks

In 1982, S&G patented a changeable safe-deposit lock having a single or double-key configuration (**4462230(224)**). These devices have one or two stacks of vertically slideable adjustable fences, that are carried on a bolt. They are held in an adjusted position by a clamping assembly that utilizes a changing screw that is accessible from the rear of the lock.

The S&G 4110 and 6805 were designed around the 1982 patent and have a changeable fence that allows instant programming to fit any key. The 4110 is a single-key, seven-lever lock and is used in safe-deposit boxes and other applications. The 6805 also has seven levers and is used in high-security containers. Within the 4110 and 6805, all of the levers have their gating in the exact same position. All tumblers are identical and can be interchanged. There is an individual fence for each lever gate, the position of which is altered based upon the key bittings. After insertion and rotation of the key for which the lock is presently set, the screw that holds the fence stack is loosened and a new key inserted. The position of each fence is changed to fit the new key.

Exploded views 1, 2, 3, 4, 5, 6..

The 6805 is UL listed and has the added security feature of a closed sweep and serrations for pick resistance. A moveable bolt actuator must be rotated past a certain point in order for the bolt to move, once all of the levers are aligned to their gates. The levers can be "read" in this lock with a borescope in order to determine markings that correlate to the depth of each cut. See Chapter 31 for a discussion of decoding.

22_1.11 Instakey Programmable Lock

Instakey (Smith) received a patent for a programmable lock in 1988 (4741188). The company has become a leader in supplying changeable systems, especially for retail, government, and educational facilities that require the capability to instantly change keying combinations without removing a core. The system is cost effective in comparison with removable core systems, or when the services of a locksmith are required to recombinate a cylinder. An employee can be easily trained to change combinations for any one cylinder, or a group of cylinders.

Instakey technology can be applied to a variety of hardware configurations, including small format interchangeable core cylinders, and Medeco Bi-axial. Instakey has agreements to supply cylinders for Best, Falcon, Medeco, Corbin-Russwin, Cisa, and

Pfaffenhain. Keyway groups have been assigned by these manufacturers for use by Instakey customers on an exclusive basis. In most instances, both the OEM and Instakey name will appear on the face of the cylinder to indicate its functionality.

22_1.11.1 Overview of the System

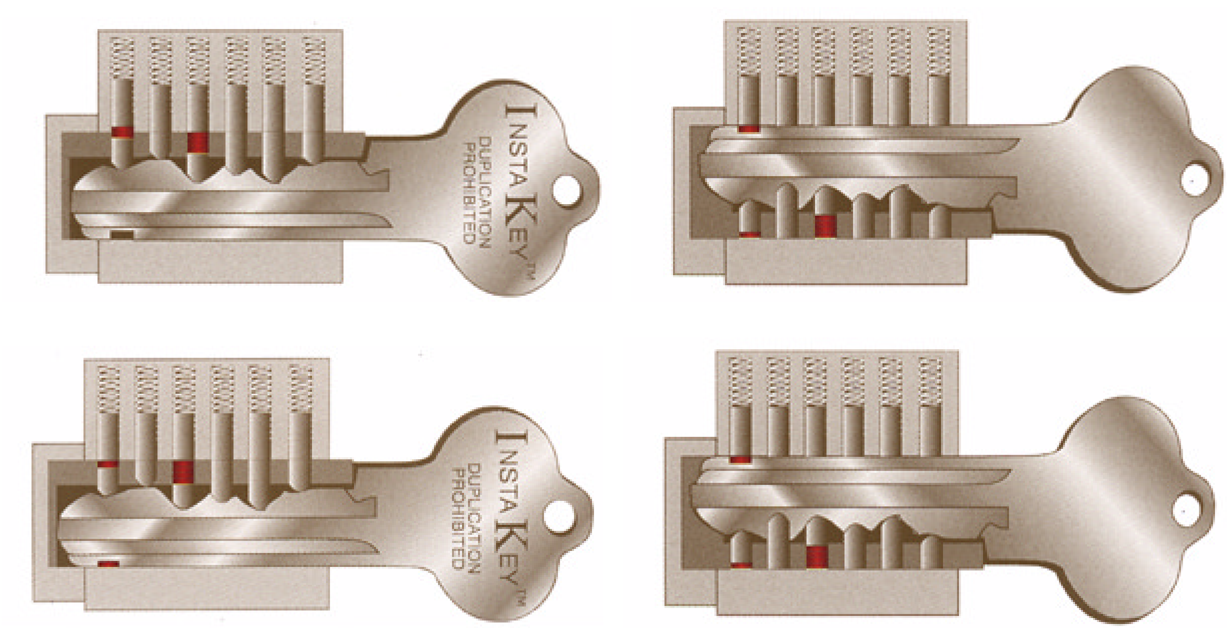


Figure LSS+2201 The Instakey cylinder has a wider than normal base at the bottom of the keyway. This allows room for the tumbler segment that has been

sliced during reprogramming to be removed from the lock. A slot that corresponds with the chamber position that is being programmed allows the transport of the wafer from shear line to the base of the plug. The slot in the programming key is slightly deeper than the depth increment of the tumbler.

An Instakey cylinder utilizes programmable pin stacks to allow for instant reprogramming. Special pins are available for many different manufacturers as well as the Instakey brand. The normal depth increment for Instakey SFIC is .0125". Master keying and programming utilize a two-step progression; thus, .025" is the minimum depth for each pin segment. Pin stacks are available in .025" (1 depth) .050" (2 depths) .075" (3 depths) and .100" (4 depths). The specially glued pin arrays can be placed in three different chambers, which are normally the fifth, sixth, and seventh position (measured from the tip).

Instakey normally supplies a programming "kit" that contains one or two new keys that can be utilized in the event that a lock requires reprogramming. The lock can be programmed a total of twelve times before it must be exchanged. All change keys are usually not supplied to the end user. The company maintains a sophisticated on-line tracking system for each of its customers so that Instakey and the specific location always know the programming sequence for any given lock and inventory.

Combinations can be changed at the change key, master key, and control key levels. To change the bitting combination for a given cylinder, the next step-programming key (with a slot at the base of the blade) is inserted and rotated a full revolution. This action will slice the next section in the programmable pin stack and park it above shear line. As the plug rotates, the pin segment is picked up by the slot in the key. When the key is returned to "home" position, the pin is carried out of the plug as part of the key. The combination has now been changed, and the last step-key will no longer function. In the case of change key reprogramming, it can be seen that the overall pin stack height for the master key or control key will not be affected because each programming step of two depth increments is added to the new key that operates the lock. That is, the code sequence for a given chamber always runs from the deepest cut to the shallowest. Increments for the Instakey SFIC cylinder are measured from 0-9, where 0 is the shallowest depth.

INSTAKEY SFIC(225)

Depth	Space	Increment
0		.0319
1	.086	.0306
2	.236	.0294
3	.386	.0281
4	.536	.0269
5	.686	.0256
6	.836	.0244
7	.986	.0231
8		.0219
9		.0206

Figure LSS+2202 Table showing depth and spacing for Instakey small format interchangeable core system.

Code progression for a sample lock is shown below.

INSTAKEY PROGRAMMABLE LOCK SAMPLE SYSTEM CODE PROGRESSION		
SEQUENCE	CHANGE KEY	PROGRAMMING KEY
1	3250989	
2	3250789	3250789
3	3250589	3250589
4	3250389	3250389

22_1.11.2 Detailed System Operation

A customer will be supplied with a system that is programmed for the first step. In the progression table above, the sequence begins with the bitting code of 3250989. The customer would usually be supplied with the next step-programming key and change key, which have the same value of 3250789. We note the following characteristics of the system from the progression table:

- **Chambers 5-6-7 are utilized for programming;**
- **The key is coded from tip to bow;**
- **There are programmable pin segments in all three chambers;**
- **Any chamber can be utilized for programming, but only three chambers are ever utilized for this purpose;**
- **Each programmable pin segment measures .100", which is equal to eight depth increments. Because this is a two-step system, each removable pin segment is equal to .025";**
There are a total of ten depths for this specific lock, each with a depth increment of .0125";
- **Each time the cylinder is reprogrammed, the pin stack in only one chamber is acted upon;**
- **When the cylinder is reprogrammed, the special tumbler for a specific chamber is raised two depth increments (one pin segment) above shear line, sliced and removed;**
- **A cylinder can only be reprogrammed with the use of a special key that contains a slot at the base of the blade, corresponding with the location of the programming pin;**
- **Each time the lock is reprogrammed (up to twelve times), one segment is removed from the plug. When this occurs, the previous step key will not function, as its bitting value will be two depth increments below shear line;**
- **Programming pins can be sliced with a regular change key. However, the segment cannot be removed from the plug. This has significant implications with regard to the security of the lock, and is discussed in a later section, and in Chapter 31 with regard to the extrapolation of the top level master key;**
- **Reprogramming of the lock is done in sequence, beginning from chamber 5, then 6, then 7;**
- **As the length of the pin stack is shortened by the removal of a**

pin segment, so the length of the bitting value of the key is correspondingly increased. That is, every time a pin segment of two depth increments is removed from the plug, the value of the next change key is increased (the bitting is shallower) by two depth increments;

- **Each programmable pin segment can contain one, two, three, or four segments, each of which are equal to two depth increments;**
- **The change key, master key level, or control key (in removable core locks) can be altered independently;**
- **In the removable core lock, the control lug is only acted upon by the first four chambers;**
- **Unless specifically programmed, the value of the control key will never be affected by reprogramming;**
- **The base of the keyway has been specifically widened to allow for the removal of the programmable pin segments. Generally, this modification is performed by the original equipment manufacturer for Instakey;**
- **Restricted blanks can be replicated on the Easy entrie profile milling machine;**
- **If the customer is provided with more than one programming step key, and the wrong key is utilized for reprogramming, confusion can result because the lock will be out of sequence with the information retained by Instakey;**
- **If the customer is provided with all twelve step keys, each can be made to open the lock, creating a serious security problem, detailed below.**

In the diagram below, the programming progression is graphically illustrated for four cylinders in the system shown in figure LSS+2203, above. The system is very basic, and does not take into account either master key or control key. The diagrams show the bitting of each step key #1-4 (green). Note that the "0" cut in chamber four shows as only one pin length. The bottom pins in chambers five and seven are shown in blue. Although a "0" value pin also appears in chamber six, it is not shown, other than as the bitting height of the key. The red segments indicate programmable pins that are raised by the action of each sequential step key and removed from the plug. The actual depth code values are shown in yellow. The depth increments are shown in tan, to the right of the diagrams. An overlay of the actual photograph of the third step key is shown for combination 3250589.

The pinning values for this lock are shown in the table below.

INSTAKEY PINNING CHART FOR SAMPLE SYSTEM FOR STEP #1 3250989							
SHEAR LINE	3	2	5	0	9	8	9
PROGRAMMING PINS, FOUR SEGMENTS, EIGHT DEPTH INCREMENTS					2		
					2		
					2		
					2		
BOTTOM PIN	3	2	5	0	1	0	1

22_1.11.3 Security Issues

There are a number of real and potential security considerations and issues involving the use and reprogramming of any lock that utilizes the Instakey technology.

Programmable chamber identification: Although the factory routinely utilizes chambers 5-6-7 for programming, this is not a required constant, and can be modified. If an employee or other individual has access to more than one step key, it may be relatively easy to determine which chambers are utilized for reprogramming.

Torque: The amount of torque that is required to sever a pin is minimal. In fact, the manufacturer only utilized a glue bond between programmable pin segments to make the lock more resistant to picking. If more than one programming step key is obtained and inserted into the lock, multiple pin segments can be severed. This will result in significant key interchange issues, creation of incidental master keys, and reduction in pick resistance.

Key Interchange: If multiple pin segments are sliced but not removed from the lock, then serious key interchange will result, as well as the creation of incidental master keys and cross keys. It may be impossible to determine if programmable pin segments remain in the lock after being severed.

Sabotage potential: A system may be sabotaged by being reprogrammed by an unauthorized individual. This could occur if a change key was modified by adding two depth increments to one of the chambers utilized for programming, and a slot cut in at the base of the key to correspond with one or more chambers.

Extrapolation of the top level master key: If an Instakey lock is probed, as described in chapter 31, then multiple pin segments may be severed without knowledge, creating key interchange and incidental master keys. It will also cause confusion to a covert entry team attempting to decode the TMK, because multiple shear lines are created as pins are severed.

Pick Resistance: The pick resistance of a cylinder will be reduced if pin segments are sliced but not removed.

22_2.0 Changeable Combination Padlocks

Many changeable key and combination padlocks have been designed during the past 150 years. These are configured as removable core, rotating thumbwheel, pin tumbler, axial pin tumbler, and combination lock. The Corbin Sessamee and equivalent Master Lock design (**5109684(226), 3983724(227)**) utilize a programmable thumbwheel and gear arrangement to alter the relationship between a number on a thumbwheel and fixed detent within a padlock. Tension is released from the two components to change their relative indexing and four digit combination. See **Chapter 23.**

Harry Miller was granted several patents for high-security combination padlocks that were produced by Sargent & Greenleaf (**2852928(228)**, 2831447, **3533253(229)**) beginning in the 1950s. Produced primarily for government use, these locks offer a high level of resistance to surreptitious and covert entry. See also (2673457) (**2814940(230)**) (**2830447(231)**) (3024640) (**4404823(232)**). The combination is reset by the introduction of a special change key at the back of the lock. The relationship between each gate and spindle can be changed while maintaining security against manipulation. They are described in **Chapter 23.**

22_3.0 Survey of Other Programmable Locks

Many other locks that are capable of being programmed have been invented. These include a battery-operated access control device using a keypad for entry of the combination (**5083122(233)**) an axial lock (**3868838(234), 3330141(235), 3572070**) changeable keys for combination locks (**1899739(236)**) safe-deposit locks (**1863525(237)**) and a key-operated combination lock with programmable gated tumblers (**4375159(238)**).

BOOK TWO: ENTRY

Methods of Entry

PART I: INVESTIGATION

PART II: GENERAL INTRODUCTION TO BYPASS: SILENT NON-DESTRUCTIVE ENTRY

PART III: DESTRUCTIVE ENTRY

Book II is divided into three parts, within which an analysis of destructive and non-destructive methods of entry is presented. The material explores how locks and locking systems can be bypassed and compromised using surreptitious techniques, as well as by force.

Part A, INVESTIGATION, has four chapters (chapters 24-27), that provide detailed information about the analysis of locks and keys, from the perspective of the criminal investigator and the forensic criminalist.

The emphasis is on **Non-Destructive Entry**, first offering an extensive checklist to determine, document, and establish whether a crime has been committed, and possibly by what means.

Although it is recognized that almost all intrusions are by force, the most serious offenses involve an aspect of covert entry. Common burglars do not pick locks or manipulate safes. However, in the realm of compromise of data, internal thefts, acts of espionage and sabotage, surreptitious entry becomes a critical factor.

Part B, GENERAL INTRODUCTION TO BYPASS, provides extremely detailed information regarding surreptitious methods of entry, such as picking and impressioning. Chapter 28 provides an overview of the primary techniques employed in opening locks, with the focus placed upon picking and impressioning. In Chapters 29-31, specific information is provided regarding each primary classification of lock and how they can be opened. For the crime lab technician and criminal investigator, this material will provide a thorough understanding of the techniques utilized in bypass. This information should be equally useful to the intelligence officer and technical support specialist. They have the responsibility to effect surreptitious and undetected entry for the purpose of court- ordered electronic surveillance, execution of search warrants, intelligence gathering and other operations.

Part C, DESTRUCTIVE ENTRY, contains one chapter, Chapter 32. It examines the tools and techniques utilized in the forced-entry of locks and enclosures. A brief discussion of forensic examination, in the context of forced-entry of safes and vaults, is also presented in Chapter 35.

PART A: Investigation

Locks, Safes and Security

CHAPTER TWENTY-FOUR: INVESTIGATION

Investigation and Evidence Involving Locks and Keys

24_1.0 Introduction

This chapter will provide a comprehensive checklist for the criminalist and investigator about the methods of surreptitious or covert (non-destructive) entry and bypass of locks and locking systems. The primary focus is upon locks that utilize keys. Later chapters will offer specific information about bypass of each generic type of lock.

Doing research on different bypass techniques is important for the forensic investigator. Courtesy of Don Shiles.

We will examine circumstances where locks are bypassed through manipulation of their components in a non-destructive manner that neither leaves obvious physical evidence or affects the operation of the lock subsequently. Then, the analysis of internal and external components for signs for surreptitious entry will be presented. Examination of locks that have been the subject of forced-entry is covered in **Chapters 26**, **27**, and **32**.

Locks and locking systems are examined at crime scenes and in secure areas suspected of being compromised for many reasons. Keys, specialty tools, lock-picking tools, key blanks, code books, and other indicia of criminal activity may also be relevant and are analyzed to determine:

- **Evidence of entry;**
- **Was a lock picked or otherwise bypassed;**
- **Prove or disprove unlawful entry;**
- **Identification of perpetrator;**
- **Identification of methods of entry;**
- **Develop investigative leads;**
- **Link individuals with prior criminal activity;**
- **Link associates through a terrorist and criminal association file.**

Locks are examined, either before or after an incident has occurred, concerning the following:

- **Criminal investigation;**
- **Civil insurance claim;**
- **Security investigation regarding breach, espionage, sabotage, or terrorist activity;**
- **Prevention of loss;**
- **Safety of life or property;**
- **Collateral issues involving liability and insurability.**

Often, the criminalist is asked to determine whether a lock has been bypassed, opened with keys, or by other means. Bypass techniques will include but not be limited to:

- **Decoding and key generation or simulation;**
- **Top level master key decoding and extrapolation;**
- **Picking;**
- **Impressioning;**
- **999 rapping;**
- **Other forms of manipulation;**
- **Drilling and repair;**
- **Drilling and replacing the entire lock;**
- **Altering the pin-stack prior to entry;**
- **Using an unauthorized key;**
- **Prior replacement of one or more locks.**

Techniques for bypassing locking systems can take many forms: some simple, and some very complex. Although in the vast majority of burglaries entry is accomplished by force, there are serious instances of covert entry. Internal theft, sabotage, espionage, and other crimes generally rely upon such techniques.

Many variables can affect the ability to compromise a locking system. Thus, the detection of the method of entry may be quite difficult. In many instances, such evidence may only be gathered through the logical inference of facts, for there is often no physical evidence from which to draw such conclusions.

The analysis of a crime scene to determine methods of covert entry is quite complex and often inconclusive. Most crime laboratories throughout the world do not conduct such inquiries on a routine basis. The examinations can be quite difficult, time consuming, and require expertise not ordinarily available or possessed by the criminalist.

The forensic investigator must be concerned with what the evidence both proves and does not prove. This is extremely important, because erroneous conclusions can easily be drawn from physical evidence. Such conclusions would be subject to rigorous cross-examination.

Analysis of a case involving forensic locksmithing. Courtesy of Don Shiles.

For example, marks may be found on internal locking components that may have been caused by picking. Such marks may just as easily have occurred during normal use.

In the view of the author, this chapter is one of the most important in this text. The preceding 23 chapters all have provided the foundation and theory to support the data presented in this and the following eleven chapters. The information provided here will sensitize the criminalist and investigator to the many possible means that may have been employed to effect entry or compromise a locking system. Those responsible for providing a solution to a given set of facts that are encountered or developed at a crime scene must be able to ask many probing questions. The importance of this material is to raise the threshold of awareness of relevant issues that must be factored into an analysis of any suspected bypass.

The chapters are organized to provide a basis for the evaluation of the potential for bypass and a determination of the most likely methods of entry. Information will also be provided to indicate situations where indications of entry have been fabricated by alleged victims.

In some cases, investigators may first have to conduct a lengthy inquiry to determine one or more ways to bypass a lock or locking mechanism in order to reach a conclusion as to probable entry methods. Most often, a manufacturer will not provide any relevant information regarding its bypass. In fact, they will generally state that the lock is secure against attack, and will rarely admit or be aware of design defects or methods of compromise.

Locks can be analyzed both in the field and in the laboratory, thus allowing two distinct inquiries to be pursued with some overlap. Special care must be taken at the scene to insure that the laboratory examination is not compromised due to improper techniques.

In order to competently investigate covert entry, a thorough understanding of the following topics (covered in Chapters 1-23) by both the investigator and criminalist is essential:

- **Anti-picking features**
- **Bypass capability and methods of entry**
- **Bypass techniques**
- **Code cutting of keys**
- **Cross-keying**
- **Databases and reference materials for locks**
- **Decoding of locks**
- **Differs and depth coding: theory and reality**
- **Disassembly of locks**
- **Evidence of bypass**
- **Forensic analysis of locks**
- **Forensic disassembly of locks**
- **Identification of locks, keys, and components**
- **Impressioning**
- **Key-duplication procedures**
- **Keying of locks**
- **Keying systems, including master keying**
- **Keyways and restrictions**
- **Locking hardware**
- **Locks and theory of operation of each type of mechanism**
- **Manufacturing specifications for locks and keys**
- **Metals and Metallurgy**
- **Methods of forced-entry**
- **Picking**
- **Safes: construction, locks, and methods of entry**
- **Security systems and access control**
- **Specifications for key machines**
- **Tolerance specifications**

- **Tools utilized in bypass**

24_1.1 Case Examples

The following simple factual situations encountered during the course of investigations conducted by the author illustrate the variety of issues that can confront the investigator or criminalist. Hopefully, the material presented will provide many potential avenues of inquiry. These cases will be revisited at the end of **Part A.** Also included are summaries of cases that have been worked by Hans Mejlshede, Don Shiles, and other forensic locksmiths.

Case example, burglary investigation. Courtesy of Don Shiles

Case example of hotel lock bypass. Courtesy of Don Shiles.

Case example, Courtesy of Hans Mejlshede.

Investigative clues that develop during a case. Courtesy Jim Bickers.

Case #1: Money is missing from an inner locked drawer that is contained within a safe. There are no signs of forced-entry.

Case #2: An apartment has been broken into. Property, including jewelry, is missing. There is a large insurance claim based upon the loss. There are tool marks on the face of the lock and within the keyway.

Case #3: A lock shop has been burglarized. The insurance company believes that the burglary report is false; that the owner setup the loss, because the high-security locks cannot be bypassed.

Case #4: Property is missing from an office. All employees have been polygraphed with negative results.

Case #5: Confidential information has been compromised from a computer. The keyboard is always locked at night or when not in use. An employee is suspected.

Case #6: Upon opening the store on Monday morning after a three-day holiday, there is money missing from the safe. There is no sign of forced-entry. The theft obviously occurred over the weekend; the manager is the prime suspect because he was the only individual having the combination. The lock is a Sargent & Greenleaf 6730, 3 combination, with 1,000,000 permutations.

Case #7: A theft of jewelry occurred in a hotel room safe, at a very exclusive resort. There are no signs of forced-entry, either in the safe or door lock. The guest has been polygraphed with negative results.

Each of these cases should immediately cause certain initial questions to be raised. The purpose of this chapter is to sharply define issues in order to make a case solution possible. The following discussion is concerned with any crime, suspected crime, compromise of a secure area, or other incident where the critical element, as a condition of entry, is bypass of a locking system or component.

A comprehensive checklist is presented in order that a possible determination can be made as to methods of entry or compromise and the resulting development of investigative leads. This outline will also provide the information necessary for a thorough analysis of the locks, keys, locking systems, and access control for a given area.

It is the author's intent to provide a road map for the criminalist and investigator, which explores the intricacies of locks and how they can be compromised.

24_2.0 Preliminary Field Investigation Checklist

Before beginning an examination in the field or crime lab, it is important that the criminalist and investigators focus upon exactly what information is being sought. Initially, and depending upon who is conducting the inquiry, one must consider precisely what data is required if the investigation is to be successful. Simply stated, what do you need to know at the conclusion of the examination in order to identify perpetrators, produce investigative leads, or reconstruct events? The following **Preliminary Field Investigative Checklist** can provide

many avenues of inquiry at the crime scene or remote physical location to help answer that threshold question.

The checklist will focus on **locks, keys, and locking systems** that are examined at the scene, rather than in the crime laboratory. A preliminary and cursory forensic inquiry and examination in the field can yield valuable information and provide investigators with relevant leads, often quickly. The material is organized under two main headings: **Bypass of the Components of the Lock;** and **Keys. Components** encompass internal and external parts, and secondary-locking mechanisms including strikes, bolts, and cylinder-securing devices. **Keys** involve key system analysis and key control. Under each category, both summary information and relevant areas of inquiry are presented.

The starting point for any inquiry is to determine how entry was accomplished: was it by forced or surreptitious means, and if a lock was operated, opened, or bypassed in the process? In other words, are there visible signs of entry.

24_2.1 Actual Method of entry:

Preliminary questions that must be addressed prior to a forensic analysis and evaluation of lock sub-systems will include:

- **Was a lock opened, operated, or used to gain entry;**
- **Are there obvious methods of entry available. What are they;**
- **Could there have been an open window or door or a lock left unlocked;**
- **Is the apparent method of entry consistent with operating the lock;**
- **Was entry in fact accomplished;**
- **If entry was not completed, why not;**
- **If surreptitious entry is suspected, was a key possibly involved;**
- **Is the suspect lock presently working, and, if so, does it operate normally;**
- **What actually unlocked the mechanism;**
- **Is the physical evidence consistent with what was required to open the door or lock:**
- **Physically, what tools were required to effect entry;**

- **How much time was required to effect entry;**
- **How much noise or attention would be expected during entry;**
- **Was any property damaged during the entry process;**
- **Was any trace evidence left at the scene, or taken from the scene;**
- **Was any tool mark evidence left at the scene;**
- **Were any implements of the crime left at the scene such as tools indicating interruption of the entry process. This information may provide further evidence of the skill level of the perpetrator;**
- **Were any dangerous conditions created as the result of entry, i.e., explosives, loose debris or other items, weakened items, poisonous or toxic gasses or substances, or other hazardous materials;**
- **If the motive for entry was burglary, analyze what was taken. Does the value of the goods and method of attack seem consistent. If it appears that entry is connected with an insurable loss or the theft of records that might provide evidence of a crime, the likelihood of simulated surreptitious entry must be even more closely examined;**
- **Were standard universally coded keys utilized to gain access. This would include elevator keys, power panels, telephone panels, lockers, gates, alarm panels, and other access control devices that are keyed alike throughout a geographic area or industry. An excellent example are the elevators in New York state and New York city. Ordinances require that all elevators within the five boroughs of New York be keyed alike for fireman access. Likewise, a state law requires all elevators anywhere in New York be keyed alike (other than New York City).**

If one or more employees could have caused the loss, either intentionally or through negligence, then consideration of the level of employee compensation versus the potential for compromise must be evaluated. That is, an overall security rating of the system must be undertaken and compared to the likelihood that an employee was responsible.

- **Could an employee have left duplicate keys in a desk drawer or other unsecured location that would allow**

access;

- **Although an employee states that it is certain that he or she locked a specific mechanism, is there a possibility that in fact the employee forgot or intentionally caused the lock to remain open. This is especially relevant if insurance coverage is based upon the affected area being secured;**

The burden of proof in any given loss should also be considered. Does the insurance company require that "approved" locks be utilized in order for coverage to be in effect? If so, are such locks in use?

- **Was the suspect mechanism locked or unlocked when the intrusion was discovered. If the lock was picked, generally it will remain in the unlocked position, especially in higher security devices. It is the author's experience that most intruders will not take the time to repick a lock to the original position. However, this is by no means a certainty, especially if the thief is attempting to shift blame to others or conceal the fact altogether;**
- **How often is the lock operated each day. This will provide information for the forensic examiner regarding internal tool marks;**
- **Has anyone inserted a key into the lock since the suspected entry;**

It is extremely important to determine if anyone else has used the lock since entry occurred. This is critical when looking for tool marks, metal fragments, and debris that may have been transferred from the user of the key to internal components.

24_2.2 Purchase, Installation, and Service

- **Where and when were locks purchased;**
- **Were they factory or locally keyed;**
- **Who installed the locks;**
- **Is there any coincidence between recent burglaries and the use of a common locksmith;**
- **Who maintains the locks;**
- **Are lock service records kept that include system coding data;**

- **How are records stored and at what location;**
- **If kept on computer, are files secure;**
- **Were locks originally registered with the factory. If so, have there been any recent additional key requests of the manufacturer or local locksmith.**

24_2.3 Security Rating of the Lock and Lock System

- **Are high-security locks installed. Does the lock carry a UL 437 or equivalent EC rating;**
- **What is the tumbler orientation of the lock (vertical or horizontal) and how does this affect pick resistance;**
- **Are security pins (serrated, mushroom, spool) employed. Are telescoping pins present for extra security;**
- **Does the lock utilize a paracentric keyway for added pick resistance;**
- **Has special pick or decoding tools or procedures been developed for this type of lock. Are there known picking or bypass techniques;**
- **What is the pick resistance or ease with which the lock can be bypassed;**

Pickability or ease with which a lock can be picked. Courtesy of Hans Mejlshede.

- **Do locks utilize high-tolerance components, factory original keys, and incorporate anti-pick features;**

24_3.0 Bypass and Compromise of Locks: Internal and External Components

Locks may be surreptitiously bypassed through external means such as picking and impressioning or by internal manipulation or alteration of components.

24_3.1 Internal Bypass

This requires that the lock be taken apart, altered, and reassembled without any visible outward signs. Locks may be

internally bypassed by:

- **Altering the pin-stack prior to entry:**
  - **removing one or more tumblers to reduce pick resistance;**
  - **adding one or more tumblers to create multiple shear lines;**
- **Manipulation of lock mechanism;**
- **Removal of retaining screws from cylinder;**
- **Disassembled, decoded, and reassembled;**
- **Drilling and repair not visible to naked eye.**

24_3.1.1 Altering the Pin-Stack Prior to Entry

The pin-stack may have been altered for several reasons, all of which may reduce security. Alterations include:

- **Removal of security tumblers;**
- **Addition of pins to increase the number of shear lines (and reduce pick resistance);**
- **Placement of extra master pins within the lock to allow a different key (cross-key) to open the lock.**

The addition of master pins will allow an individual to be in possession of a key for a given lock that does not match the change key. Thus, a defendant might claim that he had no knowledge that the key would open a lock, and in fact the key should not have worked but for the addition of pins.

24_3.1.1.1 Removal of One or More Tumblers to Reduce Pick Resistance

One or more sets of tumblers may be removed from a lock to reduce pick resistance. Security tumblers may likewise be replaced with standard lower or upper pins.

24_3.1.1.2 Adding One or More Tumblers to Create Multiple Shear Lines

Master pins may be added to individual pin stacks to increase the number of shear lines (and cross-keying combinations). This will reduce pick resistance.

24_3.1.2 Manipulation of Lock Mechanism

Locks may be manipulated in a variety of ways to accomplish opening. Picking, impressioning, 999 rapping, visual decoding, use of a blank key, specialized decoding and other forms may all be employed. In one instance, a European lock manufacturer assembled pin tumbler locks at two different facilities, which resulted in the use of slightly different pin diameters for top and bottom pins, allowing the lock to be easily opened with a blank key. As described in chapter 29, a blank may also be utilized to pick the lock.

24_3.1.3 Removal of Retaining Screws from Cylinder

The setscrews may be removed or loosened from a cylinder, permitting release or rotation to actuate secondary locking mechanisms.

24_3.1.4 Disassembled, Decoded, and Reassembled

Locks may be disassembled, decoded, and then reassembled in order to derive change keys or master keys.

24_3.1.5 Drilling and Repair Not Visible to Naked Eye

Locks may be drilled, opened, and repaired without leaving any visible trace. This is especially true in the case of combination locks used in safes. Such techniques may also be employed in penetrating high-security locks.

24_3.2 External Bypass

External bypass encompasses any action done to the lock through external manipulation or usage that does not require disassembly or modification of internal components. Locks may be externally bypassed through:

- **Use of a key;**
- **Decoding (visual, use of shim wire, extrapolation of top level master key, or special tool);**
- **Manipulation;**
- **Bypass of secondary locking bolt or locking**

mechanism;
- **Drilling and replacing the entire lock;**
- **Using an unauthorized key;**
- **Prior replacement of one or more locks.**

The following discussion summarizes external methods of bypass and associated issues.

24_3.2.1 Use of a Key

Obviously, the simplest way to open a lock is by a key. The many ways to obtain keys are described in later sections.

24_3.2.2 Decoding

Decoding procedures take many forms. Information, however derived, is used to produce a working key. Decoding may require that the lock be disassembled, although there are some sophisticated methods that will leave no trace. These methods include:

- **Visual observation of wafers, levers, or tumblers;**
- **Use of a borescope inserted into the keyway;**
- **Use of special plastics and metals to sense tumbler position;**
- **Use of shim wire decoders, either through the pin chambers or around the plug;**
- **Use of pressure-sensitive materials.**

24_3.2.3 Manipulation

A lock may be opened through many forms of manipulation that include picking, impressioning, 999 rapping, and decoding. Detailed information regarding each of these procedures is presented in other chapters of this text. A summary will be provided here.

24_3.2.3.1 Picking

This process involves the insertion of specialized tools into a lock in order that the tumblers can be moved to shear line to allow rotation of the plug. As shown in **Chapter 29**, there are many different types of picks, depending upon the technique applied and the preference of the user. Locks may be picked

using conventional techniques with a pick gun or snap tool, by special pick tools, or by an electric impact pick. Generally, picking will leave internal marks, discussed more fully in later chapters. It is not, however, axiomatic that tool marks will remain. Depending upon the skill of the operative, the type of picks employed, and the composition of the pin-stack, marks may or may not be visible.

Picking is accomplished by moving individually or in concert each tumbler, disc, wafer, lever, or ward to its shear line position. The concept is very simple. In practice, of course, many factors affect the ability to pick a given lock.

24_3.2.3.2 Impressioning

This technique allows keys to be produced for locks without requiring disassembly. There are several different methods, depending upon the mechanism and personal deference. These include:

- **Standard techniques;**
- **Use of foil in dimple locks;**
- **Use of a special brass, lead, latex key, or hybrid key surface.**

Impressioning will generally leave internal tool marks. See **Chapter 30.**

24_3.2.3.3 999 Rapping

This is a procedure to open pin tumbler locks. It requires that a specially cut blank be inserted and “rapped” in order to create shock waves so that tumblers might be bounced above shear line. The technique is essentially identical in theory to the use of a pick gun.

24_3.2.4 Bypass of Secondary Locking Bolt or Locking Mechanism

Depending upon the design of the lock and its interface with the bolt works, strike, and other components, bypass of such systems can be quite simple. For example, a piece of spring steel may be inserted through the keyway and can then be used to rotate the cam in order to engage the strike release.

24_3.2.5 Drilling and Replacing the Entire Lock

If the original lock has been drilled, removed, and replaced, added difficulty might be encountered in detection.

24_3.2.6 Prior Replacement of One or More Locks

Locks may have been removed and replaced without the necessity of drilling as described above. For example, the author has encountered many cylinders that have loose or missing setscrews in metal door frames. These locks can be easily removed, decoded, or replaced.

24_3.2.7 Using an Unauthorized Key

If an unauthorized copy of a key has been utilized, it may be very difficult to detect and prove. There are certain methods, however, that may be employed. See the section on Keys in **Chapter 27**.

24_3.3 Queries Regarding External and Internal Bypass

- **Could simple tools have been utilized to externally manipulate locking mechanisms? For example, could an opening tool have been inserted into a mail slot in the door in order to gain access to the bolt works. Specially designed tools slip under the door, climb vertically on the locked side, and grip the handle to allow opening. A search for tool marks should be made if such access is suspected or possible;**

Mail slot bypass device. Courtesy of Hans Mejlshede.

- **Does examination of the strike and lock case indicate that they are functioning properly, correctly installed, and fitted;**
- **Are there any missing components;**
- **Are there any other obvious possible methods of entry;**
- **Could the hinge pins have been removed and replaced;**
- **Is the lock, or any component, missing;**
- **Is the cylinder loose, indicating possible**

manipulation;

- **Determine if there is access to setscrews for mortise cylinders. Can the entire cylinder be rotated, to allow the bolt to be withdrawn or removed. Have retaining screws or pins been loosened or removed in order to facilitate rotation;**
- **Check the threads on any mortise locks for wear. Look for scoring on the grooves that would indicate that the lock was forcibly spun against the setscrews. Feel whether the cylinder is loose or can be rotated;**
- **Check for marks on the side of cylinders and guard rings, indicating that tools were used to forcibly rotate the lock. Look in the side channel of the cylinder, for scratches, indicating forced rotation. Also, look for a broken setscrew tip in the door frame. The screw may have been sheared through torque and then replaced;**

Tools can be made to wrench the guard ring free. A piece of pipe that fits over the guard ring and cylinder, with a bolt through it to allow tightening and a rod for torque, works quite effectively.

- **Check for color differences in the metal of the lock and housing caused by rust or corrosion. This could indicate that the lock has been moved after being in place for a long time. Then, check maintenance records to see if the cylinder has been repaired recently;**
- **Check the surface of the cam that faces the inside of the keyway. Bypass can be accomplished using a piece of spring steel with a sharpened end, by forcing it to the back of the lock, then rotating the mechanism;**
- **Was the plug found in a picked position. In the case of a removable core lock, is the plug picked to the control shear line;**
- **Can the plug be rotated using a screwdriver, knife, or similar object, without inserting a key. If so, this would indicate that most if not all tumblers have been removed, possibly for maison keying;**
- **Does the system rely upon direct or indirect locking**

action, making manipulation more difficult;

- **Is the pin-stack correct. Do all keys fit the lock. Are there any extra pins. Have pins been removed. Are security pins, bearings, or special tumblers used in the target lock in the same proportion or configuration as in other similar locks within the facility;**
- **Are there any fingerprints on the exterior surfaces of the lock or on internal components. Are there any handprints or palm prints present on any surface affecting entry;**
- **Do the physical characteristics of the suspect lock match all other locks within the facility that were installed at the same time;**
- **Do pins appear to be more or less worn than in similar locks at the location;**
- **Is there any corrosion on the suspect lock. If so, is it consistent with other locks in the facility.**

24_3.4 Bypass and Compromise of Locks: Using Keys

There are many ways that a lock can be bypassed; one of the simplest means is to use a key. This is perhaps the most important threshold question to resolve. If it appears that a key was used to gain access, as opposed to other means of surreptitious entry, then the inquiry must focus on whether the key was intentionally or accidentally acquired.

Keys (and their coding information) may be obtained through a variety of schemes. Any inquiry involving the possible use or compromise of keys will of necessity require an analysis of the key system in place for a given lock, as well as a consideration of many interrelated factors.

Master key records. Courtesy of Hans Mejlshede.

24_3.4.1 Queries Regarding Use of Keys

- **Could keys have been lost, left in a desk or other area, or misplaced that were later found, used, and then returned. Are keys missing or stolen;**
- **Are there any key control procedures to determine:**

- **Who has keys for which locks;**
- **Accountability for all duplicate keys;**
- **Accountability for all blanks;**
- **Accountability for all old keys that are presently out of service. This is especially important in the case of restricted keyways, because keys can be cut down or built up to create a different bitting pattern;**

- **What is the procedure relating to former employees;**
- **Are duplicates kept for all locks, and if so in how many different locations;**
- **When were specific locks last rekeyed;**
- **How many keys are in inventory for any specific lock;**
- **Is a record of loaned keys maintained;**
- **Is there an access log to key cabinets and areas where keys are maintained and duplicated or locks serviced;**
- **Could someone have let an unauthorized individual into a secure area. Is contract maintenance, cleaning, or work staff utilized;**
- **Could change keys or master keys have been loaned, even briefly, to open a door. This is especially important in hotel thefts where guests often approach staff, claiming that they lost or forgot their key or left it in the room. Possession of a key, even for a few seconds, can yield code numbers and allow an individual to visually decode the key or make an impression;**
- **Are there secondary access keys for emergency use or for lock bypass. For example, many hotel card locks also have bypass keys for maintenance and security staff;**
- **Does the lock incorporate special mechanisms, such as the Corbin split ring, to prevent cross-keying;**
- **Are restricted keyways employed;**
- **Does the facility utilize a complex and integrated lock design, incorporating electronic + mechanical, or mechanical + magnetic, sidebar, or similar hybrid systems;**
- **How complex and secure is the master keying system.**

Is cross-keying prevented. How many keying levels are present;

- **Is there one top level master key for all cylinders within the system? What locks are master keyed? Can the decoding and extrapolation procedures explained in chapter 31 regarding the use of a change key to decode the TMK have been utilized;**
- **What master key scheme is employed within the facility: total position progression, rotating constant, Page, or was a non-standard system used to generate differs;**
- **Are there more than two bottom pins in any chamber, indicating that a non-standard master keying scheme was employed;**
- **Do locks have instant rekey capabilities that may in fact lower the security rating and subject them to bypass;**

24_3.5 Keying System Analysis

Keying system analysis requires an evaluation of keys in terms of keying differs, master keying, key control, codes, and storage of system data. Tracing the origin of keys back to a specific lock is also possible and is covered under **Forensic Analysis of Locks: Keys.**

The following material examines significant factors relating to keys within a keying system and specific issues that must be considered.

24_3.5.1 Keying System

- **Has the lock been keyed individually, or is it part of a complex keying system. If complex, is there the potential of cross-keying;**
- **How many levels of master keying are employed, and does the system employ recognized keying schemes to limit the number of cross-key combinations;**
- **Is a maison keying system in place. If so, locks are generally quite easy to pick; their security is very low. In some maison systems, almost any key can be inserted, jiggled, and made to turn the plug;**
- **Are removable or interchangeable core systems in**

use. Are there any missing cores. Could the control key have been compromised.

24_3.5.1.1 Master Key Levels

- **How many keying levels are present within the suspect lock;**
- **Was the system devised using an industry-recognized program following accepted keying standards. Are standard code depths utilized;**
- **How many sectional keyways are employed within the system;**
- **How many master keys are unaccounted for;**
- **Who has been issued master keys;**
- **How difficult are the keys to decode, especially the top level. What is the code for the master key;**
- **How easy would the lock be to pick or bypass;**
- **How long has the present master key system been in use;**
- **When was the change key last altered;**
- **Are any locks capable of instant rekey or reprogramming;**
- **How many locks are keyed alike;**
- **Have all individuals having keys that would fit the suspect lock been identified;**
- **Are the same keyways and combinations used in different locations, either by design or by accident;**

The system must be examined to determine if there are duplicate keys used in different areas within a large facility or complex by more than one individual working for the same entity. It may also be possible that an individual with no connection whatsoever to the subject location will have had a key that opened a specific lock by accident.

24_3.5.1.2 Number of Differs

The differs for a given lock should be calculated from the number of tumblers, depth, and spacing. This will provide an index as to apparent security. Knowledge of whether a maison keying system is used will also indicate the level of security. The

number of differs or tumbler combinations and the probability of a random opening must be considered. The use of the same keyway, the length of time that a given keyway has been in use for a given area, and cross-keying potential must all be factored into the evaluation.

24_3.5.1.3 Cross-Keying Potential and the Number of Incidental Master Keys

An analysis of the keying system will reveal whether an established scheme was utilized to reduce or eliminate cross-keying.

- **Is there any protective hardware to prevent cross-keying;**
- **What is the potential that a key not associated with the specific system will open the lock. This will require a complete examination of the keying scheme to determine all possible cross-keying combinations;**
- **How many incidental master keys will open a specific cylinder.**

24_3.5.1.4 Duplicate Keys

- **How long has the same key been used in a given lock;**
- **When was the last time the lock was rekeyed;**
- **Have keys been lost;**
- **How many keys may be in circulation for the lock. In Denmark, for example, if it can be proven that over ten keys are unaccounted for, then no insurance coverage will be in effect.**

24_3.5.1.5 Age of Lock

- **What is the vintage of the lock and keyway. When was it first introduced. This may give an indication of the number of keys in existence on a global basis.**

24_3.5.2 Codes and Code Numbers

Keys can be produced by number. Direct or indirect code numbers stamped on keys or cylinders, as well as internal identification

numbers, can allow the generation of factory original keys. Key codes can be found on a system list, can be derived by decoding the key or the lock, or can be obtained from the manufacturer. Locks may be compromised by obtaining their direct coding information. This will allow keys to be surreptitiously created. Data for a given lock may be obtained by various means, including:

- **Gaining physical possession of the key and copying it;**
- **Visually decoding the bitting, then utilizing that code for creation of a duplicate key at a later time;**
- **Viewing code numbers stamped on the key;**
- **Obtaining codes from an internal system list, from the locksmith who installed the system, or from the manufacturer;**
- **By impressioning;**
- **By use of a borescope to read the wafers, levers, or tumblers;**
- **By visual external decoding of the tumblers;**
- **By disassembling the lock;**
- **By shim wire decoding.**

24_3.5.2.1 Sources for Codes

Codes may also be determined by taking the lock apart and measuring tumblers, or by the use of special decoding tools that use shim wires as manufactured by Falle-Safe and others. Keys can be visually decoded, especially if there are distinct depth levels. In this connection, the number of depths utilized by the manufacturer should be considered.

- **Determine if the keyway for a particular lock is listed on the standard HPC, Silca, or other manufacturer key reference used in conjunction with code- cutting machines. The HPC HKD-75 handheld decoder, for example, has data for all standard keyways to allow rapid decoding.**
- **Was the lock removed, either in the process of gaining entry or prior to entry, to obtain coding information or to produce keys for later entry;**
- **Was the original lock removed and replaced by a**

different cylinder;

- **Is there a possibility that more than one lock has been removed or tampered with, either in the same or different areas of the facility;**
- **Could locks have been removed or stolen on prior occasions, in contemplation of the present incident;**
- **Is it possible to disassemble one lock and derive the master key coding for the entire facility, including the suspect lock. It is generally impossible to decode one lock and successfully produce a master key in a conventional system. This is because there may be more than one chamber containing master pins or more than one master pin for each chamber.**

Depending upon the construction of the lock and the requirements of the keying system, a lock may have several different shear lines. In that event, many combinations may be generated before the proper system master code could be determined. To work on a cylinder that is master keyed, both the change key and master key are required. However, it is possible to decode certain **positional** master key systems with only one lock. See **Chapter 11.**

24_3.5.3 Key Duplication and Generation

Keys can be produced using many different processes of duplication and generation techniques.

24_3.5.3.1 Could Keys have been Copied Surreptitiously

Keys can be copied by physical duplication through the use of a key machine, by code, by visual decoding, by silicone, wax or clay impression, by photograph, by tracing, or by the use of a copy machine. See **Chapter 8** for a detailed discussion of copying techniques.

Keys can be copied by taking a 1:1 image using a copier machine. Courtesy of Hans Mejlshede.

24_3.5.3.2 Can Keys be Easily Duplicated by Machine

It is imperative to determine the availability of blanks. It may also be prudent to check with the local distributor of the type of lock under examination in order to determine if there are many other customers in a given area using the same keyway.

- **Do locks utilize a standard or restricted keyway. If restricted, what is the security level of restriction, and what does the term "restricted" really mean;**
- **If restricted keyways are used, can blanks be milled or simulated using a similar blank;**
- **If sectional keyways are utilized within a large system, how easy is it to modify one section for use in another. If this is possible, examine other sections for the same or similar key code;**
- **Are restricted keyways in use by other non-related lock owners;**
- **Does the manufacturer maintain key code control and coordination with all customers in the area;**
- **Can the manufacturer trace keys to an owner through registration;**
- **Who stocks or sells blanks for locks that have been compromised;**
- **Are blanks maintained on premises. Can they be obtained at the local hardware store or locksmith;**
- **Is there anything special about the keyway.**

24_3.5.3.3 Missing Keys used to Produce Different Keys

- **Are there any keys that are missing. If so, could these have been utilized to produce a key for the suspect lock.**

24_3.5.3.4 Special Key Cutting Machine

- **Was a special cutting machine required to produce keys to a given lock. If so, who manufacturers such a machine. Who has one in the local area. The EVVA 3KS system, for example, requires a machine costing in excess of $150,000 to duplicate its**

complex laser-track keys. The likelihood of conventional duplication is virtually nonexistent. However, a simple clay impression is easy to accomplish.

24_3.5.3.5 Could Keys have been Borrowed and Copied

- **Was a copy or extra key made recently. If so, at what location. Could the operator have made a duplicate key without the knowledge of the customer;**
- **Can an examination be made of source keys in an attempt to determine if copies were made. For example, the author reviewed evidence of key copying from a rental car company where Mercedes-Benz automobiles were stolen in Germany. It was determined that there were distortions in the guide pin of the key cutter that were reproduced on the copied keys, thus proving that copies were made from originals. See subsequent material regarding forensic analysis of keys.**

24_3.5.3.6 Suspect Having Access to Keys

- **Who had access to keys that may have been copied or duplicated. Are extra keys kept in a secure area or in a locked key case. If keys are kept in such a key caddy, how difficult is the lock to pick. Generally, most key containers utilize wafer or tubular cam locks that are easily bypassed;**

- **Did the perpetrator have access to blank keys, out-of-service or old keys, or missing keys with the same keyway that could have been used to produce a key for the lock.**

24_3.5.3.7 Key Control for a Specific Lock

Each manufacturer establishes and implements certain key control guidelines, criteria, and technical standards for a lock. This is to protect their legal standing to restrict the sale and distribution of keys, key codes, blanks, and key duplicating machines. If no patent or copyright protection is in force, then

lock and key manufacturers have no proprietary or intellectual property rights that would prevent others from making facsimile products. Key control is a significant component of any investigation involving the surreptitious bypass of a lock. The following issues must be pursued:

- **Is patent or copyright protection for the keyway and keys in effect. Such protection will restrict the availability of and trafficking in blank keys through unauthorized channels because of the heavy penalties associated with infringement;**
- **Are knockoff or facsimile blanks available in the area where the suspect lock is installed;**
- **Are proprietary and unique key sections available for complex installations. This would include related master key sections.**

24_3.5.3.8 Does the Lock Mechanism Employ Secure Keying Techniques

- **Can an individual with limited access to other similar keys modify them to operate more locks than intended**

24_3.5.3.9 Does the Lock have a High Key Differing Potential

Often, the blade depths for any bitting surface is divided into ten steps of approximately .015″ each. When the tolerance at shear line exceeds .005″, a bitting step of .015″ is too small to offer any real security. Bitting steps of less than .060″ invite cross-keying problems. If a master key system is in place, then several million theoretical key differs must be available to yield only a few thousand non-interchangeable keys, especially in many of the high-security locks.

24_3.5.3.10 Is the Lock Recognized as a High-Security Device

Is there universal government acceptance of the lock for high-security applications. As detailed in **Chapter 10**, the prime criteria for a security rating, especially UL 437, includes pick resistance, key control, and resistance to penetrating tools.

CHAPTER TWENTY-FIVE: LOCKS AND FORENSICS

Forensic Examination: Specifications, Operation, and Security

25_1.0 Forensic Analysis of Locks and Keys

Methods of forensic analysis. Courtesy of Don Shiles.

Information during a forensic investigation. Courtesy of Don Shiles.

Chapters 25-26-27 deal with the forensic examination of locks and keys in the laboratory. We begin with a summary of precautions and procedures designed to safeguard evidence that is to be evaluated and to preserve vital information about such evidence. Data is then presented regarding the individual lock components to be examined and each specific type of forensic examination to be performed. The author is indebted to Hans Mejlshede for his assistance in research for much of the material in this chapter. Many of the graphics and audio segments that have been included within Chapter 24-27 were prepared by Mr. Mejlshede.

Chapter 25 will also provide information regarding the preliminary analysis of a lock to determine its operation, specifications, and security.

Chapter 26 will detail the techniques and analytical criteria for developing tool mark and trace evidence left in a lock. **Chapter 27** will look at keys from the perspective of identification of suspects, locations, and property. Generally, disassembly of the lock will be conducted in a laboratory environment. See **Chapter 16** for detailed disassembly procedures. The analysis of locks for possible covert entry is one of the primary functions of the forensic examination.

The Forensic locksmith is often called upon to investigative covert entry. Courtesy of Hans Mejlshede.

25_1.1 Preliminary Considerations and Precautions

If a forensic examination is to be performed, additional precautions need to be taken both at the scene and in the laboratory. It is important that all evidence be preserved from the crime scene. Forensic locksmiths should be cautioned that if cylinders have been attacked, they should be replaced, and the suspect components preserved and transmitted to the laboratory for further analysis.

It is essential to save the pins from a lock that has been the subject of a burglary attack. Courtesy of Hans Mejlshede.

Preliminary issues in the examination of a lock. Courtesy of Don Shiles.

25_1.1.1 Precautions and Procedures at the Scene Prior to Laboratory Examination

- **Be certain to log which way the cylinder plug must be rotated to open while in the door. Log this information and draw an arrow on the face of the lock or on the evidence tag;**
- **Seal both ends of the cylinder with tape so that no material can leave or enter the lock;**
- **Identify each lock to its source location;**
- **Photograph each lock taken from the scene prior to disassembly;**
- **If electronic locks are involved in the investigation, be certain to download the contents of memory to preserve audit trails of entry/exit history. Determine if external electrical supplies provide power to run computers within locks; the removal of such power may erase volatile memory. Determine if there are onboard backup batteries such as lithium cells, prior to disconnection of any power source;**
- **All telephones associated with locked areas should be checked for redial,**

stored number, and last number dialed capabilities. If the telephone is so equipped, this information should be captured and downloaded prior to using the telephone or removing power from the instrument;

- **Be certain to document whether cylinders have been repaired after a burglary or loss. In such cases, new cylinders should be installed, and the original mechanism retained as evidence;**
- **Draw an arrow on the cylinder to indicate which way the plug was turned to open the lock;**

Removal of cylinder and its analysis must be done correctly. Courtesy of Hans Mejlshede.

25_1.1.2 Precautions and Procedures in the Laboratory

The following checklist provides minimum guidelines as to required documentation prior to conducting a forensic analysis of any lock. There may be some overlap in procedures between examinations.

- **Be certain that the work area is clean and devoid of other lock components or contaminants. If the examination is being conducted by a forensic locksmith, it is recommended that the normal work area not be utilized;**
- **If the components of the lock are to be cleaned, be certain to inspect them first. There may be valuable evidence in the appearance of grease or other lubricants that may be lost in the cleaning process.**

Care must be exercised in cleaning of components. Courtesy of Hans Mejlshede.

Use of WD-40 to clean and lubricate. Courtesy of Hans Mejlshede.

A clean work area for the forensic locksmith is a necessity. Courtesy of Hans Mejlshede.

- **Verification that the lock can be destroyed, if necessary, in order to empty chambers and to examine**

interior portions of the plug. This may be especially important in the case of padlocks if they cannot be disassembled;

- **All observed marks and tracks, regardless of origin:**
  - **Any marks caused to be made by the examiner upon any internal or external component of the lock;**
  - **The presence of marks on each pin;**
- **All foreign materials in the plug, including metal fragments, grease, oil, graphite, paper, glue, foreign metal;**
- **Identification of each pin within each pin-stack, noting the order and sequence within the plug;**
- **For each pin:**
  - **the diameter;**
  - **the color;**
  - **the design of the bottom and top (square, rounded, chamfered, pointed);**
  - **the type of pin (driver, wafer, bottom, security);**
  - **the presence of ball bearings;**
- **Documentation of all steps performed in the examination process;**
- **Mark the side of the plug to denote case information;**
- **Note and document the proper cam orientation. In most cylinders, the screw holes are countersunk from the outside;**
- **Verification that the lock was sealed when received;**
- **Upon receipt of sample, with cover letter requesting specific examinations, documentation of all identifying data regarding the lock, including:**
  - **Manufacturer;**
  - **Model and any numbers stamped on the side of the cylinder;**
  - **Year when model discontinued, if applicable;**
  - **Generic type of lock: warded, lever, wafer, pin**

tumbler, combination, electronic, hybrid, instant rekey;

- **Code numbers stamped on the lock;**
- **Keyway identification;**
- **Lock shell material;**
- **Plug material;**
- **Pin tumbler, lever, or wafer material;**
- **Security rating of lock;**
- **Estimated age of the lock;**

- **Is the lock new or worn, and degree of use, expressed on a 1-6 scale:**

1	***new, no visible wear***
2	***very little use, high tolerances***
3	***average wear***
4	***heavy use, high wear***
5	***old, low tolerance***
6	***unreliable erratic operation***

- **All components should be photographed. Frame sequence numbers should be logged with a description. All photographs should be made in the same manner to allow an accurate comparison;**

- **Photograph of:**

  - **all items received with cover letter;**
  - **cylinder, front view;**
  - **cylinder, side view;**
  - **bitting of key to allow decoding from photograph, if necessary;**
  - **all internal and external parts, both prior to removal from the lock and upon examination;**

- **Sequentially numbered negatives or frames for all photographs. Use one film roll for each case, or imprint case number and sequence number on each photograph;**
- **Utilize a databack or other time-date generator on the camera that will produce the time, date, and frame or case number. Be**

certain not to utilize an orange or red background when using time-date backs, due to the imprint color utilized;

- **Choose a high f-stop for better depth of field when shooting microphotographs.**
  F22 will yield significantly better photographs when shooting marks on pins.

- **Color coding of each tumbler, if relevant, to document position in plug or shell. Often, pins are also factory color-coded by length. This information needs to be recorded. The author may also color-code individual pins, by position within the plug, irrespective of the factory-coding scheme. From the front of the plug, pin 1=brown; pin 2=red; pin 3=orange; pin 4=yellow; pin 5=blue; pin 6=green; pin 7=violet; pin 8=grey; pin 9=white;**

- **Pin-stack length and diameter for each chamber, and insure that top and bottom pins have the same diameter;**
- **All pin-stack permutations in order to determine every depth combination that will open the lock. This will include all change keys, master keying levels, and cross-keying possibilities;**
- **The surface design of the lower tumbler that contacts the bitting surface (rounded, chamfered, pointed, square, steel bearing);**
- **Inventory of all components that have been examined and which are contained within the lock. An inventory should include the physical number of parts for each category listed below, as well as identification of the part itself, and notation of any missing parts. The parts list should include:**

- **Springs;**
- **Plug and plug cover;**
- **Wafers, levers, tumblers (including upper, lower, and master pins);**
- **Secondary pins;**
- **Ball bearings;**
- **Keyway guides;**

- **Spring-retaining cover;**
- **Setscrews for chamber sealing;**
- **Tailpiece and screws;**
- **Anti-drill pins;**
- **Sidebar and springs;**
- **Shell.**

- **Documentation regarding the orientation of sidebar inserts (such as in ASSA locks);**
- **Check for foreign object at the front of the keyway, placed to delay entry of authorized individuals in order to give illegal entrants notice and time to flee;**
- **Setup a similar cylinder pinned to same combination. This cylinder may also be utilized as a control for picking;**
- **Setup similar cylinder, pinned to same combination,and picked using 999 keys;**
- **Availability and use of modeling clay to hold components for examination and photography.**

25_1.1.3 Special Precautions in the Laboratory

The criminalist must be certain that the following procedures are followed to insure valid results, protect against the destruction or contamination of evidence, and to thwart defense objections:

- **If analyzing electronic locks such as utilized in hotels, be certain to verify whether the lock maintains an audit trail of transactions. If so, download all information prior to disassembly;**

- **Determine how many pin chambers the lock contains and if there is a pin-stack for every chamber. This is very important to learn prior to disassembly, because the lock may be a six tumbler mechanism but only loaded for five pins;**

- **If the plug is improperly withdrawn from the shell (removed without rotating at least 30º from shear line) then a top pin can drop into an empty bottom chamber. This will generally destroy a spring, make**

removal difficult, and mark internal surfaces;

- **Use extreme caution when taking a cylinder apart not to disturb the rotational position of pins. Although this may not be relevant in some investigations, the orientation of pins can be extremely important to document certain types of picking techniques. Thoroughness also dictates the practice;**

Forensic implications of using a shim to open a lock prior to analysis. Courtesy of Hans Mejlshede.

- **If a dimple lock is to be taken apart, check to be certain that all pins are in pin chambers prior to disassembly. In certain instances, if a lock has been picked and the plug remains in that state, drivers can drop out of their chambers. Likewise, if the plug is rotated in a profile cylinder to what would normally be the position where springs and drivers would be ejected, pins can fall into the open area;**
- **Pin-stack combinations must remain intact. A mix-up in the order of pins can be disastrous. This is especially true in the case of master pins;**

- **If the lock is to be cleaned prior to disassembly, be certain to keep the wash that was utilized. This will retain any foreign materials that are present. The author does not believe that washing should be done;**
- **Use nylon, plastic, or wooden tweezers or tongs. Standard tweezers may also be coated with Plasti-Dip or other silicone-based materials;**

Use of plastic tweezers. Courtesy of Hans Mejlshede.

Use of rubber or silicone-coated tweezers. Courtesy of Hans Mejlshede.

- **Use setup tray to maintain the integrity of tumblers;**
- **Prior to disassembly, be certain to examine the plug for brass debris;**

- **Setup the identical lock body (duplicate) with the same springs and drivers using new pins to test tension, metal loss, and marking.**

25_1.2 Forensic Examination of Locks: Specific Components to be Evaluated

Examination of a lock and disassembly. Courtesy of Don Shiles.

The following items, parts, and components must be closely examined and inventoried anytime a thorough forensic examination for physical evidence of bypass and operational characteristics is to be conducted:

- **Cylinder (internal and external);**
- **Plug;**
- **Pins, wafers, levers, discs;**
- **Springs;**
- **Plug and Cylinder (together);**
- **Key, plug, and pins (together);**
- **Pins and shell (together);**
- **Brass spring retainer;**
- **Plug-securing means: screws, arc ring, cam.**

25_1.2.1 Examination to be Conducted

Six primary forensic examinations and evaluations may be conducted, depending upon the evidence sought. They are:

- **Lock specifications and data;**
- **Operation of the lock;**
- **Security of the lock;**
- **Indication of manipulation and bypass: tool marks;**
- **Material transfer;**
- **Keys.**

Was the lock picked? Courtesy of Don Shiles.

Within the category of **Indication of manipulation and bypass,**

there are four subcategories:

- **Method of entry and whether destructive or non-destructive;**
- **Presence of tool marks and how they were created;**
- **Type of tools used to effect bypass;**
- **Skill of the perpetrator.**

The remainder of this chapter will examine and evaluate the operation, specification, and security of a lock with an emphasis upon underlying theories and procedures. The reader will recognize that some material has been repeated in slightly different form from earlier portions of **chapter 24** based upon the specific emphasis of each section. Some material will overlap between areas of inquiry. This is especially true in the case of tool mark examinations. Information presented in each of the areas of examination can and often will relate to the presence or absence of marks.

The author has attempted to organize the data in the most relevant and coherent form. However, the reader must consider all information in the examination process, in order to look at the lock as a composite of its individual components. Finally, it will be noted that details of dissecting the plug have been placed in the section dealing with tool marks rather than in the preceding text, because the procedure is germane to that specific topic.

25_1.2.2 Queries During Analysis of Locks and Keys

Examination of a lock and marks that are visible. Courtesy of Don Shiles.

The examiner will be concerned with the following issues during the analysis of a lock, keys, and associated hardware:

- **Construction of pins;**
- **Trace pick gun marks from the tip of the gun to the depressions on the pin;**
- **Match striae created by the pick upon the pin or chamber;**
- **Analysis of the area of marking on the pin, which may**

indicate the bypass technique;

- Angle of attack of bypass tool and location of the lock as to the type an depth of the marks that have been created;
- Which direction does the lock open;
- How often is the lock used on a daily basis;
- Type of metal and hardness and oxidation potential;
- Number of individual marks on each pin;
- Relationship between marks on each pin;
- Has the cylinder been replaced;
- If a 999 key was utilized, where should marks appear within the keyway;
- Have retaining screws been removed from the back of the cam, indicating service or replacement;
- Has lacquer on the cylinder been disturbed from the factory original condition;
- Is the cylinder factory OEM;
- Have the top pins been replaced. Do they conform to factory original specifications;

Changing or removal of top pins. Courtesy of Hans Mejlshede.

- Does the lock utilize balanced drivers to prevent the use of a comb;
- What is the length of the lower pins, and would their length require the use of a specific tension wrench, or placement of that wrench at a certain point in the keyway;
- Are there excessive markings for the method of bypass, indicating that an attempt has been made to simulate such marks in order to mask a crime, or mask a modus operandi;

An attempt may be made to mask pick marks so that the perpetrator is not identified. Courtesy of Hans Mejlshede.

Many car thefts are simulated for insurance claims. Courtesy of Hans Mejlshede.

- Are there markings only on the first two or three pins, indicating an attempt to mask criminal activity;
- If the investigation involves an insurable loss, has there ever been any history of late payment of premiums;
- If a burglary, is the item or items of such value as they would be stolen in the manner indicated;
- All keys for a specific lock should be inspected for irregularities;

Obtaining all keys that fit a particular cylinder. Courtesy of Hans Mejlshede.

- **The security of a lock and the difficulty of bypass will directly correlate to the number of markings on the pins and chambers;**
- **Is the lock master keyed;**
- **Is there any metal residue on the floor under the lock, caused by picking or drilling;**
- **Is there a different level or wear on different locking components, such as latches and bolts, indicating that certain parts have been replaced as part of a false insurance claim or other ruse;**
- **Is the method of entry or bypass different than the "usual" technique in such cases;**
- **Are there marks on the back of the cylinder or cam;**

Marks on the back of the lock from bypass. Courtesy of Hans Mejlshede.

- **Analysis of wear patterns on pins;**
- **Does it appear that a pick gun has been utilized, based upon rotation patterns on the pins;**
- **Is there evidence of a pick gun being inserted into the keyway;**
- **Determination of when pick marks were made, based upon surface oxidation;**

Oxidation and dating of marks in a forensic examination. Courtesy of Don Shiles.

- **Could marks on pin have been caused by the use of steel keys with rough cuts, produced by inexpensive cutters. In such cases, the bitting surface can act as a saw;**
- **If there is forced entry, compare the apparent method of bypass and the presence of pick marks to determine if there is an attempt to mask the real method of entry in order to hide the identity of the perpetrator;**
- **If the investigation involves a lever lock, there may be more evidence of bypass due to the inherent difficulty in manipulating this mechanism. Lever locks are typically mortised into the door, which makes them more secure than exposed cylinders. Marks will also be present on the bellies of the levers;**
- **If the use of a 999 key is suspected, be certain to inspect**

the keyway for markings, as well as pins;

25_1.3 Possible Defense Theories or Contraindications

It is never too early to consider potential defense arguments to conclusions drawn by the criminalist, as a lock is analyzed. In fact, the conduct of any forensic investigation into bypass requires that **all** possibilities be considered, especially where there appears to be physical evidence to support a theory of surreptitious entry. Conflicting indications of bypass can be found in many locks. Often, marks are produced from normal wear, service, age, or other external non-related causes. These must be distinguished from actual evidence of bypass. The following possibilities must be considered in any inquiry where physical marks or trace evidence is identified within a lock. Factors that may affect the production of marks and which should be analyzed will include:

- **Spring tension on each tumbler;**
- **Hardness of tumblers;**
- **Bearings;**
- **Design of key and sharpness of ramp angles;**
- **Driver and lower pin length as it affects compression of springs.**

25_1.3.1 Earlier Picking Attempts

- **Could there have been an earlier attempt to pick the lock;**
- **Could someone have previously attempted to claim surreptitious entry to collect insurance which caused marks to be made;**
- **Could a locksmith have made the marks in an attempt to open the lock;**

25_1.3.2 Normal Use

- **Could marks have been caused by normal use of the lock. For example, could an improperly cut key have scored the pins or shell.**

25_1.3.3 Tool Marks

- **When were the marks created. Can they be dated with any reliability;**
- **Does corrosion exist around the marks. Is such corrosion consistent with other corrosion in or around the cylinder;**
- **Could the marks be interpreted to have been present for quite some time. Can it be proven that the marks were made within the time frame of the incident or event under investigation;**
- **With respect to markings on pins, are there inconsistent marks or marks only on one or two pins. This might indicate that these were produced from a jagged key angle and not from a pick. Do not be fooled by marks on only one pin: locks are not picked in that fashion unless the perpetrator was interrupted almost immediately or did not understand how to rake a lock;**

- **Could the marks be false and have been created by a screwdriver, ice pick, or other sharp implement to simulate surreptitious entry;**
- **Are the marks consistent with lock-picking or impressioning techniques. Why and how would the marks have been made;**
- **Could a locksmith have previously worked on the lock and allowed a top pin to drop into the plug, catching a spring between the plug and shell. The subsequent use of excessive force to rotate the plug would result in markings being produced;**

- **Has the lock been disassembled previously for maintenance, repinning, or keying;**
- **Are there spots on the bottom of tumblers indicating improper fitting keys, worn keys, or errors in spacing that requires the key to be lifted or retracted slightly in order to raise tumblers to shear line;**
- **Is there scoring in the upper surface of the shell which intersects the top chambers and appears to**

follow the rotation of the plug. If so, it is generally due to keys that raise lower tumblers slightly higher than shear line;

- **Are there marks on all top surfaces of the lower pins, or scoring of the cylinder walls. This may indicate a loose plug caused by cam-retaining screws that do not hold the plug firmly. Try inserting and removing the correct key. If it is difficult to withdraw, this may be the cause of such marking;**
- **Could keys have been duplicated on inferior knockoff blanks that were too wide for a particular keyway, thereby removing metal upon insertion;**
- **Could internal wear be based upon the way in which keys were originally cut, excessive spring tension, or the age of the lock;**
- **If striations are found on the side of the keyway, can they be correlated to the pressure required to turn the lock mechanism and matching striations on key blanks.**

25_1.3.4 Keys

If keys are found on suspects or seized during search warrants or inventories, careful consideration must be given to the following issues:

- **Does the key fit the suspect lock properly or is the fit loose, tight, or in other respects not correct. Perhaps the wrong blank was used in the duplication process or the key was designed to fit another lock and has nothing to do with the one being examined. There are many similar keyways throughout the world. Some are interchangeable. Just because a key fits a particular lock does not mean that it was cut for that lock;**

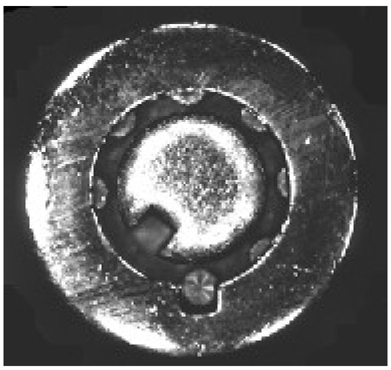
- **The internal components are so worn that many keys, if jiggled, will open the lock. This is especially true in the case of car locks: tryout keys work on this principle. To disprove, take 25 random keys and attempt to open by manipulation. Determine the tolerance of lock parts by micrometer measurement.**

This will allow an extrapolation of the potential number of keys that will open the lock;

It is difficult to bypass laser track locks through the use of jiggle keys. Courtesy of Hans Mejlshede.

The reverse of this argument is also true. Keys found on a suspect may not properly fit a lock, but that does not necessarily mean that they will not open it. If the key is close to that which would open the mechanism, then careful attention should be paid to the suspect key to determine if in fact if was **intended** to open the lock.

- **A suspect lock may have been altered with added pins in order to allow keys to fit that are not listed in the master system layout. In some cases this has been done intentionally so that possession of a key may not constitute a crime, or evidence;**



- **The absence of tool marks within a suspect lock may be relied upon or introduced by insurance companies or defendants as evidence that the lock was not picked or that there was no surreptitious entry. That conclusion does not automatically follow.**

There may be several explanations for a lack of marking. If picking was accomplished with a rake using very light tension or pins were picked in the conventional manner (one at a time), no indication may be left. If the lock utilizes nickel silver pins or plug, this metal will be much more resistant to scoring. If a key was run through the lock several times after picking, such may obscure any trace.

- **Indentations on the face of a plug can be construed to mean that 999 rapping was employed. However, it may also indicate heavy use of the lock. Follow-up examination of the pins is required in this event;**
- **Scratches on the sides and bottoms of the pins can show that a 999 rapping technique was applied or that there was too steep a ramp angle on the key and it was forced into the lock. The insertion of a poorly designed or improperly cut key can definitely cause marking on the sides of tumblers. This possibility must be carefully considered.**

25_1.3.5 Picked Tubular Locks or Cylinders

Sometimes, an axial pin tumbler lock or other cylinder is found with the plug rotated to a partially picked position. This will generally indicate that bypass has been attempted or accomplished and that the perpetrator was trying to return the plug to the locked position. However, it is possible to create this condition by cutting the guide pin off any tubular key and moving the plug to a partially rotated position.

It is not conclusive that the lock was picked or otherwise bypassed just because the plug is rotated. It may be possible in rare instances that the key's top guide pin has been worn away or removed for some legitimate purpose. If this occurs, then the lock may be left in what appears to be a picked condition although that was not the intent. Placing an axial lock in a partially rotated state can be done for security reasons. Locks may be set to this position in order to prevent unauthorized keys from being inserted. Sabotage may also be a factor.

25_2.1 Lock Specifications and Data

The lock as an entity should be examined both externally and as to each component to determine if there are discrepancies or differences between the target and factory original.

25_2.1.1 Queries Regarding Lock Specifications and Manufacturing Data

- **What is the length of each pin-stack, in order to assess the potential for bypass by a comb pick. This condition is referred to as balanced drivers,**

meaning that the overall length of the bottom and top pins is constant.

The length of the upper and lower pins, including all master pins for each cut, must be calculated and compared to the length of each upper chamber. If the length of the chamber is greater than the total length of all pins and spring for that chamber, then a comb pick may be utilized.

- **Does the lock have all original factory components;**
- **Examine the way the lock has been assembled, and determine if there is any deviation from factory standards;**
- **Is it possible that the lock was recombinated and that driver pins were not changed at the same time or that previously used lower pins were inserted;**
- **Are components missing;**
- **Have non-original components been substituted, such as pins, springs, cam, or plug;**
- **Are pins color coded from the factory;**
- **Has the spring-retaining tab been removed, replaced, or altered;**
- **Is the lock keyed to the original combination;**
- **Does the pin-stack match codes stamped on factory original keys with respect to depth of bitting;**
- **Can all pins (within a chamber) be forced into the upper chamber above shear line;**
- **Does there appear to be any damage to any lock component;**
- **Is the diameter of the plug equal to factory specifications;**
- **Is the design of the plug-shear line interface round or flat? A higher tolerance is achieved with a round plug;**
- **Are bottom tumblers round, pointed, or flat;**
- **Are steel bearings used by the factory. If so, are they present in the target lock;**
- **Have springs of the proper tension, length, and diameter been installed;**
- **Does the plug rotate freely in the lock with the proper key inserted;**

- **Do tumblers catch or hang, either in the shell or plug;**
- **Must keys be jiggled in order for the lock to work;**
- **Is there any distortion of the plug or shell, indicating that excessive torque has been applied;**
- **Are cam-retaining screws tight;**
- **Does the manufacturer use security tumblers? If so, are they present in the lock;**
- **What is the security rating of the lock;**
- **Does the lock carry a UL 437 or equivalent EC rating;**
- **Are there any obvious defects or problems with the operation of the lock.**

25_2.2 Operation of the Lock

Analyzing the operation of the lock can yield valuable information about its condition, age, wear, formation of internal markings, and (of equal importance) missing, replaced, non-standard or out-of-place components. The criminalist will be concerned with each internal and external component and their interaction.

A decision must be made by the criminalist as to whether to conduct a cursory review to determine if the lock is functioning properly prior to a detailed forensic examination.

If there is a possibility of the destruction or alteration of internal markings, then great care must be used. This is especially true if keys are inserted and removed from a working lock. Depending upon the bitting surface, side-milling, and tolerances, unwanted marks or artifacts may be created in the examination process. Alternatively, if the lock is disassembled and the plug dissected then a proper determination of operation cannot be made following the evaluation criteria in this chapter. If a lock is to be first evaluated to determine its operational characteristics, all of the components must be examined, cataloged, and checked. Special attention must be paid to those items detailed below.

25_2.2.1 Summary Mechanical Evaluation

Proper operation of the lock must be determined prior to dissection, assuming the lock has not been damaged during entry.

At this point, observations must be made regarding operational characteristics. The reader will note some duplication of information in subsequent sections. This section describes gross distortions or irregularities regarding the operation of the lock and its components. In **Chapter 26** specific indicia will be examined with respect to the presence of tool marks.

25_2.2.2 Queries Regarding Mechanical Operation

- **After examination of the entire length of the keyway, are there any broken key parts or foreign materials present. If so, is there a possibility of a match between a broken key and the hey head;**
- **Is there a stuck key lodged in the plug. If so, is it back cut, indicating that an amateur produced it or that impressioning was attempted;**
- **Does the proper key fit and open the lock;**
- **Is the key properly matched to the keyway;**
- **Is the cam tight or loose. If the cam is loose (retaining screws allow movement of the cam when the proper key is inserted and removed), then excessive and unexplained marking may appear;**

- **Does the lock exhibit smooth or rough operation: do the pins bind, or must the key be lifted to work;**
- **Do all keys work;**
- **Are all springs intact, and do they have the proper length and tension;**
- **Is the plug correct for the given lock;**
- **Is the spring-retaining clip secure. Has it been removed and replaced;**
- **Is the plug rotated to a picked position;**

- **Is there visual evidence of bypass, including tool marks, metal fragments or filings, distortion of the plug, broken keys in the plug, or other marks;**
- **Is there any foreign material in the plug, including Freon residue;**
- **Are there any metal scrapings within the lock, in the keyway, or chambers;**
- **Does it appear that excessive pressure was applied to the plug, causing marks to be made between the**

plug and shell;
- **Are there marks that appear to have been caused by picking or other forms of manipulation. If such marks were from picking, how old are they. When were they made. Could normal operation of the lock cause the questioned marks.**

25_2.3 Chambers, Plugs, Pins, and Springs

25_2.3.1 Chambers

Chambers must be examined for deformation and obvious scoring that may have been caused by improperly cut keys that did not raise all tumblers precisely to shear line. In addition, gross evidence of impressioning may be present. Attention must also be paid to the potential of drilling that can be evident in the plug and/or shell.

25_2.3.2 Plugs

A complete examination of the exterior and interior segments of the plug must be conducted. Depending upon whether dissection is performed, the plug may be examined with a microscope, borescope, or ophthalmoscope.

25_2.3.2.1 Queries Regarding Plugs

- **Is there evidence of external scoring around the circumference;**
- **Has the top of the plug at shear line been filed;**
- **Is there warping, bending, flattening, or distortion of the wards in the keyway;**
- **Are there unexplained marks, spots, dents, scratches, tracks, or other indicia of bypass.**

25_2.3.3 Pins

Pins can provide valuable information regarding disassembly, alteration, and replacement of the lock.

25_2.3.3.1 Queries Regarding Pins

- **How many chambers are in the plug, and is there a**

tumbler set (lower pin, upper pin, master pin in the case of complex systems, and spring) for each chamber;

- **Is the correct diameter pin present within each chamber;**
- **Is there a great deal of play between the chamber and pin;**

If low tolerance exists between the pin and its chamber, the lock may be easy to decode by using the Falle-Safe decoder. This sophisticated instrument allows a shim wire to enter between the lower pin and chamber to decode each tumbler. It is described in **Chapter 31.**

- **Are driver pins too long or too short for a given depth of bitting. If so, can a comb pick force all lower pins into the shell to create another shear line. Long drivers may also indicate that the lock has recently been rekeyed by an amateur;**

If springs are compressed into the shell, the overall length of the pin-stack should be measured. There may be a defect in the design of the lock or in factory pinning. Compressed springs will cause marks to be produced on the tops of driver pins.

- **Do the pins appear to be factory original, or have they been replaced. Do they appear old or new;**
- **Have the tops of the pins been filed;**
- **Have lower pins been loaded upside down as drivers, indicating an amateur was working on the lock;**
- **Is there correct driver and lower pin orientation;**
- **Does it appear that the lock has been rekeyed improperly;**
- **Has the combination been altered. Does it appear that pins have been added or removed to make picking easier, to allow the use of cross-keys, or other unauthorized keys;**
- **Have old pins from other locks been used, indicating that an amateur may have done the work;**
- **Does the manufacturer use color coded pins on this series of lock. Are the pins in fact color-coded. If not, should they be. Have colored and non-coded pins been mixed;**

- **Is the lock pinned with mushroom, spool, or other forms of security tumbler. If so, is the correct number present. What is the factory original standard with respect to the number of security pins, their position, and design. Generally, up to three security tumblers will be utilized;**
- **Are there any master pins. If so, their position and precise length must be documented with extreme caution;**
- **Have master pins been used that are too thin, causing operational problems. Jammed wafers could indicate that tumblers had been added, the lock was not keyed to industry standards, or was worked on by an amateur;**
- **Have only some of the chambers been loaded with pins. Although this may seem unusual, each lock must be evaluated on a case-by-case basis. The author has investigated many system where six-pin locks are keyed with five tumblers;**
- **Would the tumbler combination allow the removal of a key when the plug is normally locked. This may give a false indication of picking because some keys are improperly cut or designed and may be withdrawn in a rotated (non-vertical) position;**

If the key design is in an ascending stair-step pattern with the deepest cuts at the tip, it may be possible to withdraw the key from the lock while the plug is rotated. Example: a bitting pattern of 765432 (from the tip), with "7" being the deepest cut, can quite possibly be removed without engaging the tumblers during withdrawal.

25_2.3.4 Springs

Springs can also provide valuable information. Evidence from springs can indicate if the lock has been worked on recently, whether it has been taken apart by an amateur or by one in a hurry, and whether comb picking has been attempted.

25_2.3.4.1 Queries Regarding Springs

- **Are all springs worn to the same degree. Are some more worn than others;**

- **Are springs missing;**
- **Are springs compressed;**
- **Are some springs very old, while some appear new;**
- **Are some springs crushed or broken;**
- **Are all springs in place. Is there a spring in every chamber, and are they the correct length and tension;**
- **Are the springs operational, compressed, extended, or broken;**

> **If springs appear to be compressed, this may indicate improper driver length for a given chamber. This can demonstrate that the lock was not keyed by the factory as original or was rekeyed by an experienced locksmith.**

- **Have any of the springs been sheared. This would indicate that the lock may have been disassembled by an amateur, having caught a spring in an empty chamber. Are there fragments of springs that would indicate the same condition.**
- **Are any of the springs noticeably weak or not functional which may indicate age or use; Are the springs the correct diameter for the given chamber. If not, this may indicate replacement by an amateur;**
- **Are the springs all the same color. If not, this can indicate that the lock has been worked on, perhaps recently. If that might be the case, could the lock have been disassembled prior to its bypass to compromise its security, either intentionally or through amateur workmanship;**
- **Will the springs compress if there is a high cut on the key bitting. This may indicate that drivers are too long for a given depth tumbler position, possibly pointing to rekeying of the lock.**

25_2.4 Security of the Lock

Whenever a lock is to be subjected to forensic examination, an assessment must be made as to the ease with which it may be bypassed. This evaluation will often yield valuable leads as to perpetrators, possible physical evidence that may be recovered

from the lock, and specific types of tests that may be performed. The reader is directed to **Chapter 10** for evaluation criteria of high-security locks.

As was pointed out earlier, a security rating can be rather elusive in terms of what it defines. Although specific industry standards have been developed in the United States (UL 437), England (BSI ratings) and Europe (EC ratings), such security ratings are not absolute. In terms of surreptitious entry, the target and the lock protecting it may attract perpetrators and tools equal to the task, and potentially not contemplated or understood by the standards rating organization.

Manufacturers of some of the highest security locks in the world, such as Medeco (U.S.), Chubb (UK), Keso (Swiss), Mul-T-Lock (Israel), Abloy (Finland), and Abus (Germany) often claim that their locks are impervious or highly resistant to bypass. The author, from personal experience, can attest that locks produced by each of these companies can be defeated and opened. The author has utilized extremely sophisticated bypass tools to subvert mechanisms developed by each of these (and other) manufacturers of the highest security mechanisms. The description and use of such tools is covered in depth in the video supplement to **LSS+**.

An example illustrates the point. A Chubb Isolator safe that is equipped with a high-security eight-lever lock (such as the 6K174) has apparently has been compromised. The manufacturer advises that this lock is virtually impossible to pick or manipulate. This information should not automatically lead an investigator or criminalist to conclude that it was an inside job. Quite the contrary. The author has utilized tools that can penetrate this lock without leaving a trace in as little as fifteen minutes.

Although the Isolator is one of the finest high-security safes offered by Chubb, the lock still provides the primary defense against entry. In reality, the safe simply protects the lock from attack. The lever lock, regardless of design, is still a lever lock. Inherent to its basic design is the capability of compromise. There is little that a manufacturer can do, given the sophistication of tools and techniques, to absolutely prevent against bypass.

The most important fact for a criminalist to remember is that almost any lever, disc, or pin tumbler lock can be compromised, given the proper tools and expertise. These tools, and

individuals capable of operating them, do exist. In any major investigation, one should never lose sight of the fact that covert bypass may be entirely possible. In the civil legal arena, it should also be remembered that insurance companies generally do not define what constitutes a "secure lock," although they often require them to be installed in order to extend coverage. This problem within the insurance industry is going to have to be addressed.

This section shall summarize, in the form of questions, the basic criteria with which to assess the security of a lock in terms of the following:

- **Resistance to physical attack;**
- **Difficulty and likelihood of covert methods of bypass;**
- **Likelihood of random opening, rather than premeditated attack.**

In the beginning of **Chapter 24**, a number of questions were raised regarding locks and locking systems as part of an initial survey that would be made at the outset of an investigation. Those questions were general in nature. In assessing the security of a lock that may have been compromised, the following additional, specific questions and related issues must be considered.

25_2.4.1 Queries Regarding Security

- **What is the estimate of the security rating of the mechanism:**

1. **NO SECURITY**
2. **LOW SKILL TO BYPASS**
3. **MODERATE TO MEDIUM SKILL REQUIRED**
4. **ADVANCED SKILL REQUIRED, TIME CONSUMING**
5. **VERY DIFFICULT, TIME CONSUMING, SPECIAL TOOLS AND EXPERTISE REQUIRED, OR NOT REALISTIC TO PICK THE LOCK IN THE AVAILABLE TIME. SEE UL STANDARDS**

- **What type of mechanism is employed;**
- **Can the secondary locking system be bypassed;**
- **Does the mechanism meet high-tolerance standards;**
- **Does the mechanism utilize dual-locking systems, such as pin tumbler + sidebar;**

- **Is it easy or difficult to move a pick in the keyway;**
- **Are there any secondary locking pins which restrict the plug from turning, such as in the DOM dimple lock;**
- **Are there deep cuts next to shallow ones, making picking difficult;**
- **Are there anti-pick mechanisms, such as detectors, floating levers, sidebars, or special locking components that will engage if picking occurs, such as in the EVVA DPX sidebar lock;**
- **Was the plug found in a picked position;**
- **How difficult is picking;**
- **Can the lock be easily impressioned;**
- **Can the lock be 999 rapped;**
- **Can the lock be decoded;**
- **Are cylinder-retaining screws loose;**
- **What lock profile is used: .S. cylinder, European;**
- **Can the locking mechanism be bypassed through sophisticated means as described in LSS+/X CD/ROM;**
- **Is it classed as a high-security mechanism;**
- **Does it have a UL 437 rating;**
- **Are all chambers active and pinned;**
- **Are all components working;**
- **Are security pins installed;**
- **What is the design of the keyway? Will it frustrate picking;• Are there known ways to bypass the lock;**
- **Are there anti-drill pins;**
- **Has the plug been drilled at shear line;• Has the lock been modified in any way from factory standard;**
- **Are there special decoding tools available for this lock;**
- **Has the lock been tampered with;**
- **Has the lock been worked on by an amateur locksmith. For example, has the top of the plug at shear line been filed flat;**
- **Have pins, wafers, or levers been filed;**
- **Can the plug be turned with a screwdriver;**
- **How many tumblers must be manipulated to open the**

lock;

- **Were Maximum Adjacent Cut Standards (MACS) followed when the particular cylinder was keyed;**
- **How many total pin tumblers, levers, or wafers are present;**
- **What is the basic type of locking mechanism;**
- **Can the lock be decoded rather than picked; then a key produced from the decoding process;**
- **Is the pin-stack configuration or combination extremely conducive to picking. Are all tumbler positions close to the same depth, or in a stair-step pattern;**
- **Is maison keying in effect. How many tumblers are present;**
- **Is complex master keying employed. How many levels. Are there many cross-combinations available;• Are there any wards or obstructions in the keyway;**
- **Is the tolerance between plug and shell quite sloppy, either due to poor manufacturing controls or because the top of the plug was filed by an amateur locksmith;**
- **Is the horizontal center-point alignment between chambers erratic, allowing ease of picking;**
- **Is the suspect lock inherently easy to pick due to its design (especially if a wafer mechanism);**
- **Can the lock be opened by inserting a pocket knife to lift all tumblers because the length of the pins are quite similar;**
- **Is the lock combinated so that rocker picks could easily simulate the depth pattern;**
- **Were standard pins and depths utilized during keying;**
- **Every manufacturer has different standards for bitting. These apply to depth and spacing and determine differs and thus security. Failure to adhere to such standards will diminish the security of the lock. Representations by manufacturers as to the actual number of differs may not be accurate. See LSS+/X CD/ROM for a description of the Medeco Biaxial lock, for example.**

25_3.0 Forensic Experts in Locks and Keys

What is an investigative locksmith? Courtesy of Don Shiles.

Definition of an Investigative locksmithing. Courtesy of Don Shiles.

Purpose of investigative locksmithing. Courtesy of Don Shiles.

LSS202: Forensic investigation and the locksmith, by Don Shiles

The **International Association of Investigative Locksmiths (IAIL)(239)** has been organized to train and certify professional locksmiths that conduct forensic examinations involving locks, keys, keying systems, security containers, arson investigations, compromise of security systems, and the investigation of crimes relating to motor vehicles. The association has developed job specifications, procedures, and analytical techniques for examining locks, keys, and vehicles for evidence of bypass, tampering, or fraud. Training is also provided with regard to evidence collection and preservation, and presentation of findings in court. I.A.I.L. is the most recognized private association relating to the forensic examination of locks.

Forensic locksmithing history and the role of Art Paholke. Courtesy of Hans Mejlshede.

Forensic locksmiths may be called upon by insurance companies, criminal investigators, security management, and crime laboratories to conduct primary analysis, or to aid other specialists in the investigation of cases involving potential bypass or forced entry of locks and safes, and cases involving fraud where locks, keys, or keying systems may have played a role.

The investigative locksmith gets involved in insurance fraud cases. Courtesy of Hans Mejlshede.

These experts often have experience and insight that may be lacking in other disciplines due to their daily contact with locks, safes, and security issues. Assuming that they have the requisite background and qualifications, they can be invaluable

in certain investigations. Unfortunately, most law enforcement agencies do not have the in-house expertise to properly evaluate locks and related systems.

Required background of the forensic locksmith and investigator. Courtesy of Don Shiles.

The beginnings of the forensic investigation of locks and keys began with the Chicago Police Department sometime around 1970, when Art Paholke, a police officer assigned to the criminalistics laboratory, began developing techniques for the examination of locks, safes, keys, and keying systems. Although he has long since retired, he is credited with developing many of the techniques and procedures that are utilized today.

Art Paholke is the father of modern forensic locksmithing. Courtesy of Hans Mejlshede.

It is critical the competent experts be utilized in cases involving the potential compromise of security systems. Throughout the Forensic Section (Chapters 24-27) reference is made to defense theories and evidence that may be presented to dispute, discredit, or disqualify the admission of physical evidence or expert testimony. It is therefore of vital important that evidence be identified, gathered, preserved, and analyzed correctly in order to assure a valid case resolution.

There are many integrated disciplines and areas of knowledge and expertise that must be mastered in order for the forensic locksmith to competently perform his job. These include:

- **Crime Scene Processing:**
  Making an assessment as to whether a lock, key, keying system, or security system has been or is at risk of compromise;
  Securing a crime scene;
  Physical examination of a crime scene;
  Collection and storage of evidence;

- **Tool Marks:**
  Identification of tool marks; Performing basic tool mark classifications;
  Evidence from tool marks;
  Submission of tool mark evidence to laboratory;

Casting and Impressioning;

- **Forensic Photography:**

Macro lens, Courtesy of Hans Mejlshede.

Data back for documentation of images. Courtesy of Hans Mejlshede.

Photographic equipment requirements. Courtesy of Hans Mejlshede.

Ring strobe is a necessity for forensic photography. Courtesy of Hans Mejlshede.

- **Admission of Evidence:**
  Chain of Custody; Depositions and courtroom testimony;
  Rules of Evidence;Qualifications for Forensic Locksmiths;

- **Specialized Forensic Investigations:**
  Compromise involving security containers;
  Restoration of obliterated tool marks;
  Automobile Theft investigations;
  Arson investigations;

- **Forms and Reports:**
  Specimen Report;
  Forensic Inspection Report;
  Case Report;

- **Reference Files:**

This section shall provide an outline of the criteria and general duties of a forensic locksmith, as well as the legal requirements and guidelines that must be adhered to in order for evidence to be legally competent. For a more detailed discussion regarding specific processes and procedures, the reader may wish to obtain the I.A.I.L. Forensic Locksmithing Manual. Appreciation is expressed to James Glazier, President of I.A.I.L. for assistance in developing certain multimedia segments contained within this section.

25_3.1 I.A.I.L. General Qualifications for Forensic Locksmith

The International Association of Investigative Locksmiths has developed general standards for their members to define basic qualifications for a forensic locksmith. These are reproduced below.

Definition of a forensic locksmith.

Professional Qualification Standards for Certified Forensic Locksmiths

Chapter 1. General:

1-1 Scope. This standard identifies the professional level of performance required for a Certified Forensic Locksmith and specifically identifies the job performance requirements necessary to perform as a Certified Forensic Locksmith.

1-2 Purpose. The purpose of this set of standards is to specify the minimum job performance requirements for service as a Certified Forensic Locksmith in both the private and public sectors. It is not the intent of these standards to restrict any jurisdiction from exceeding these minimum requirements. Job performance requirements describe the performance required for a specific job. The complete list of requirements for each duty describes the tasks an individual must be able to perform in order to successfully carry out that duty; however, they are not intended to measure a level of knowledge. Together, the duties and job performance requirements define the parameters of the position of Forensic Locksmith.

1-3 General

1-3-1. The Certified Forensic Locksmith shall be at least twenty?one (21) years of age.

1-3-2. The Certified Forensic Locksmith shall have a high school diploma or a state recognized equivalent.

1-3-3. The International Association of Investigative Locksmiths, Inc. (I.A.I.L.) shall conduct a thorough background and character investigation prior to accepting an individual as a candidate for certification as a Forensic Locksmith,

1-3 4. The job performance requirements for the Certified Forensic Locksmith shall be completed in accordance with recognized practices and procedures or as they are defined by law or by the International Association of Investigative Locksmiths, Inc.

1-3-5. The job performance requirements defined in these standards

need not be mastered in the order in which they appear. Training agencies or other authorities may establish programs that prepare individuals to meet the requirements defined in these standards.

1-3-6. Evaluation of job performance shall be by individuals approved by the International Association of Investigative Locksmiths, Inc. The evaluator shall be qualified to conduct the evaluation of a Forensic Locksmith and make appropriate recommendations in relation to their certification as a Forensic Locksmith.

1-3-7. The Certified Forensic Locksmith shall remain current with investigation methodology, locksmith technology, and current requirements through attendance at workshops, seminars, classes and/or through professional publications and journals. The Certification Board of the International Association of Investigative Locksmiths, Inc. on a tri-annual basis shall evaluate this. The Certified Forensic Locksmith shall certify to their attendance and study during the prior three-year period.

1-3-8. The Certified Forensic Locksmith shall commit to the Code of Ethics of the International Association of Investigative Locksmiths, Inc.

Additional performance requirements are defined in Chapter 3 of the I.A.I.L. Professional Qualifications and Standards.

3-1-1. The Certified Forensic Locksmith shall meet the job performance requirements defined in Sections 3-2 through 3-7.

3-1-2. Because Certified Forensic Locksmiths are often required to perform activities under adverse conditions, all regional and national safety standards must be adhered to in all situations.

3-1-3. The Certified Forensic Locksmith should maintain appropriate liaison with other professionals.

3-1-4. The Certified Forensic Locksmith shall ensure that due process of law is served.

25_3.2 Crime Scene Processing

Crime scene processing involves a number of critical steps to insure the proper discovery, development, integrity, and admissibility of the evidence. Although criminalists and government investigators receive extensive training with regard to the proper techniques for processing evidence, the fundamentals are summarized below for the benefit of the forensic locksmith.

Evidence handling techniques. Courtesy of Don Shiles.

I.A.I.L. has detailed the general requirements for the correct handling of a crime scene and any evidence that it may yield where there is suspected criminal activity involving keys, locks, containers, or security systems. These procedures may slightly vary from "typical" crime scene processing.

There are five critical stages in this process:

- **Secure, survey, and examine a suspected crime scene**
- **Document the scene with photographs, video, and notes**
- **Document specific items of evidence**
- **Collect and preserve evidence**
- **Presentation of Evidence**

25_3.2.1 Securing and Examining the Crime Scene

Whenever there is an area that is thought to be a crime scene, the appropriate law enforcement jurisdiction has the responsibility of securing and protecting the area and its contents from accidental or intentional contamination or disturbance. Any witnesses or individuals with knowledge regarding the connected criminal activity must be identified and interviewed as soon after the event as possible in order to preserve the value of their information.

Each law enforcement agency develops its own procedures and protocol for processing a crime scene. However, every forensic examination of the scene of a crime involves the following steps:

- **Protect the scene;**
- **Conduct a preliminary survey of the crime scene;**
- **Physical examination of the crime scene;**
    - **Document the scene by:**
    - **written narrative or recorded statement**
    - **drawings**
    - **photographs**
    - **video**
- **Collect and temporarily store evidence;**
- **Preserve and package the evidence for transport;**

The I.A.I.L. has defined the following responsibilities for a forensic locksmith:

3-2 Scene Examination. Duties shall include inspecting and evaluating the scene so as to determine the method of access, area of access, method of defeating or bypassing the locking mechanism(s).

3-2-1. Secure the suspected area of access, locksets or access devices, doors, door frames, steering column, ignition lock assembly, and any other device or area involved using any special tools, tape or marking devices, so that unauthorized persons can recognize the perimeters of the investigative scene and are kept from restricted areas. Protect all evidence or potential evidence from tampering, damage or destruction.

(a) Requisite Knowledge: Types of evidence and the importance of security, evidence preservation, issues relating to spoliation and chain of custody.

(b) Requisite Skills: Ability to deal effectively with people in a friendly yet authoritative manner.

3-2-2. Conduct a survey of the alleged scene of forced entrance or surreptitious entry, given standard equipment and tools, so that evidence is preserved, alleged access damage is interpreted, and with relationship to property, all potential means of ingress and egress are discovered. With relationship to possible automobile theft, examine all exterior surfaces of the vehicle, wherever feasible, with regard to the use of access tools (Slim Jim and other "in-door" tools), force or other means of questioned access.

3-2-3. Conduct an interior survey, given standard equipment and tools, so that areas of potential evidentiary value requiring further examination are identified, photographed and preserved, the evidentiary value of contents is determined, and alleged methods of bypass are identified and protected.

(a) Requisite Knowledge: Knowledge of the types of locks, access control, and other security devices. Steering columns, ignition switch assemblies, ignition lock assemblies, anti-theft devices, alarm and security devices, effects of bypass methods, various methods of access and bypass and general locksmith skills.

(a) Requisite Skills: Locksmith skills including lock device installation, servicing and repairs in automotive work. Ignition lock removal and replacement, steering column service and repair, and service and repair of anti-theft devices. Photography, identification and preservation of evidence are crucial in all investigations.

3-2-4. In the event of an automobile theft or arson, examine, photograph and remove fire debris given standard equipment and tools, so that all fire debris is checked, including the ignition switch assembly, ignition lock assembly, steering column parts, steering wheel locking parts, and other components. This investigation should be coordinated with any SIU or other fire investigator with a relationship to the preservation of evidence potentially relating to cause and origin of the vehicle fire. Special attention should be paid to the relationship of all evidence recovered with the levels of evidence in the fire debris.

3-2-5. Wherever feasible, inspect the performance of the lock or access device or security system within a building or the steering column lock, ignition switch assembly, ignition lock assembly, anti-theft devices, given standard and special equipment and tools, so that a determination can be made as to the need for expert resources so that the defeated systems and the method of defeat are identified.

25_3.2.2 Documentation

Issues regarding keeping of records. Courtesy of Hans Mejlshede.

3-3. Documentation of the Scene. Duties shall include diagramming the scene, photographing, and taking field notes to be used to compile a final report.

3-3-1. Diagram the scene, given standard tools and equipment, so that the scene is accurately represented to insure that evidence, pertinent objects, significant marks and areas of damage or potential evidence are identified and accurately represented.

(a) Requisite Knowledge: Commonly used symbols and legends that clarify the diagram, types of evidence that need to be documented, and formats for documenting the scene.

(b) Requisite Skills: Ability to sketch the scene, basic drawing skills, and evidence recognition and observational skills,

Issues regarding crime scene sketches. Courtesy of Don Shiles.

3-3-2. Photographically document the scene, given standard tools and equipment, so that the scene is accurately depicted and the photographs appropriately support scene findings. It is recommended that video be used during the examination, disassembly and removal of any lock cylinder, security device, locking mechanism or automotive steering column, ignition switch assembly or ignition lock assembly. If not practical then 35mm or similar photographs must be made of each step in the removal of the aforementioned assemblies.

(a) Requisite Knowledge: Working knowledge of a 35mm or other camera and flash mechanism, types of 35mm or other cameras and lens, types of film and flash available and suitable for such tasks, as well as the strengths and limitations of each. Working knowledge of video cameras and lighting.

(b) Requisite Skills: Ability to use a 35mm or other camera, flash and other appropriate lighting. Ability to use video cameras and lighting.

3-3-3. Construct investigative notes, available documents, and interview information so that the notes are accurate, provide further documentation of the scene, and represent complete documentation of the scene findings.

(a) Requisite Knowledge: Relationship between notes, diagrams, and photos, how to reduce scene information into concise notes, and the use of notes during report writing and legal proceedings.

Issues regarding investigative reports. Courtesy of Hans Mejlshede.

(b) Requisite Skills: Data-reduction skills, note taking skills and observational and correlating skills.

25_3.2.3 Collection and Preservation of Evidence

3-4. Evidence Collection/Preservation. Duties shall include using proper physical and legal procedures to retain and preserve evidence required within the investigation.

3-4-1. Utilize proper procedures in managing facilities (buildings and vehicles), given a protocol and appropriate personnel, so that all evidence is discovered and preserved and the protocol is followed.

(a) Requisite Knowledge: Types of evidence associated with surreptitious entry, forced entry, and auto theft and evidence preservation methods.

(b) Requisite Skills: Observational skills and the ability to apply protocols to a given situation.

3-4-2. Locate, collect, and package evidence, given standard or special tools and equipment and evidence collection materials, so that evidence is collected, identified, preserved and packaged to avoid contamination and investigator-inflicted damage. Establish and maintain the chain of custody.

(a) Requisite Knowledge: Types of evidence (exclusionary or theft-supportive evidence), types, capabilities and limitations of standard and special tools used to locate evidence, types of laboratory tests available, packaging techniques and materials, and the impact of evidence collection on the investigation.

(b) Requisite Skills: Ability to recognize different types of evidence and determines evidence critical to the investigation.

3-4-3. Select appropriate evidence for analysis, given information from the investigative file, so those samples forwarded for analysis support specific investigative needs.

(a) Requisite Knowledge: Purpose for submitting evidence for examination, types of analytical services available, and capabilities and limitations of the services performing the analysis.

(b) Requisite Skills: Evaluate the alleged scene of entry or theft to determine forensic engineering or laboratory needs.

3-4-4. Maintain a chain of custody, given standard investigative tools, marking tools and evidence tags and/or logs, so that written documentation exists for each piece of evidence and maintain security of all evidence.

(a) Requisite Knowledge: Rules of custody and transfer procedures for evidence, types of evidence (e.g., physical evidence obtained

at the scene, photos and documents), and methods of recording the chain of custody.

(b) Requisite Skills: Ability to execute the chain of custody procedures and accurately complete the necessary documentation.

3-5. Interview of Individuals with Relevant Information and Examination of Exhibits. Duties shall include obtaining information regarding the overall forensic lock examination from others through verbal and written communications.

3-5-1. The Certified Forensic Locksmith shall develop a plan to obtain reports as may have been prepared or submitted by other forensic scientists relating to locks and their components. The examiner shall be familiar with documents relating to tool mark examination, testing, comparison, and any other related subjects.

The forensic investigator must prepare detailed reports. Courtesy of Hans Mejlshede.

3-5-2. The Certified Forensic Locksmith shall develop a plan of testing all evidence materials. That plan shall be subject to peer review and shall include the steps for comparison of evidence marks with test marks, preparation of error rate charts, preparation of photomicrographs to illustrate all findings, and maintain a testable method of obtaining results and references to all documents and exhibits that are utilized to support the findings of the examiner.

Opinions of examiner, and certainty of their opinions. Courtesy of Hans Mejlshede.

(a) The examiner shall meet the following tests with regard to preparation of his/her opinions and reports:

1. Whether the technique or theory has been a subject of peer review or publication in a recognized media;

2. Whether the technique or theory used may be tested or refuted;

3. The known or potential rate of error of a particular scientific technique; and

4. The degree of acceptance of a theory or technique within the relevant scientific community.

NOTE: The Court has provided a rather broad definition of the word "scientific", as referred to in Rule 702; "a grounding in the methods and procedures of science". The Court additionally stated that a scientific expert's "knowledge" means "more than subjective belief or unsupported speculation".

25_3.2.4 Presentation of Findings

3-6. Presentations. Duties shall include the ability to present findings to those individuals not involved in the actual examination and investigation.

3-6-1. Formulate an opinion as to the condition of the evidence examined (wafers, pins, springs, and other lock components as well as related items such as strike plates, door frames, etc.), so that the opinion regarding the status of the evidence examined is supported by records, reports, documents, photographs and photomicrographs.

(a) Requisite Knowledge: Analytical methods and procedures, photographic and microscope procedures, tool mark comparison techniques, locksmith procedures and technical knowledge of the profession.

(b) Requisite Skills: Analytical skills, tool mark examination and locksmith skills.

3-6-2. Prepare a written investigation report, given investigative findings, documentation and a specific audience, so that the report accurately reflects the investigative findings, is concise, expresses the examiner's opinion and is appropriate for the intended audience(s).

(a) Requisite Knowledge: Elements of writing, typical components of a written report, and types of audiences and their respective abilities and needs.

(b) Requisite Skills: Writing skills, ability to analyze information, and the ability to determine the reader's abilities and needs.

3-6-3. Testify during legal proceedings, give investigative findings, contents of reports, and consultation with legal counsel, so that all pertinent examiner's information and evidence is presented clearly and accurately, and the examiner's demeanor and attire are appropriate to the proceedings.

(a) Requisite Knowledge: Types of investigative findings, understanding of the types of legal proceedings, appropriate demeanor for each, and an understanding of legal proceedings.

(b) Requisite Skills: Communication and listening skills, ability to differentiate facts from opinions and the ability to determine appropriate procedures, practices and etiquette during legal proceedings.

3-7. Expert Testimony

3-7-1. General Witness. A Certified Forensic Locksmith will often be called to give testimony before courts, administrative bodies, regulatory agencies, and related entities. In addition to giving factual testimony, the examiner may be called to give conclusions or opinions regarding a lock or lock components or other evidentiary materials. In such instances, all testimony will be based upon the examiner's experience or lack thereof.

3-7-2. Litigation or Expert Witness. For purposes of litigation, only expert witnesses are allowed to offer opinion testimony at the discretion of the court. An expert witness is generally defined as someone with sufficient skill, knowledge, or experience in a given field so as to be capable of drawing inferences or reaching conclusions or opinions that an average person would not be competent to reach. The expert's opinion testimony should aid the judge or jury in their understanding of the fact at issue and thereby aid in the search for truth.

The opinion or conclusion of the examiner testifying as an expert witness is of no greater value in ascertaining the truth of the matter than that warranted by the soundness of the examiner's underlying reasons and facts. The evidence that forms the basis of any opinion or conclusion should be relevant, reliable and therefore admissible. The proper conduct of an examination will ensure that these indices of reliability and credibility are met. Refer to 3-5-2 and NOTE.

There may be times when the forensic investigator is pressured into altering his findings or report to suite a client, an insurance company, or law enforcement agency. It is imperative that the conclusions of the investigator be accurate, and that the results are not modified to suit anyone.

Pressure will often be applied to the forensic locksmith during the course of an investigation to change the results of a report. Courtesy of Hans Mejlshede.

25_3.2.5 U.S. Department of Justice Handbook of Forensic Science

The forensic locksmith and evidence technician may be called upon to assist with investigations involving locks, keys, and locking systems in a myriad of situations and crime scenes. For that reason, relevant sections of the FBI Handbook of Forensic Science has been reproduced here. Basic information regarding evidence collection and processing, protection of personnel from hazards including explosives, dangerous chemicals, enclosed spaces, toxic substances and general guidelines for identifying and preserving relevant evidence is presented. Although the reader may question the inclusion of certain sections, it is the author's experience that the forensic investigator may be summoned to locations where he would never expect to be called, and to analyze locks in circumstances that would be highly unlikely.

Basic Safety Guidelines for Crime Scene Investigation and Evidence Collection

Laboratory examiners, photographers, evidence team members, evidence technicians, fingerprint specialists, and others are often called upon to conduct crime scene searches and to identify bodies in mass disasters. Because of the inherent risk of exposure to human blood and other potentially infectious materials, as well as the various physical hazards present at the crime scene, the health and safety of these individuals may be compromised. For protection, it is essential that they develop and maintain am acute awareness of the hazards present in their work environment and take the necessary precautions and measures to protect themselves and their coworkers.

The purpose of this section is to identify general safety guidelines and personal protective measures that should be followed when handling potentially hazardous evidentiary materials or when exposed to hazardous environmental conditions. These recommendations are not all inclusive and should serve only as a guide and/or supplement for personal training and growth in safety awareness. The basic safety guidelines for crime scene investigation and evidence collection are intended to serve only as a starting point for good safety practices. Personnel involved

in crime scene investigations and evidence collection and handling should consult pertinent local, state, and federal laws concerning specific safely requirements and standards.

ROUTES OF EXPOSURE

Inhalation

Inhalation is the most likely route of entry for chemicals as well as some infectious agents (e.g., tuberculosis). Chemical or biological contaminants present in inhaled air can easily enter the lungs and bloodstream where they can circulate throughout the system, causing damage to target organs such as the liver and kidney. Inhaled substances can be in the form of dusts, mists (aerosols), smoke, vapors, gases, or fumes. Proper work practices, engineering controls (e.g., ventilation) and, when necessary, the use of respirators minimize inhalation of air contaminants.

Ingestion

Ingestion is a less common route of exposure for both chemical and biological contaminants. Ingestion of a corrosive material can cause damage to the mouth, throat, and digestive tract. When swallowed, toxic chemicals may be absorbed by the body through the stomach and intestines. To prevent entry of toxic chemicals or biological hazards into the mouth, always wash your hands before eating, smoking, or applying cosmetics. Also, avoid bringing food, drink, and cigarettes into areas where contamination can occur.

Skin, Eye, and Mucous Membrane Contact

Contact of chemicals or infectious materials with the skin, eye, or mucous membranes is a frequent route of entry. Chemical contact with those surfaces could result in local damage and subsequent absorption into the bloodstream, thereby causing other effects throughout the body. The effect of eye contact with a chemical can range from irritation to permanent blindness. Chemical exposure can be avoided by use of appropriate protective equipment such as gloves, safety glasses, goggles, and/or face mask.

Injection

Injection of foreign materials (chemical or biological) can cause

a serious health hazard because the material can be delivered directly to the bloodstream or become embedded in tissues. Exposure to toxic chemicals, human blood or other potentially infectious materials can inadvertently occur through mechanical injury from contaminated glass, metal, needles/syringes, or other objects. Therefore, extreme caution should be exercised when handling these or similar objects.

Crime Scene/Mass Disaster

General Precautions

No one should enter the crime scene/mass disaster without the proper safety and personal protective equipment. (See Personal Protective Equipment later in this manual.)

Individuals should not be permitted to eat, drink, smoke, or apply makeup at the crime scene/mass disaster.

The crime scene/mass disaster may be a source of contamination from a variety of sources including human blood and body fluids (both liquid and dried), human tissues and other remains.

Treat all human body fluids as potentially infectious and use Universal Precautions under Bloodborne Pathogen Safety, discussed subsequently.

In addition to the biological hazards, consideration must be given to the variety of chemical, environmental, and/or mechanical hazards that may be present at the crime scene/ mass disaster.

Always be on the alert for sharp objects such as hypodermic needles, knives, razors, broken glass, nails, and exposed or cut metals.

Broken glass which may be contaminated should never be picked up directly with the hands. It should be collected using mechanical means, such as a brush and dust pan, tongs, or forceps.

Ensure that the crime scene/mass disaster is properly ventilated.

Mirrors and flashlights should be used when looking in confined

spaces such as under car seats, beds, etc., prior to reaching into those areas with the hands.

Use a wooden paint stirrer, or other similar item, to search narrow and confined spaces, such as those found between car seats and chairs, before the hands are used.

Never recap hypodermic needles or place covers, such as pencil erasers, on the end of the needles. Place all syringes, needles, and other sharp objects in puncture?resistant containers.

Refer to Bloodborne Pathogen Chemical Safety, for specific safety procedures.

Access Control

Provide a means of controlled entry and exit for personnel and equipment entering or leaving the crime scene/mass disaster.

Provide a system for centralized decontamination of personnel and equipment and the collection of infectious waste (gloves, coveralls, etc.) to prevent transfer of potentially infectious material to noncontaminated areas such as the worker's office, car, or residence. Procedures should be established for the proper disposal of all contaminated waste.

Violent Crimes

Violent crimes pose a greater potential for contact with infectious material.

All human blood, body fluids, and tissues, from both living and deceased individuals, must be handled as being potentially infectious for hepatitis and HIV (human immunodeficiency virus).

Avoid direct contact with all human blood, body fluids, and tissues. Personal protective equipment must be readily available and used. (See Universal Precautions under Bloodborne Pathogen Safety)

Surgical caps, fluid?resistant protective clothing, face masks/shields, eye protection, shoe covers and boots should be worn in instances when gross contamination can be reasonably anticipated (e.g., autopsies, crime scenes, mass disasters).

Bombings

If a bombing incident occurs, investigative personnel should ensure that the following precautions are taken before entering the scene:

Ensure that all utilities (electric, gas, and water) are turned off. Contact local utilities or power company for assistance.

A bomb technician should first check the damaged area for unexploded bomb(s).

The structure should then be checked by engineers for hazardous structural conditions.

Do not touch or move any suspected explosive device at the crime scene until it has been rendered safe by a public safety bomb squad or military Explosive Ordnance Disposal (EOD) Unit.

Initial entry personnel should carry at least one radiation extremity monitoring alarming dosimeter/rate meter in order to identify any potential radiation hazard.

Use proper personal protective equipment such as hard hats, safety goggles, gloves, foul weather clothing, waterproof and puncture-resistant coveralls, steel/toe steel shank workboot, respirator, reflective tape for clothing, and any other protective item. (See Personal Protective Equipment).

All bombing or explosive?related evidence which consists of substances of unknown composition, such as powders or liquids, must be assumed to be extremely sensitive and capable of initiation or detonation.

Unknown substances in these matters should be examined by a bomb technician or a forensic chemist before collection.

Prior to packaging for shipment, call the FBI Laboratory, Explosives Unit at (202) 324?2696 to ascertain the quantity needed for analysis, the packaging method to be used, and the proper shipping method. Also, call for questions regarding handling of these types of substances.

All unknown substances should be labeled:

Use caution when handling. Substance is possibly flammable or explosive.

All evidence collected at the crime scene which has been examined by a forensic specialist (bomb technician or chemist) and found to be safe and nonhazardous should be clearly labeled as such. The label should be clearly visible and include the name, agency, and phone number of the forensic expert who examined the material and made the determination that it was safe.

Clandestine Drug Laboratories

Clandestine drug laboratories may present extremely dangerous situations to untrained personnel. These laboratories often contain extremely dangerous chemicals, which may be intentionally mislabeled, as well as "booby trapped," to prevent entry. They should only be searched, cleared, and decontaminated by the Drug Enforcement Administration (DEA) personnel who are trained and certified for this type of work.

When dealing with clandestine drug laboratories evacuate the scene, secure the area, and contact the nearest office of the DEA.

Removal of Hazardous Materials from the Crime Scene/Mass Disaster

All hazardous materials should be properly labeled, stating the type of hazard and any special handling procedures before being removed from the crime scene/mass disaster.

All hazardous material labels should be dearly visible and include the agency, name, and phone number of the forensic expert who examined the material.

Title 49 of the Code of Federal Regulations lists specific requirements that must be observed in preparing hazardous materials for shipment by air, highway, rail, water, or any combination thereof.

Title 49 of the Code of Federal Regulations, part 172.101 (49 C.F.R. 172.101), provides a Hazardous Materials Table which identifies those items considered hazardous for the purpose of transportation, special provisions, hazardous materials

communications, emergency response information, and training requirements.

Exposure to Critical (Traumatic) Incidents

Shootings, drownings, accidents, sexual assault and child abuse are only a few examples of critical (traumatic) incidents that law enforcement personnel are exposed to which may produce significant emotional responses. These responses may include any of the following:

Alcohol/substance abuse
Anger
Anxiety
Crying/depression
Fatigue
Flashbacks and intrusive thoughts
Guilt
Heightened sense of danger
isolation/withdrawal
Marital problems
Nightmares
Numbness
Perceptions of going insane
Startle reactions (e.g., difficulty sleeping, headaches, muscle aches, stomachaches, high blood pressure, etc.)
Trouble remembering/concentrating

For additional information or assistance concerning critical (traumatic) incidents, contact:

The International Critical Incident Stress Foundation, Baltimore, Maryland, (410) 730 4311. If emergency assistance is needed, contact the 24 hour Critical Incident Stress Debriefing (CISD) Hotline, (410) 313 2473.

Safety

Bloodborne Pathogen Safety

On December 6,1991, the Occupational Safety and Health Administration (OSHA) issued the regulation called "Occupational Exposure to Bloodborne Pathogens (BBP)," found in Title 29, Section 1910.1030 (29 C.F.R. 1910.1030) of the Code of Federal Regulations. The standard covers those occupations having a high

potential for exposure to bloodborne pathogens, including law enforcement, emergency response, and crime laboratory personnel.

Individuals covered by this standard should observe Universal Precautions to prevent contact with human blood, body fluids, tissues and other potentially infectious materials.

Universal Precautions require that employees treat au human blood, body fluids, or other potentially infectious materials to be infectious for hepatitis B virus (HBV), human immunodeficiency virus (HIV), and other bloodborne pathogens. Appropriate protective measures to be taken to avoid direct contact with these materials include:

Use barrier protection at all times;

Prohibit eating, drinking, smoking, or applying makeup at the crime scene/mass disaster;

Use gloves when there may be hand contact with blood or other potentially infectious materials. Gloves should always be worn as if there are cuts, scratches, or other breaks in the skin. In some instances where there is heavily contaminated material, the use of double gloves is advisable for additional protection;

Change gloves when contaminated or as soon as feasible if torn, punctured, or when their ability to function as a barrier is compromised;

Always wash hands after removal of gloves or other personal protective equipment (PPE). The removal of gloves and other PPE should be performed in a manner which will not result in the contamination of unprotected skin or clothing;

Wear safety goggles, protective face masks or shields, or glasses with side shields to protect from splashes, sprays, spatters, or droplets of blood or other potentially infectious materials. These same precautions must be taken when collecting dried stains for laboratory analysis;

Use disposable items, such as gloves, coveralls, shoe covers, etc. when potentially infectious materials are present;

Place contaminated sharps (e.g., broken glass, needles, knives,

etc.,) in appropriate leakproof, closable, puncture?resistant containers when these sharps are to be discarded, transported, or shipped. If transported or shipped, containers should be appropriately labeled;

Do not bend, recap, remove, or otherwise handle contaminated needles or other sharps;

Use a protective device, such as a CAR mask, when performing mouth?to?mouth resuscitation;

Decontaminate all equipment after use with a solution of household bleach (diluted 1:10, 70% isopropyl alcohol, or other appropriate disinfectants;

After all evidence e has been collected and the crime scene has been released, the owner or occupants of the affected property should be made aware of the potential risks from bloodborne pathogens;

Evidence containing blood or other body fluids should be completely dried before it is packaged and shipped to the laboratory for analysis. Appropriate biohazard warning labels must be affixed to the evidence container indicating that a potentially infectious material may be present;

To avoid direct contact and exposure to potentially infectious evidentiary materials in the courtroom, evidence contaminated with human blood or other potentially infectious materials should be placed in a sealed, transparent package and labeled with the appropriate biohazard warning label.

Additional Precautions

In addition to Universal Precautions, there are certain requirements in the OSHA BBP standard that pertain to collection, handling, storage, transport, and shipping of blood and other potentially infectious material.

Evidence specimens contaminated with wet blood or other potentially infectious materials must be placed in a closable, leakproof container (i.e., heavy?duty plastic bag) when transported from the crime scene to the drying location. After drying, the evidence must be placed in a suitable and properly labeled container before being transported to the crime

laboratory. (Note: Plastic bags used to transport evidence contaminated with wet blood or other fluids should be retained as evidence.)

OSHA's BBP standard 29 CFR 1910.1030 (g)(l)(i), requires that evidence specimens, such as liquid blood (vacutainer tubes) or other potentially infectious materials, must be placed in a closable, leakproof container and labeled (see above) or color?coded prior to being stored or transported.

Engineering and work practice controls are used to eliminate or minimize employee exposure to hazardous materials. Engineering controls (e.g., puncture?resistant containers for contaminated sharps, paint stirrers, and adjustable mirrors for locating evidence in confined/hidden spaces) isolate or remove the hazard, whether bloodborne or chemical, from the workplace. Workplace controls (e.g., hand washing facilities, wearing personal protective equipment) reduce the likelihood of exposure by altering the manner in which a task is performed.

For additional information on proper protection against blood and other potentially infectious materials, refer to "Personal Protective Equipment."

Decontamination of Nondisposable Clothing

These recommendations apply only to nondisposable clothing and not to clothing that is part of the personal protective equipment according to OSHA 29 CFR 1910.1030.

Protect hands with disposable gloves;

Remove contaminated garment carefully; protect skin and mucosal surfaces during removal, e.g., cover face and eyes with mask and goggles or face shield when removing garment over head;

Fill a sink, bucket, or deep tray with cold water and soak contaminated part of garment to remove blood or other material. Using gloves, squeeze out water from garment; dispose of water into sewer, toilet, or dirty sink; rinse sink and container with plenty of water; disinfect container if needed;

Store garment in plastic bag prior to being laundered, or place garment into tray and cover contaminated area with one of the following disinfectants:

1:20 dilution fresh chlorine bleach for fabrics that tolerate bleaching such as white coats or uniforms;

70% alcohol (ethanol or isopropyl) for delicate fabrics;

Let soak for 10 minutes, remove, rinse with water, and dry. The disinfected garment can be laundered or dry cleaned.

Chemical Safety

Depending on the type of material encountered, a variety of health or safety hazards may exist. Some of those hazards are identified by the following categories:

Flammable or combustible materials (e.g., gasoline, acetone, ether) ignite easily when exposed to both air and an ignition source such as a spark or flame;

Explosive materials (e.g., dynamite, CA, TNT, etc.) are chemically unstable. Instability determines the sensitivity (i.e., the amount of energy required to initiate a reaction). Explosives containing nitroglycerine require a minimal amount of shock to be initiated. Heat, friction, and fire are also means for initiation;

Pyrophoric material is any liquid or solid igniting spontaneously in air at or below 130° F (54° C) Examples include phosphorus, sodium, and barium;

Oxidizers are a class of chemical compounds that can react violently with flammable and combustible materials. Some common types of oxidizers include chlorates, nitrates, hydrogen peroxide, perchloric acid, and sulfuric acid. Avoid storage with incompatible materials that could react with the oxidizer or catalyze its decomposition;

Corrosive materials are those substances which can cause injury to body tissue or be corrosive to metal. Corrosive injury may be to a minor degree (irritation) or actual physical destruction of body tissues. Corrosive chemicals act on body tissues through direct contact with the skin or eyes, inhalation, or ingestion;

The key to working safely with chemicals is knowledge of their

hazardous properties, proper training in handling and disposal techniques, and emergency preparedness.

For proper protection against Chemicals Hazards, see "Personal Protective Equipment."

Latent Fingerprint Safety

Refer to Bloodborne Pathogen Safety, when dealing with any human tissue or body fluid from a living or deceased individual.

When latent print evidence is contaminated by human biological material, appropriate personal protective equipment and engineering controls must be used during the examination.

Light Source Safety

The use of ultraviolet (UV) lights, lasers, and other alternative light sources are increasing in use not only in the latent fingerprint field, but in forensic science in general. While these tools are of great value to the forensic scientist, they also create some potentially hazardous conditions, especially when the user is untrained or unaware of the hazards associated with their use. The operator of any light source must be properly trained in the use and safety of these instruments. Regardless of the light source being used, it is absolutely essential that appropriate eye wear be worn by the user and by all personnel in the vicinity of the device.

When using UV light sources, it is essential that an individual's eyes be protected from direct exposure and that prolonged exposure to the skin be avoided.

Because some lasers create an apparent point source of light which may not be visible to the viewer, there exists an enormous radiant energy which has the potential to cause irreversible damage to the retinal tissues of the eye, from both direct and/or reflected beams.

Personal protection for the eyes requires goggles which have sufficient protective material and which are fitted so that stray light cannot enter from any angle. All laser protective eye wear should be clearly labeled with the optical density and wavelength for which protection is afforded.

Avoid both direct and indirect (reflected from a polished

surface) eye and skin contact with a collimated laser beam. Eye wear, worn while conducting examinations using high?powered lasers should be approved by the American National Standards Institute (ANSI), and have an optical density of five or greater at the maximum operating wavelength.

Adequate ventilation should be provided with all lasers.

Lasers can present a shock hazard both indoors and outdoors in a wet environment.

Keep the exit port of the light source at a sufficient distance from surfaces to prevent overheating and combustion.

Firearms Safely

Weapons should never be shipped or stored in a loaded condition;

Remove all ammunition from firearms and follow the regulations for transportation;

For submission of live ammunition, bullets, and/or guns, follow approved procedures specified by the FBI or local crime laboratory.

Confined Space Safety

A confined space is an enclosed space large enough for an individual to bodily enter and perform assigned work. It has limited or constricted means of entry or exit and is not designed for continuous occupancy.

Entry into confined spaces may expose the individual to a variety of hazards, including toxic gases, explosive atmospheres, oxygen deficiency, and electrical hazards.

Conditions in a confined space must be considered immediately dangerous to life and health unless shown otherwise.

Some safety tips for working in confined spaces include:

Never enter a confined space before all hazards (atmospheric, engulfment, and mechanical) have been identified and procedures have been developed to deal with them;

Always isolate the confined space from all unwanted energy

sources or hazardous substances;

Always maintain proper mechanical ventilation in a confined space and make sure ventilation equipment does not interfere with entry, exit, and rescue procedures;

Never introduce hazards such as welding, cleaning solvents, etc., in a confined space without first making provisions for these hazards;

Always monitor for atmospheric hazards (oxygen, combustibles, toxins) prior to and during entry;

Always provide barriers, as necessary, to warn unauthorized personnel and to keep entrants safe from external hazards;

Always provide constant communications between entrants and outside attendants, and remember to have backup communications if using two?way radios;

Always wear appropriate personal protective equipment: be familiar with the use and limitations of that equipment; and be sure it is properly maintained;

Never attempt rescue in a confined space unless you are part of a designated rescue team and have the proper knowledge, skills, and equipment to effect a safe rescue;

Use of safety belts and harnesses is mandatory.

For additional information, refer to the OSHA standard for permit?required confined spaces, 29 CFR 1910.146.

Personal Protective Equipment Hand Protection

Hand protection should be selected on the basis of the material being handled and the particular hazard (biological or chemical) involved. For chemical resistance, select the glove material that offers the best level of protection for the chemicals handled. The following are some glove material types and their functions:

Nitrile (NOR) provides protection from acids, alkaline solutions, hydraulic fluid, photo solutions, fuels, lubricants, aromatic, petroleum, and chlorinated solvents. It also offers excellent resistance to punctures, cuts, and snags.

Neoprene offers resistance to oil, grease, acids, solvents, alkalies, bases, and most refrigerants.

Polyvinyl chloride (PVC) is chemically?resistant to alkalies, oils, limited concentrations of nitric and chromic acids. This material can be worn by most workers who are allergic to natural rubber.

Natural Rubber (Latex) resists mild acids, caustics, detergents, germicides and ketonic solutions, but it will swell and degrade if exposed to gasoline and kerosene. Because gloves made from natural rubber (latex) are adversely affected by exposure to high temperatures and direct sunlight, they should not be stored for an extended period of time in the passenger area or trunk of a car.

Have readily accessible hypoallergenic gloves, glove liners, powderless gloves, and other similar alternatives for those allergic to the normally provided gloves.

Check the gloves to be used for holes, punctures, and tears and remove rings or other sharp objects which may cause punctures.

Wear heavy (8?10 mil thick) latex gloves or a double layer of gloves when working with items heavily contaminated with blood or other human biological material.

Remove gloves carefully by grasping the cuffs and pulling them off inside out, starting at the wrist and working toward the fingers.

Discard disposable gloves in designated containers. Do not reuse.

Eye Protection

Eye protection is an important consideration when working at a crime scene or when handling potentially hazardous materials. Appropriate eye protection (face shields, goggles and safety glasses) should be worn when handling any of the following materials:

Biohazards
Caustics, corrosives, or irritants
Explosives
Flammable materials

Lasers radioactive materials
UV light

Types of Eye Protection

Refer to American National Standard Practice for Occupational and Educational Eye and Face Protection, American National Standards Institute, ANSI Z87.1?1989 (or latest revision) for additional information.

Safety Glasses

At the crime scene, you are likely to encounter both biological and chemical hazards. There always exists the potential for splashing biological fluids or chemicals. In addition, flying objects may enter the eyes if not properly protected. Safety glasses should be worn at all times in the presence of these hazards. In most instances, safety glasses with side shields are adequate. Where there is danger of splashing of biological fluids, chemicals, or flying particles, goggles and/or full face shields will give more protection.

Contact Lenses

Contact lenses are not to be used as eye protection. In the event of a chemical splash into the eye, it is often extremely difficult to remove the contact lens to irrigate the eye. Gases and vapors can be concentrated under such lenses and cause injury or permanent eye damage.

Prescription Safety Glasses

Crime scene personnel whose vision requires the use of corrective lenses should wear safety eye protection of one of the following types:

Prescription safety glasses with protective lenses. Safety eye wear that can be worn over prescription glasses without disturbing the adjustment of the glasses.

Safety Goggles

Goggles are not intended for general use. They are intended for wear when there is danger of splashing chemicals or flying particles.

Face Masks/Shields

Full?face masks/shields that protect the face and throat should always be worn when maximum protection from flying particles and harmful liquids (biological or chemical) is needed.

Foot Protection

Shoes that completely cover and protect the foot are recommended. Shoes that expose the foot in any way should not be worn. In addition, fabric shoes, such as tennis shoes, should not be worn as they may readily absorb liquid. Certain hazardous situations may require footwear that has conductive soles, insulated soles, steel toe and shank, and is chemical resistant.

Respiratory Protection

Certain crime scenes, such as bombings and clandestine laboratories, may produce noxious fumes and other airborne contaminants which require respiratory protection.

Safety supply companies carry many types of respirators ranging from a disposable dust mask to a self?contained breathing apparatus. Selection should be made according to the guidelines in the American National Standard Practices for Respiratory Protection Z88.2?1992, after consultation with health and safety professionals.

The critical elements for the successful use of a respirator include training, motivation, medical evaluation, fit testing, and a respirator maintenance program. Without a complete respiratory protection program, personnel will not receive the degree of protection anticipated from a respirator, even if it is a correct choice for the situation. As a minimum, compliance with Title 29 CFR 1910.134 is mandatory whenever respirators are used by personnel, whether on a required or voluntary basis.

Head Protection

Elimination or control of hazards leading to an accident should be given first consideration, but many accidents causing head injuries are difficult to anticipate and control. Where these conditions exist, appropriate head protection must be provided to eliminate injury.

Head protection, in the form of protective hats, must resist

penetration and absorb the impact. In certain situations, such as bombings which can cause structural damage to a scene, additional head protection may be necessary. Heavy?duty fireman?type hats provide added protection to the ears and posterior neck. Protective helmets also protect against electrical shock.

The standard recognized by OSHA for protective hats is contained in ANSI Requirements for Industrial Head Protection, Z89.1?1986. This standard should be consulted for further details.

Bibliography

Reference materials(240) are available for the preceding sections.

The Crime Scene

The physical evidence recovered during investigations of crime scenes is one of the critical areas in contemporary law enforcement. Often, the facts and tangible items of evidence derived from these investigations make the difference between success and failure when a case is brought to trial. With the evolution of the scientific aspects of forensic science, more attention must be awarded at crime scenes to recovering and maintaining the integrity of evidence which will be eventually examined by specialists in the crime laboratory.

One important consideration, bearing on the modern view of forensic science is that this field is sometimes associated only with work accomplished in the crime laboratory. This consideration, however, is in actuality a very limited perspective on the overall area of forensic science. It is obvious that the ability of the laboratory to provide scientific interpretations is dependent to a great extent on the recognition, recovery and documentation of evidence at the crime scene. In essence, then, the field investigator or crime scene technician is as much a part of forensic science as the highly skilled laboratory examiner. If the evidence from a scene is not properly handled, the work of the crime laboratory can be hindered to a great extent.

Therefore, it is suggested the discipline of forensic science be regarded as a multifaceted one. Each level of evidence involvement must be planned, organized, and performed with a central issue in mind: effective use of the physical evidence to its greatest potential.

It should be ensured that the crime scene searches are conducted in a systematic and methodical fashion. Numerous suggestions are presented in terms of practical aspects of day-to-day search operations.

Due to the myriad situations which can occur, it would be virtually impossible to cover all conceivable possibilities. Nonetheless, the material contained herein brings out significant concerns common to almost all agencies. Additionally, these points should serve as catalysts for the reader to generate other important items based on specific agency needs.

Practical Suggestions Regarding Crime Scene Administration and Management

Preparation

Accumulate packaging and collection of materials necessary for typical search circumstances;

Prepare the preliminary format for the paperwork needed to document the conducting of the search;

Ensure that all specialists are aware of the overall forms of evidence usually encountered as well as the proper handling of these materials;

Evaluate the current legal ramifications of crime scene searches (e.g., obtaining of search warrants);

Discuss the search with involved personnel before arrival at scene, if possible;

Identify, when feasible, a person?in?charge prior to arrival at scene;

Make preliminary personnel assignments before arrival at scene, if practicable;

Consider the safety and comfort of search personnel. When encountering a potentially dangerous scene or inclement weather, be prepared with:

· **clothing**

- **communication**
- **lighting assistance**
- **shelter**
- **transportation**
- **food**
- **medical assistance**
- **scene security**
- **equipment**

Assess the personnel assignments normally required to successfully process a crime scene.

The following information is provided as an example of the personnel responsibilities. (Depending on circumstances and personnel availability, it may not be feasible to have one person assigned to each duty. It is relatively common for one individual to accomplish two or more responsibilities.

Person-In-Charge
- **administrative log**
- **narrative description**
- **preliminary survey**
- **scene security**
- **final decision making**

Photographer
- **photographs**
- **photographic log**

Sketch Preparer
- **sketch**
- **documentation of items on sketch**

Evidence Recorder
- **evidence log**
- **evidence custodian**

In instances of prolonged search efforts, consider the use of shifts using two or more teams. Transfer paperwork and responsibility in a preplanned manner from one team to the next.

Organize communication with services of any ancillary nature (e.g., medical examiner, prosecutive attorney) in order that questions which surface during crime scene search may be resolved. Take steps to organize a command post headquarters for

communication, decision making, etc., in major or complicated crime scene investigations.

The possibility of coordinating multijurisdiction scene investigations should be explored. It is advantageous to have working agreements that are mutually acceptable to potentially involved agencies. These agreements should be made before confusion occurs in an actual multijurisdiction case, rather than as a later crisis response.

Approach Scene

Be alert for discarded evidence;

Make pertinent notes;

Establish frame of mind to take control of scene regardless of circumstances observed on arrival;

Consider personal safety.

Secure and Protect Scene

Take control on arrival;

Determine extent to which scene has thus far been protected;

Check for adequate scene security even if advised that it has been protected prior to arrival;

Obtain information from logical personnel who have entered scene and have knowledge relative to its original conditions;

Identify one individual who is designated as the person?in?charge for final decision making and problem resolution;

Take notes: do not rely on memory;

Keep out unauthorized personnel: begin recording who enters and leaves;

Evaluate Physical Evidence Possibilities;

Initiate Preliminary Survey

The survey is an organizational stage to plan for the entire search'

Cautiously, walk through the scene;

Maintain definite administrative and emotional control (usually the person?in?charge);

Select appropriate narrative description technique;

Acquire preliminary photographs;

Delineate extent of the search area: usually expand initial perimeter;

Organize methods and procedures needed: recognize special problem areas;

Determine manpower and equipment needs make specific assignments;

Identify and protect transient physical evidence, e.g., evidence that can be lost such as hairs, fibers, dust, etc.;

Develop a general theory of the crime;

Make extensive notes to document the scene's physical and environmental conditions, assignments, movement of personnel, etc.;

Evaluate Physical Evidence Possibilities

This evaluation begins upon arrival at scene and becomes detailed in the preliminary survey stage. Based on the preliminary survey, establish evidence types most likely to be encountered.

Ensure collection and packaging equipment is sufficient for task at hand: given scene may require special techniques not normally used.

Focus first on evidence that could be lost (e.g., detached from garment) and leave the least transient forms of evidence to be last;

Ensure all personnel consider the great variety of possible evidence, not only evidence within the scope of their respective specialties;

Focus first on the easily accessible areas in open view and progress eventually to possible out?of?view locations: look for purposely hidden items;

Consider whether the evidence appears to have been moved inadvertently;

Evaluate whether or not the scene and evidence appear intentionally contrived;

Prepare Narrative Description

The narrative is a running, written description of the condition of the crime scene in general terms.

Represent the scene in a general to specific reference scheme;

Use photographs to supplement narrative description;

Use a systematic approach in recording the narrative; no item is too insignificant to record if it catches one's attention;

Do not permit the narrative effort to degenerate into a sporadic and unorganized attempt to recover physical evidence. It is recommended that evidence not be collected at this point, under most circumstances;

Methods of narrative include: written, audio, and video (sight/sound or sight only).

Depict Scene Photographically

Begin photography as soon as possible: plan before photographing;

Document the photographic effort with a photographic log;

Ensure that a progression of overall, medium, and close?up views of the scene is established;

Use a recognized scale device for size determination when

applicable;

When a scale device is used, first take a photograph without the inclusion of this device;

Photograph the evidence in place before collecting and packaging;

Be observant of and photograph areas adjacent to the crime scene, points of entry, exits, windows attics, etc.;

Consider the feasibility of aerial photography;

Photograph items, places, etc., to corroborate the statements of witnesses, victims, and suspects;

Take photographs from eye level, when feasible, to represent the scene as would be observed by normal view;

Points to Consider

Use two-dimensional photographs supplemented by diagrams and sketches;

Do not hesitate to photograph something which has no apparent significance. Film is relatively cheap compared to the importance of providing evidence to the investigator;

Prepare Diagram and Sketch of Scene

The diagram establishes a permanent record of items, conditions and distance-size relationships: diagrams supplement photographs;

Draw a rough sketch at the scene, which is normally not drawn to scale;

Typical material on the rough sketch:

specific location
date
time
case identifier
preparer/assistants
weather conditions
lighting conditions
scale or scale disclaimer

compass orientation
evidence
measurements
key or legend

Number designations on the sketch may be coordinated with same number designations on the evidence log in many instances.

This sketch should contain sufficient measurements and details to be used as a model for a drawn?to?scale diagram, if necessary.

Be sure to select the sketch technique before beginning the sketch. Ensure that enough room is allowed to include all pertinent information and measurements.

General progression of sketches:

· lay out the basic perimeter;
· set forth fixed objects, furniture, etc.;
· insert evidence as it is recovered;
· record appropriate measurements;
· set forth the key/legend, compass orientation, etc.

Conduct Detailed Search/Record and Collect Physical Evidence

Accomplish the search based on a previous evaluation of evidence possibilities.

Conduct search from general to specific, regarding evidence items.

Use specialized search patterns when possible, (e.g., strip, grid, spiral, quadrant or zone).

Mark evidence locations on the diagram/sketch.

Complete the evidence log with appropriate notations for each item of evidence.

Have at least two persons:
· see evidence in place before collection;
· observe it being recovered;
· mark evidence (mark item itself whenever feasible);
· place identifying marks on evidence containers.

If feasible, have one person as an evidence custodian especially

in relatively complicated crime scenes involving large amounts of evidence.

Do not excessively handle the evidence after recovery.

Seal all evidence containers at the crime scene.

Do not guess on packaging requirements: different types of evidence may necessitate different containers.

Photograph all items before collection and enter notations in the photographic log (remember to use a scale device when necessary).

Do not forget entrance and exit areas at the scene for potential evidence.

Be sure to obtain appropriate known standards (e.g., fiber samples from a
known carpet).

Always make a complete evaluation of the crime scene. Do not rely on the results of Laboratory tests only.

Constantly check paperwork, packaging notations, and other pertinent recordings of information for possible errors which may cause confusion or problems at a later time.

Four Basic Premises to Consider

The best search options are often the most difficult and time consuming.

You cannot over?document the physical evidence.

There is only one chance to perform the job properly.

There are two basic search approaches, in this order:

1. A cautious search of visible areas, taking steps to avoid evidence loss or contamination;
2. After the cautious search, a vigorous search for hidden or concealed areas.

Conduct Final Survey

This survey is a critical review of all aspects of the search.

Discuss the search jointly with all personnel for completeness.

Double?check documentation to detect inadvertent errors.

Ensure that photographs are taken of scene showing the final condition after completion of the search.

Check to ensure all evidence is accounted for before departing the scene.

Ensure all equipment used in the search is gathered.

Make sure possible hiding places or difficult access areas have not been overlooked in a detailed search.

Critical issues:

Have you gone far enough in the search for evidence, documented all essential things, and made no assumptions which may prove to be incorrect in the future?

Release Crime Scene

Release the crime scene only after completion of the final survey.

At minimum, documentation should be made of:
· time/date of release.
· to whom released.
· by whom released.

Ensure that the evidence found at the crime scene is gathered according to legal requirements, is documented, and is appropriately marked for future reference.

Once the scene has been formally released, reentry may require a warrant.

Only the person?in-charge should have the authority to release the scene.

Ensure that all personnel follow this rule.

Release the scene with the notion that there is only one chance to perform the job correctly and completely. Release then occurs

once personnel are satisfied this is the situation.

Consider the need for experts (e.g.,blood pattern analyst, medical examiner) to observe the scene before it is release
.

Examinations of Explosives

The Explosives Unit conducts examinations of Improvised Explosive Device (IED) remains, commercial explosives, blasting accessories, military explosives, ordnance items, including toolmark and bomb components. The Explosives Unit may assist in processing bombing crime scenes and handling of explosives. To request assistance or information, call the FBI Laboratory, Explosives Unit at (202) 324?2696. Send correspondence, evidence, or samples to:

Director
Federal Bureau of Investigation
Attn.: FBI Laboratory, Explosives Unit
lOth Street and Pennsylvania Avenue, N.W.
Washington,D.C. 20535

Examinations of Bomb Remains

Bomb remains are examined to identify bomb components such as switches, batteries, detonators, tape, wire and timing mechanisms. Also identified are fabrication techniques, unconsumed explosives, and overall construction of the bomb. Instrumental examination of explosives and explosive residues are carried out by the Materials Analysis Unit in conjunction with bomb component examinations.

Toolmark Examinations

All bomb components are examined for toolmarks, where possible. Tools utilized in the construction of the bomb are identified for investigative purposes.

Reference Files

The Explosives Unit also maintains extensive reference files on commercial explosives, blasting accessories, and bomb components. These files contain technical data that include known standards of military and commercial explosives, time fuses, detonators, batteries, tape, switches, and radio control systems.

Handling Explosives

Explosive devices or bombs should be handled only by qualified police or military bomb disposal personnel.

Shipping Explosives

Explosives are classified as hazardous materials. Special packaging is required, and the amount to be shipped is regulated. Call the Explosives Unit each and every time an explosive is to be shipped for examination. The shipping instructions furnished must be strictly adhered to for meaningful forensic examination as well as safety.

Examinations of Explosives by the Materials Analysis Unit

Examinations in cases involving IEDs are performed by the Materials Analysis Unit to assist the Explosives Unit in the determination of:

· Whether unknown substances are high explosive, low explosive, or incendiary in nature.

· Whether recovered explosives are consistent with known explosive products by compositional analysis.

Sometimes, the type of explosive can be determined by examinations of residues from the scene of a bombing. It should be noted that most residues remaining after the detonation of an explosive charge are water soluble. For this reason, these residues must be protected against exposure to excessive moisture. Also, other residues evaporate quickly, necessitating the immediate sealing of collected debris in new, airtight paint cans.

Post-blast Investigation Guidelines

The processing of bombing crime scenes, in spite of often massive destruction, must be conducted on the theory that everything at the scene, prior to the explosion, is still present unless vaporized by the explosion. While complex, it is possible to determine the cause of an explosion from the components found at the scene.

Purpose of Post-blast Investigation

The purpose of the Post-blast investigation process is to determine what happened, how it happened, and to gather evidence.

Special Considerations

The following steps are to assist in the preparation, supervision, and evaluation of activity connected with a bombing crime scene. The topics covered are not meant to be all inclusive, and no attempt has been made to comment on the many aspects of a bombing investigation. A comprehensive course of instruction in Post-blast crime scene processing is available through the Explosives Unit in the Post-Blast Investigator's School. For further information, contact the Explosives Unit.

Formulate a Plan of Action

Formulate a plan adapted to the particulars of the bombing crime scene. This plan should include consideration of the creation of an on?scene control center; establishment of a chain of command; assignment of various tasks such as evidence collection, photography, fingerprint processing, and crowd control; protection of the crime scene; acquisition of necessary equipment; periodically evaluating progress; providing pertinent information to the public; and public safety.

Control Center

Consider establishing an on?scene control center, particularly after a large bombing which may require days or even weeks to complete the investigation of the crime scene. The control center should coordinate efforts among investigative personnel, representatives of other agencies, and utilities, as well as handle inquiries from sightseers, persons associated with the scene, relatives of victims, and the press. One person should be in overall command of the bombing investigation, another person over the management of the crime scene search efforts, and yet another controlling the collection and handling of evidence. These three individuals must maintain close coordination and continually exchange information on an expeditious basis. The crime scene manager should report directly to the person in charge of the entire investigation.

Safety

Evaluate safety conditions at the outset of the crime scene search and on a continuing basis throughout the search. Consider

the possibility of additional devices, a device that has failed to function, the presence of live explosives in the debris, the presence of utilities (gas, electrical, etc.) in the vicinity of the blast, structural damage to buildings and, most importantly, the safety of crime scene personnel, residents, and the public. Only public safety or military explosive ordnance disposal personnel should handle suspected IEDs.

Protection of the Crime Scene

Take adequate safeguards to protect the crime scene from fire, law enforcement, utility, and rescue personnel as well as others, such as sightseers, victims, and individuals with a personal interest in the property. Also, since most residues remaining after the detonation of an explosive are water soluble, the crime scene should be protected as much as possible from exposure to excessive moisture such as rain, snow, broken water/sewer pipes, etc.

Crime Scene Photography

Take appropriate photographs to give an accurate photographic representation of the crime scene. These photographs should be made immediately before, periodically during, and at the completion of the crime scene processing. Properly identify each photograph as to location and orientation; coordinate the photographs with diagrams, maps and/or blueprints; and consider the necessity of aerial photographs.

Crime Scene Specialists

If there are no available trained specialists to handle and process bombing crime scenes, make arrangements to obtain such specialists. Although the basic principles of conducting a crime scene search apply in a bomb scene search, individuals with specialized knowledge of explosives, improvised explosive devices, damage produced by explosive charges, and other facets associated with bomb scene searches, such as the search and collection of physical bombing evidence are extremely valuable to the effective and efficient processing of a bombing crime scene. These specialists need not be qualified bomb disposal specialists. They should be the first persons to be selected for the evidence and crime scene search coordinator positions.

Equipment

Promptly make arrangements to obtain the necessary equipment to move debris and material at the scene. Although the equipment needed at a crime scene varies from incident to incident, the following is a typical representation of the necessary basic equipment:

Hand Tools: Shovels, rakes, brooms, bolt cutters, wire cutters, sledge hammers, hammers, screwdrivers, wrenches, chisels, hacksaws, magnets, flashlights, knives, 50' measuring tapes, and traffic wheel?measuring devices.

Personal Equipment: Hard hats, safety goggles, face masks or respirators, work and rubber gloves, foul weather clothing, coveralls, and work shoes.

Heavy Equipment: Dump truck, front?end loader, bulldozer, crane, and shoring materials.

Other Equipment: Screens for sifting debris, wheelbarrows, metal trash cans, power saws, cutting torch equipment, ladders, portable lighting equipment, metal detectors, plastic sheeting, photographic equipment, and rappeling equipment.

Crime Scene Kit: Usual equipment used for the collection, preservation, and identification of physical evidence.

Vehicle: If the suspected target or container was a vehicle, if possible, bring to the scene an identical vehicle to assist in identifying fragmented or distorted items.

Search for Evidence

Bear in mind that the search for evidence at a bombing crime scene is critical; it may contain important evidence for identifying the bomber(s) and/or assisting in the successful prosecution of the matter. The following guidelines are general in nature, as the exact method of searching depends on various uncontrollable factors.

It is extremely important that the area be photographed before a search begins, and when evidence is located.

Place one person in overall charge of the collection of the evidence from the various collectors, as valuable evidence may not be admissible in court if a proper "chain of custody" cannot be established. Include the location where evidence was

recovered. A diagram of the crime scene is always useful.

Do not stop the search after a few items have been found. Valuable evidence may be overlooked.

Avoid the tendency to concentrate only on obvious explosive?related physical evidence such as: safety fuse, blasting caps and leg wires, explosive residues, or unconsumed explosives, as this may result in overlooking other valuable evidence.

Look for evidence such as: fingerprints, hair and fibers, soil, blood, paint, plastic, tape, tools and/or toolmarks, metals, writing paper, printing, cardboard, wood, leather and tire tread?shoe print impressions which may produce a lead in the investigation.

Conduct a well?organized, thorough, careful search to prevent the necessity of a second search. However, have a secure disposal site for debris, should a second search be necessary.

Normally, initiation of the search should start at the site of the explosion and work outward. If the bomb crater is in earth, obtain soil samples from the perimeter, sides, and bottom of the crater, making sure to dig into the substrata. Soil samples should also be taken away from the scene for comparison purposes. If the crater is in another type of material, take samples from similar areas.

Sift small debris through a 1/4" wire screen onto an insect?type screen. Usually, screens are placed on 2?foot square wooden frames constructed from 2"x4" lumber.

X-ray the bodies of victims who were in close proximity of the explosion site, for possible physical evidence and, if possible, have the evidence removed. Victims' clothing should be retained as residues may be present on the clothing.

Search a sufficient distance from the seat of the explosion. Evidence has been found up to several blocks away from large explosions. A basic rule of thumb is to extend your perimeter half the distance past the site where the most remote piece of evidence was located.

Determine the probable flight path of bomb components to prevent needless searches.

Search trees, shrubbery, telephone poles, and the roofs, ledges and gutters of buildings. Instances have occurred where physical evidence was carried away on the tires of vehicles responding to the crime scene.

Establish a search pattern for large areas. A line of searchers moving forward has been found to be a satisfactory method. A bomb scene specialist should follow the line of searchers to evaluate the items found, control the searchers, and furnish guidance. If a second search is desired, the positions of the searchers on the line should be rotated. Charting the areas to be searched will ensure a thorough search pattern.

Retain all items foreign to the scene and items which the searchers cannot identify after seeking the assistance of those familiar with the bombed target.

Toolmark Identification

Toolmark identification is a microscopic side?by?side comparison that attempts to link a particular tool with a particular mark to the exclusion of any other tool produced. Such a singular identification can be accomplished by comparing both class characteristics (those marks left by a particular group of tools, such as a screwdriver blade that is one fourth of an inch wide) and the unique microscopic marks that could only have been left by one individual tool and no other.

The term "tool" is used in a very broad sense. It could mean a screwdriver blade, vice grips, a knife or a pry tool. It could also be the comparison of a piece of paint on a tool with the surface upon which that tool was used. Further, it could be the comparison of two pieces of rubber that have been pulled apart from each other, as can happen in a car stripping operation. The tools that can be compared in these types of examinations are only limited by the imagination of the police officer or laboratory examiner.

Conclusions

· Examinations may positively conclude that a tool did or did not produce a toolmark. Exams may also conclude that there are not sufficient individual characteristics remaining within the toolmark to determine if the tool did or did not produce the questioned toolmark.

· Class characteristics could not eliminate a particular tool and subsequently, the tool could have been used to produce a certain mark.

Toolmark Examinations

Examination of the toolmark can determine:
· Type of tool used (class characteristics);
· Size of tool used (class characteristics);
· Unusual features of tool (class or individual characteristics);
· Action employed by the tool in its normal operation, and/or in its present condition;
· Most importantly, if the toolmark is of value for identification.

Types of Toolmark Examinations

Fracture Matches

Fracture examinations are conducted to ascertain if a piece of material from an item such as a metal bolt, plastic automobile trim, knife, screwdriver, wood gunstock, rubber hose, etc., was or was not broken from a like damaged item available for comparison. This type of examination may be requested along with a metallurgy examination if questioned items are metallic in composition

Marks in Wood

This examination is conducted to ascertain whether or not the marks left in a wood specimen can be associated with the tool used to cut it, such as pruning shears, auger bits, etc. This examination may be requested along with a wood examination.

Pressure/Contact

Pressure or contact examinations are conducted to ascertain whether or not any two objects were or were not in contact with each other either momentarily or for a more extended time.

Plastic Replica Casts of Stamped Impressions

Plastic replica casts of stamped numbers in metal, such as altered vehicle identification numbers, can be examined and compared with each other as well as with suspected dies.

Locks and Keys

Lock and key examinations can be conducted to associate locks and keys with each other. Such associations are useful in establishing a conspiracy or link of commonality between or among individuals. It is often possible to illustrate this through their possession of keys which will operate a single, lockable instrumentality (e.g., vehicle, safe house, padlock, etc.). Laboratory examination of a lock can determine whether an attempt has been made to open a lock without the operating key.

Key without Lock

1. A key can be decoded to determine the manufacturer from a lock and code;

2. A determination can be made as to whether or not any number of keys were cut to operate a common lock;

3. A determination can be made as to whether a key is an original or a duplicate.

Lock without Key

1. Locks can be decoded to determine manufacturer and code.

2. Operating keys can be cut which will operate the lock.

3. A determination can be made as to whether an attempt has been made to compromise the lock (open it without the use of the operating key).

Lock with Key

1. A determination as to whether a key will operate a particular lock;

2. In obtaining and submitting lock and key evidence, identify type of lock and key and their function. Consideration should be given to the following:

If possible, submit operating key with lock;

In cylinder locks, remove the entire lock assembly, inducing the strike plate into which the locking bolt is thrown. While strike

plates are usually in door frames, locks are usually in doors.

In automobile locks, remove lock cylinders from doors, trunk and ignition.

Do not insert keys to operate lodes unless necessary to prevent destruction in lock removal.

In cases where the lock has been partially destroyed, look for and collect internal lock parts, e.g., lock pins, wafers, etc., that could be found at the scene.

Restoration of Obliterated Markings

Obliterated identification markings are often restorable, including markings obliterated by melting of the metal (welding, "puddling"). Obliterated markings can also be restored on materials other than metal, such as wood, plastics, and fiberglass. Because different metals and alloys often require specific methods for restoration of obliterated markings, the Laboratory should be contacted for number restoration procedures for field processing of items too large or heavy for submission to the laboratory.

Obtaining Evidence in Toolmark Cases

If possible, submit the actual toolmarked area for direct comparison. (Note: In footmark cases, the Laboratory will routinely make a plastic replica cast of the footmark for a possible future comparison with marking stamps.) If it is not possible to submit the original item of evidence, prepare and submit a cast of the toolmark, preferably in plastic. The instructions on how to prepare a plastic replica cast or impression are furnished below.

Photographs, although helpful in presenting the overall location of the mark, are of no value for identification purposes.

Do not forget to obtain samples of paint, safe insulation, and any other material likely to appear as foreign deposits on tools.

Do not place the tool against the footmark for size evaluation to avoid contamination.

Instructions for making a plastic cast or impression of stamped numbers in metal:

Recovering stamped numbers from keys and locks. Courtesy of Hans Mejlshede.

Take all casts and impressions before attempting any number restoration;

Use a suitable plastic replica kit to take a cast and impression. For best results, different formulas may be used in different temperature conditions. If possible, move the item to a heated area or garage;

Since the plastic replica will duplicate any foreign material left in the stamped characters, the first priority is cleaning the number area of foreign matter. Remove paint and dirt with a suitable solvent (acetone, gasoline or a commercial paint remover).

You may use a soft brush, such as a toothbrush, to help clean down to the bottom of the stamped impression area, but never use a wire brush as this will produce extraneous marks which scratch the numbers and make identification of the stamps impossible.

It is permissible to use '`Naval Jelly" to remove rust from the stamped numbers;

Build a dam around the stamped characters to retain the plastic while it hardens;

The dam material should be soft and pliable, such as caulking cord, "Play Dough," or modeling clay;

Ensure there are no voids around the dam to prevent leaking;

Following instructions in the kit, mix the liquid and powder from the kit for one minute in the plastic jar which contains the powder and pour into the prepared dam;

The plastic liquid should take no longer than 1/2 hour to harden. Wait until the cast is cool to the touch before removing it. If the cast has a lot of paint and rust, take additional casts and submit the best one to the Laboratory.

Submitting Toolmark Evidence

Pack to preserve the evidence and prevent contamination. Pay particular attention to the part of the tool which could have made the mark;

Identify each item to facilitate court presentation. Consider the possibility that the object from which the specimen was cut may be needed in court;

Submit the tool rather than making test cuts or impressions in field;

Mark ends of evidence which are or are not to be examined.

Reference Files

National Automobile Altered Numbers File (NAANF): The FBI Laboratory maintains in the NAANF selected specimens, including surface replica plastic impressions of altered vehicle identification numbers found on stolen cars, trucks and heavy equipment. The purpose of this file is to have a central repository for such specimens of altered numbers so that comparisons can readily be made at any time in an attempt to identify recovered stolen cars and possibly link such vehicles with commercialized theft rings nationwide, or other cases investigated by the FBI.

National Vehicle Identification Number Standard File (NVSF): The FBI Laboratory maintains in the NVSF standards of VIN plates from each factory of the major manufacturers of American automobiles. The purpose of this file is to enable the Laboratory to determine whether or not a submitted VIN plate is authentic.

Additionally, it gives the Laboratory the capability, in the event that bogus VIN plates are being prepared in an automobile factory, to identify not only which factory is involved, but also which machine is being used to produce the bogus VIN plates. Any suspect VIN plate encountered in investigations should be forwarded to the Laboratory for examination.

Hair and Fiber Examinations

Hairs and fibers examinations aid the investigation by placing the suspect at the scene of the crime, identifying the scene of the crime, identifying the weapon or the instrument of the crime, identifying hit?and?run vehicles, and corroborating witness

testimony. Questions concerning the collection, packaging and submission of this type of evidence should be directed to the Hairs and Fibers Unit, telephone (202) 324 4344. Evidence or samples should be sent to:

Director Federal Bureau of Investigation Attn.: FBI Laboratory, Hairs and Fibers Unit 10th Street and Pennsylvania Avenue, N.W. Washington, D.C. 20535

Examinations are valuable in that they assist in placing the suspect at the scene of the crime:

· Hairs or fibers found on victim's and suspect's clothing in crimes of violence such as rape, assault, and murder.

· Hairs or fibers from suspect found at the scene of crimes such as burglaries armed robberies and car thefts.

Identifying the scene of the crime:

· Hairs or fibers left at the scene of crimes such as murder, rape, and kidnapping.

Identifying the weapon or the instrument of a crime:

· Hairs or fibers on knives or clubs.

Identifying hit?and?run vehicles:

· Hairs or fibers adhering to suspect automobile.

Examinations are also valuable in that they corroborate the witness testimony.

Fiber Examinations

Examinations identify the type of fiber:
· Animal (wool)
· Mineral (glass)
· Synthetic (man?made)
· Vegetable (cotton)
· Determination as to whether or not questioned fibers are the same type and/or color and match in microscopic characteristics with those fibers of a suspects or victim's garments.

· **Not positive evidence, but good circumstantial evidence.**

Fabric Examinations

A positive identification can be made if a questioned piece of fabric can be fitted to the known material Composition, construction, and color fabrics are compared.

Cordage/Rope Examinations

A piece of rope left at the scene of the crime may be compared with similar suspect rope.
· Composition, construction, color and diameter can be determined.
· Manufacturer can sometimes be determined, if a tracer is present.

Botanical

Botanical examinations are conducted where plant material from a known source is compared with plant material from a questioned locale.

Wood-Types Examinations

The presence of a suspect at the crime scene can often be established from a comparison of wood from clothing, vehicle, or possessions with wood from the crime scene. Specific source:

· **Side or end matching**
· **Fracture matching.**
· **Species identification.**

Miscellaneous Examinations

These examinations include the following:
· **Fabric impressions;**
· **Glove prints;**
· **Feathers;**
· **Clothing manufacture's source information through label searches.**

Materials Analysis Examinations

These examinations entail the use of instrumentation such as infrared spectroscopy, X-ray diffractometry, capillary phoresis, high performance liquid chromatography, gas chromatograph/mass spectrograph, or other techniques to identify or compare the chemical compositions of paints, plastics, explosives, cosmetics, tapes, soil, glass and related materials. Other services include metal analyses, metallurgy, and bullet lead comparisons by elemental analysis. Also available are methods to mark materials, but they are not presented in this handbook.

Cosmetics, Paints, Plastics, Polymers, and Tapes

Cosmetics

Unknown or suspected cosmetics and/or makeup can be compared with a potential source in assault cases such as rape. The investigator should be alert to the possible transfer of such materials between victim and suspect.

Automobile Paints

It is possible to establish the color, year, and make of an automobile from a paint chip by use of the National Automotive Paint File which contains original paint systems representing paints used on all makes of American cars, light, medium, and heavy trucks, vans, and many popular imported cars such as Mercedes-Benz, Volkswagen, Porsche, Audi, BMW, Honda, Subaru, Nissan and Toyota.

A very careful search of the accident or crime scene and the victim's personal effects should be made to locate small chips because:

Paint fragments are often found in the clothing of a hit?and?run victim. Therefore, the victim's clothing should be obtained and submitted to the Laboratory whenever possible.

Paints may be transferred from one car to another, from car to object, or from object to car during an accident or the commission of a crime. Occasionally it is better to submit an entire component such as fender or bumper if the paint transfer is very minimal.

Non-automobile Paints

Paint on safes, vaults, windowsills, door frames, etc., may be

transferred to the tools used to open them. Therefore, a comparison can be made between the paint on an object and the paint on a tool.

Plastics, Polymers, and Tapes

It is usually not possible to specifically identify the source, use, or manufacturer of plastic items from composition alone, but the Laboratory can make comparisons such as:

Trim from automobiles, depending upon the uniqueness of the composition, are compared with plastic remaining on the property struck in a hit?and?run type case. In some instances where the manufacturers part number is present on the trim, the specific year and make can be determined.

Plastics comprising insulation on wire used in bombings or other crimes are compared with known or suspected sources of insulated wire.

Plastic/rubber tapes from crime are cotton. compared with suspected possible sources.

Polymers used in surgical cloth?backed tape are compared with known sources.

Miscellaneous plastic material from crime scenes is compared with possible sources.

A positive identification may be made with the end of a piece of tape left at the scene of the crime and a roll of suspect tape. If no end match is possible, composition, construction, and color can be compared as in other types of examinations to associate the question tape with the known.

General Notes to Investigators

If paint samples are to be obtained from any painted-surface, if possible, chip the paint from the surface down to the foundation! substrate rather than scrape it off. When paint is chipped off a surface, its layer structure is intact. Each layer is a point of identification. It is better to have multiple layers of paint on a questioned and known specimen rather than only the top top layer in the known specimen for Comparison and identification purposes.

Be extremely careful in obtaining, packing and marking small paint chips and other small particles of evidence. Be sure they are placed in a leakproof container such as a pillbox or screw?top vial.

1. Do not stick small paint particles on adhesive tape. Small particles have to be removed from the adhesive, laboriously cleaned, and prepared for sophisticated instrumental analyses. Contamination at the time of procurement could prevent a meaningful analysis.

2. Do not put small particles in cotton. It is difficult to remove the particles from the cotton;

3. Do not send small particles in an envelope, unless protected in a "druggist" fold to prevent small particles from leaking and contaminating other evidence.

Mineralogy Examinations

Mineralogy includes many materials, mostly inorganic, crystalline or mineral in nature. Comparisons will, by inference, connect a suspect or object with a crime scene, prove or disprove an alibi provide investigative leads or substantiate a theorized chain of events.

Materials include glass, building materials, soil, industrial dusts, safe insulation, minerals, abrasives, other debris and precious stones/gems.

Soil, Glass and Building Materials

A mineral can generally be thought of as a naturally occurring inorganic compound having a definite chemical composition and a well?defined crystal structure. Materials such as soil, glass, and a variety of building products either consist of or directly derive from rocks and minerals. Quartz and feldspars are common components in most soils, but quartz sand is the principal ingredient in common window glass and Portlandite is the man-made mineral found in hardened concrete. Additionally, wallboard, safe insulation, industrial abrasives, gemstones and other related products are fundamentally minerals

Forensic Utility of Soil

Soil is generally considered to be the natural accumulation of weathering rocks, minerals and decomposing plants. The formation of soil is a dynamic process influenced by geologic parent material, relief, climate, biological activity, and time.

Soil may be developed in place or after being deposited by wind, water or/and man. Additionally, and of forensic significance, soil may contain man?made materials such as fragments of brick, roof shingle stones, paint chips, glass, and other compounds. These man?made materials improve characterization and, consequently, may strengthen the association between specimens.

Glass

The American Society for Testing and Materials (ASTM) defines glass as "the inorganic product of fusion which has cooled to a rigid condition without crystallizing." However, conceptually, and for practical purposes, glass can be regarded as a hard, rigid, brittle solid that is usually translucent to transparent. The examination of glass can be divided into several categories based on its optical, physical and chemical properties.

Fracture Analysis

Given that glass behaves like a brittle solid when broken, the resulting fracture or perforation may yield valuable information regarding the type and general speed of the responsible object, and sometimes, the general direction of impact, also referred to as the angle of incidence.

With regard to the type and general speed of the object, there are two general categories: fractures and perforation that are characteristic of objects traveling at what can be described as a "high velocity," and those believed to have been traveling at a relatively "low velocity."

High velocity impact fractures and perforations are usually characteristic of the projectile being propelled by a means other than "arm thrown," namely, a bullet from a firearm, a rock from a slingshot, a BB from an airgun and the like. These fractures and/or perforations typically produce an individual hole with small and limited radial fractures. They morphologically resemble a "cone," with a greater amount of glass absent on the opposite side of the impact.

Low velocity impacts, conversely, are characterized by an

increased number of well developed radial fractures, usually accompanied by concentric fractures surrounding the point of impact.

There are a number of variables that contribute to the resulting characteristics of the fracture: the size and hardness of the projectile, its shape and density and the distance between the "shooter" and the window, which relates to the projectile's initial and terminal velocities. Also, the thickness and type of glass affect the type of fracture or perforation to be sustained by the window. Accordingly, the interpretation of the fracture can depend upon reasonable assumptions that are likely developed through other aspects of the investigation.

When large pieces of glass are recovered from two different locations, there exists the possibility that pieces from each source may be physically fitted together. This type of association is considered "individual" or single source, to the exclusion of another source. It is possibly the strongest association between glass specimens.

Submitting Glass Specimens

Glass specimens, depending on their size, should be properly preserved. Large sheets or containers should be packaged in hard, sturdy, shock absorbing containers.

Smaller particles travel well in 35 mm film canisters. All specimens should be sealed, and known and questioned specimens should be isolated from each other to prevent cross?contamination in the case of damage and leakage during shipment. When the size of recovered glass is too small for fracture fitting, optical and compositiona1 analytical techniques will be employed to compare the specimens.

The omnidirectional nature of breaking glass serves law enforcement by typically transferring glass particles from the window to the suspect's hair and/or clothing and, subsequently, to the soles of his/her shoes. Particles may also become embedded in the object used to break the glass. Accordingly, the proper preservation and examination of these specimens may associate a suspect with the crime scene long after they have departed.

Typical window glass can be compositionally considered a soda?lime? silicate; soda, referring to the sodium component, derived (in part from salt lime contributes calcium and comes

from limestone, silicate refers to the element silicon which quartz sand provides: this is a simplified/idealized formula.

The complete elemental composition is responsible for a variety of glass properties. Some are desirable ones to facilitate the manufacturing process, others tailored to end use properties like transparency. There are numerous elements that, although minor in proportion, significantly contribute to the product.

Historically, refractive index (RI) determinations have been used to compare small particles of glass (particles as small as specks of finely ground black table pepper).

The RI of glass is dependent upon its composition and temperature. The temperature of the specimen is controlled by the laboratory, its composition established by the manufacturer as per the recipe given desired properties. By determining the RI of glass particles, the examiner can indirectly infer something about the composition. If two particles share the same RI, they likely have similar compositions and, hence, could have been produced by the same manufacturer at the same time.

If particles are of sufficient size, similar to that of very coarse sand (1?2 mm) they can be analyzed compositionally. Specific elements can be identified in concentrations measured in parts per million(PPM). When specimens are compositionally indistinguishable there is increased scientific certainty that they share the same origin.

Building Materials

Building materials encompass a variety of construction?related products, and selected building materials are generally natural or man made mineral and/or rock products.

Hardened concrete can be differentiated from other seemingly similar samples by comparing its color, texture and composition to include its aggregate. A wide variety of mineral aggregates are used that may help restrict the number of possible sources from which a piece of concrete block or similar building material could have originated.

Wallboard is principally gypsum. When discovered on tools or clothing it can support the modus operandi as observed from the crime scene. Additionally, the composition of wallboard can vary from type to type and manufacturer to manufacturer, hence, it too

can sometimes be somewhat specific regarding its origin.

Explosives

Instrumental analyses of explosives and explosive residues are conducted to determine:

From unknown substances, if they are high explosive, low explosive, mixtures of explosives, or incendiary mixtures.

From confiscated or unknown explosives, if they are (by compositional analysis) consistent with known explosive products or homemade mixtures like those used in previous bombings.

From explosive residues, the type of explosive(s) used to cause the explosion.

While some explosive residues are water-soluble and they must be protected against rain or excess of moisture, other residues evaporate quickly. They should be collected as soon as possible in airtight containers and submitted to the Laboratory in a timely fashion. Explosive residues can be deposited on metal, plastic, wood, paper, glass, etc.

The presence of a trained explosives chemist at crime scenes is very important, but if not possible, evidence collected for residue analysis must never be touched by "unprotected" hands and must be packaged in clean containers.

Metallurgy Examinations

Metals or metallic objects may be metallurgically examined for comparison purposes and/or informational purposes.

Examinations for Comparison Purposes

To determine if two metals or two metallic objects came from the same source or from each other, the Laboratory must evaluate surface characteristics, microstructural characteristics, mechanical properties, and composition.

Surface Characteristic: Are evaluated from macroscopic and microscopic features exhibited by the metal surface on fractured areas, accidental marks or accidentally damaged areas, manufacturing defects, material defects, fabrication marks, and

fabrication finish. The fabrication finish reveals part of the mechanical and thermal histories of how the metal was formed, e.g., if it was cast, forged, hot rolled, cold?rolled, extruded, drawn, swaged, milled, spun, pressed, etc.

Microstructure Characteristics: Are revealed by optical and electron microscopy of the internal structural features of a metal. Structural features include the size and shape of grains; the size, shape and distribution of secondary phases; nonmetallic inclusions, and other heterogeneous conditions. The microstructure is related to the composition of the metal and to the thermal and mechanical treatments which the metal had undergone; it therefore contains information concerning the history of the metal

Mechanical Properties: Describe the response of a metal to an applied force or load, e.g., strength, ductility, and hardness.

Composition: Determines the chemical elemental make?up of the metal, including major alloying elements and trace element constituents. Because most commercial metals and alloys are nonhomogeneous materials with substantial elemental variations, small metal samples or particles may not be representative of the composition of the bulk metal.

Examinations for Informational Purposes

Some of the types of information which can result from metallurgic examinations of metals or metallic objects in various physical conditions:

Broken and/or mechanically damaged (deformed) metal pieces or parts.

1. Cause of the failure or damage, i.e., stress exceeding the strength or yield limit of the metal, material defect, manufacturing defect, corrosion cracking, excessive service usage (fatigue), etc;

2. The magnitude of the force or load which caused the failure;

3. The possible means by which the force or load was transmitted to the metal and the direction in which it was transmitted;

Burned, heated, or melted metal.

1. Temperature to which the metal was exposed;

2. Nature of the heat source which damaged the metal;

3. Whether the metal was involved in an electrical short?circuit situation.

Rusted or corroded metal

To determine the length of time a metal has been exposed to the environment, it is necessary to submit information concerning the environmental conditions surrounding the item when it was recovered.

Cut or severed metal

1. Methods by which a metal could be severed are by sawing, shearing, milling, turning, arc cutting, flame cutting (oxyacetylene torch or "burning bar"), etc.

2. Relative skill of the individual who made the cut.

Metal Fragments

1. Method by which the fragments were formed;

2. If fragments had been formed by high velocity forces, this may possibly determine if an explosive has been detonated and the magnitude of the detonation velocity;

3. Possible identification of the item which was the source of the fragments;

Nonfunctioning watches, clocks, times and other mechanisms.

1. Condition responsible for causing the mechanism to stop or malfunction.

2. Whether the time displayed by a timing mechanism represents a.m. or p.m. (usually calendar?type timing mechanisms only).

Items unidentified as to use or source

1. Possible identification of use for which the item was designed, formed, or manufactured, based on the construction of and the type of metal in the item.

2. Possible identification of the manufacturer and of specific fabricating equipment utilized to form the item.

3. Identification of possible sources of the item if an unusual metal or alloy is involved.

Objects with questioned internal components

X-ray radiography can nondestructively reveal the interior construction, and the presence or absence of defects, cavities, or foreign material.

Packing and Shipping Evidence

Today's mandatory regulations help ensure that there will be no problems encountered in the shipment of hazardous materials. Regulations are enforced by agencies empowered by specific legislation such as the U.S. Code of Federal Regulations (CFR).

The following pages contain excerpts of Title 29, Occupational Health and Safety Administration (OSHA); Title 42, Department of Health and Human Services; Title 49, Department of Transportation (DOT); International Air Transport Association (IATA); and shipping, handling, and labeling rules for hazardous and nonhazardous materials.

For information on shipping regulations for blood, urine and other liquid diagnostic specimens containing etiologic agents, contact IATA 1001 Pennsylvania Ave., N.W., Washington, D.C., 20004, telephone (202) 624-2977. When using the U.S. Postal Service, it is advisable to contact the Postal Inspector in your jurisdiction since the U.S. Postal Service has specific restrictions for mailing. For information on shipments that are sent to the FBI Laboratory, call the FBI Laboratory before shipping.

Inquiries concerning the Code of Federal Regulations may be addressed to the Director, Office of the Federal Register, National Archives and Records Administration Washington, D.C., 20408 (telephone 202-512-1557). The sale of the Code of Federal Regulations is handled by the Superintendent of Documents, Government Printing Office, Washington, D.C. 20402, telephone (202) 783-3238.

Proper Sealing of Evidence

A package containing evidence must have an invoice letter, and it is imperative to have access to this invoice without breaking the inner seal of the package. This must be done to comply with regulations that establish that examiners must receive any kind of evidence as it was sealed and packed by the sender. The first person to receive a package may not be the examiner. The method permits access to the invoice without breaking the inner seal.

1. Pack bulk evidence securely in box.
2. Seal box and mark it "evidence."
3. Place copy of transmittal letter in envelope and mark it "INVOICE."
4. Stick envelope to outside of sealed box.
5. Wrap sealed box in outside wrapper and seal with gummed paper.
6. Address to: Director. Federal Bureau of Investigation
Attention: FBI Laboratory 10th Street and Pennsylvania Ave., N.W.
Washington, D.C. 20535
Place the label under a clear Yellow plastic cover or yellow tape (ONLY on packages containing evidence).
7. If packaging box is wooden, tack invoice envelope to top under a clear yellow plastic cover or yellow tape.

8. REMARKS:
If evidence to be sent falls into the category of Hazardous Materials, call for instructions). Please use clear yellow plastic cover or yellow tape ONLY for packages containing evidence

Packaging and Labeling of Etiologic Agents

The Interstate Shipment of Etiologic Agents (42 CFR, Part 72) was revised July 21,1980, to provide for packaging and labeling requirements for etiologic agents and certain other materials shipped in interstate traffic. For further information on any provision of this regulation contact Centers for Disease Control, Office of Health and Safety, 1600 Clifton Road, Atlanta, Georgia 30333. Telephone: (404) 639-3883.

General Information

Prior to sealing a packaging container, all unused space in the container must be filled with brown wrapping paper, bubble wrap, or any other acceptable packaging filler to prevent the material from shifting and breaking open in transit.

For sealing, use extra gummed paper tape or nylon?reinforced filament tape. However, be aware that some shippers insist on the use of one of these two kind of tapes.

Packaging containers (i.e., envelopes, boxes, tubes, etc.) must be reinforced with continuous nylon?reinforced filament tape placed around the container.

Standard opaque packaging containers must be sealed with plastic or gummed paper tape so that it appears "mummy wrapped." Thereafter, at least three continuous strips of nylon reinforced filament tape must be placed around the container .

Allow application and retention of adhesive stamps, postage meter impressions and postal endorsements made by hand stamp, ball?point pen, or number two pencil. The use of masking, cellophane, nylon?reinforced, and/ or plastic tape on the outer finish of registered mail is prohibited.

Packaging containers must not be reused for shipment purposes. Standard opaque packaging containers may be reused only when the container is structurally sound, with no holes, tears, or missing flaps.

Obsolete address mailing labels and markings must be removed or covered prior to shipment.

Shipments must have the sender's and recipient's complete telephone number.

All packages must pass the National Safe Transit Association Project 1A Testing in addition to any regulations set forth by the Title 49 (Code of Federal Regulations).

The U.S. Department of Transportation (DOT) and the International Air Transport Association (IATA) define "Dangerous Goods" as "Hazardous Materials."

Boxes containing Hazardous Materials require specific DOT Diamond Labels on at least two sides of the package. For more information write or call Federal Express or UPS.

The IATA mandates: training and periodic recertifications for persons handling Hazardous Materials Dangerous Goods, and the IATA Dangerous Goods Regulations and U.S. Department of

Transportation Emergency Response Guidebook, two manuals that must be readily available at workplaces where employees handle Hazardous Materials/Dangerous Goods.

Title 29 ? U.S. Department of Labor Occupational Safety and Health Administration (OSHA), 200 Constitution Ave., N.W. Washington, D.C. 20210, telephone: (202) 219-8151

Title 29, Part 1910 sets forth specific safety and health standards as they relate to the workplace.

Title 42 ? U.S. Department of Health and Human Services, Office of Health and Safety, 1600 Clifton Road, Atlanta, Georgia 30333 telephone: (404) 639-3883

Title 42 has specific regulations for Interstate Shipment of Etiologic Agents, see page 94.

Title 49 ? U.S. Department of Transportation 400 7th Street, Southwest, Washington, D.C. 20590 telephone: (202) 366 4000

CAR Title 49, Section(s) and/or Subpart(s) for D?Marking specify that the person who offers hazardous material(s) for transportation must mark each package in the manner required by this title, a telephone number is provided to obtain specific directions.

25_3.3 Tool Marks

Tool marks play a critical role in the development of evidence in both covert and forced entry cases involving locks, safes, security containers, keys, and keying systems. The topic is more thoroughly covered in Section **32_4.0**.

25_3.4 Forensic Photography

The author recommends the following photographic equipment for documenting forced entry of locks, safes, and containers, for for recording tool marks on lock components. Both film and digital imaging is suggested. Although Canon is recommended for its optics and functionality, the author has also utilized the Minolta 9XI camera, lens and ring strobe. This system was first introduced in 1992, but is still one of the best macro photography options available.

Digital imaging has progressed to the point that it is an

acceptable alternative for film, unless enlargements are required. **Canon** (D30) and **Nikon** (Coolpix 990 and 995) produce the best hardware for the forensic locksmith. A camera with a minimum of 3,000,000 pixels is required, with the capability of shooting in low resolution (72 dpi) mode, as well as high resolution (300 dpi). The Nikon is ideal for macrophotography because of its extremely sharp lens complement. The Canon D30 with ring strobe and macro lens produces superior photographs. All of the digital images contained within this Infobase were produced with either the Nikon or Canon.

- **Canon 35mm EOS-1 series camera body**
- **Canon 100mm macro lens**
- **Canon ring light MR-14EX**
- **Canon D30 Digital camera body**
- **Nikon CoolPix model 990 or 995**
- **Minolta 9XI camera body**
- **Minolta 100mm macro lens**

Additional items for photo documentation that should be available to the forensic locksmith or criminalist include:

- **Comparison microscope with camera port 10x-40x minimum**

Discussion regarding microscopes for use in forensic analysis. Courtesy of Hans Mejlshede.

- **Ruler**
- **Wide-angle lens**
- **Tripod (small and large)**
- **Copy stand**
- **Filter kit**
- **Adjustable multielement fiber optic light source**

25_3.5 Admission of Evidence

The end result of all investigations is the development of legally admissible evidence. In order for evidence to be accepted by a court, it must be relevant, competent, and material. Each of these legal concepts is briefly explained in the I.A.I.L. manual, and in numerous legal and criminal investigation textbooks.

Suffice it to say, if these three primary criteria are not met, the evidence will not be accepted by any court.

In order for a forensic locksmith or criminalist to testify in a case involving locks and related matters, he or she must demonstrate expertise so that the trier of fact can rely upon the evidence presented by such an expert. Defense counsel will attempt to show that an expert does not have sufficient training or knowledge to state an opinion about a particular set of facts. Only an expert witness can state an opinion regarding a hypothetical or actual set of facts.

The investigative locksmith as a witness. Courtesy of Don Shiles.

The following issues and facts can provide the ability to destroy the value of testimony, and may lead to its rejection by a court.

- **Reliance or use of misleading data or information in testimony;**
- **Failure to adhere to established procedures in the course of an investigation or analysis;**
- **Showing bias;**
- **Lack of knowledge regarding a relevant issue;**
- **Failure to maintain a proper chain of custody;**
- **Evasive or misleading statements during testimony;**
- **Intentional disregard of relevant information during the course of an inquiry;**
- **Testimony based upon contingent fee or similar payment arrangement; Recantation of prior reports or testimony;**
- **Conducting an investigation, or testifying on matters beyond raining or expertise;**
- **Failure to complete an investigation in a timely manner, unless good cause is shown; or failing to take into account facts that subsequently became available;**
- **Conflicts of interest;**
- **Prior relationships with defense or prosecution counsel that could influence the results of an inquiry.**
- **Failure to consult professional literature, if required;**
- **Failure to consider all factors in an investigation;**
- **Adopting a condescending attitude while testifying;**
- **Losing composure while testifying.**

- **Previous inconsistent statements;**
- **Proving that a statement of fact is not true;**
- **Character of witness is questioned;**
- **Sensory defect in witness which prevents accurate testimony;**
- **Violation of professional code of ethics(241).**

25_3.5.1 Court Rulings and Federal rules on Admissibility

There are a number of significant court rulings on the admissibility of evidence and expert witnesses. In **Kumho Tire v. Carmichael**, 526 US 137 (1999) the United States Supreme Court enlarged the authority of judges to act as "gatekeepers" with regard to expert testimony.

Kuhmo involved a suit against a tire maker for design defects that resulted in a fatal accident. The expert witness for the Plaintiff determined concluded that there was a defect in the manufacture of the tire. The defendant countered that the Plaintiff's expert failed to follow reliable methodology in his analysis, based upon the standard set forth in **Daubert v. Merrill Dow**, 509 US 579 (1993). The case was appealed; the appellate court reversed the lower court but the Supreme Court affirmed the lower courts ruling. Kumho was cited and affirmed in **Weisgram v. Marley Company**, 169 F3d. 514, (2000) by the Supreme Court.

As a result of these rulings, expert scientific testimony, at least in Federal courts, will be scrutinized with regard to whether the expert's theory or technique has been tested, reviewed by other experts, is accepted by the technical community, and whether error rates have been considered. Such rulings will not be reversed unless there is an "abuse of discretion" on the part of the trial judge.

Federal Rules of Evidence control the admissibility of evidence in federal trials. Federal Rule 702, cited in Kumho and Daubert, specifically applies to expert witnesses.

Rule 702.(242) Testimony by Experts [Proposed Amendment]

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise.

Rule 703(243). Bases of Opinion Testimony by Experts [Proposed Amendment]

The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence.

Rule 704.(244) Opinion on Ultimate Issue

(a) Except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact.

(b) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone.

Rule 705.(245) Disclosure of Facts or Data Underlying Expert Opinion

The expert may testify in terms of opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross-examination.

Rule 706. Court Appointed Experts

(a) Appointment.

The court may on its own motion or on the motion of any party enter an order to show cause why expert witnesses should not be appointed, and may request the parties to submit nominations. The court may appoint any expert witnesses agreed upon by the parties, and may appoint expert witnesses of its own selection. An expert witness shall not be appointed by the court unless the witness consents to act. A witness so appointed shall be informed of the witness' duties by the court in writing, a copy of which

shall be filed with the clerk, or at a conference in which the parties shall have opportunity to participate. A witness so appointed shall advise the parties of the witness' findings, if any; the witness' deposition may be taken by any party; and the witness may be called to testify by the court or any party. The witness shall be subject to cross-examination by each party, including a party calling the witness.

(b) Compensation.

Expert witnesses so appointed are entitled to reasonable compensation in whatever sum the court may allow. The compensation thus fixed is payable from funds which may be provided by law in criminal cases and civil actions and proceedings involving just compensation under the fifth amendment. In other civil actions and proceedings the compensation shall be paid by the parties in such proportion and at such time as the court directs, and thereafter charged in like manner as other costs.

(c) Disclosure of appointment.

In the exercise of its discretion, the court may authorize disclosure to the jury of the fact that the court appointed the expert witness.

25_3.6 Specialized Forensic Investigations

Forensic investigators are called upon to assist law enforcement, insurance agents, and corporate security in many types of investigations where they may have expertise in specific types of locks, locking systems, containers and motor vehicles. Such investigations may involve forced and covert entry or sabotage.

Experts are often required in motor vehicle cases relating to theft and arson.

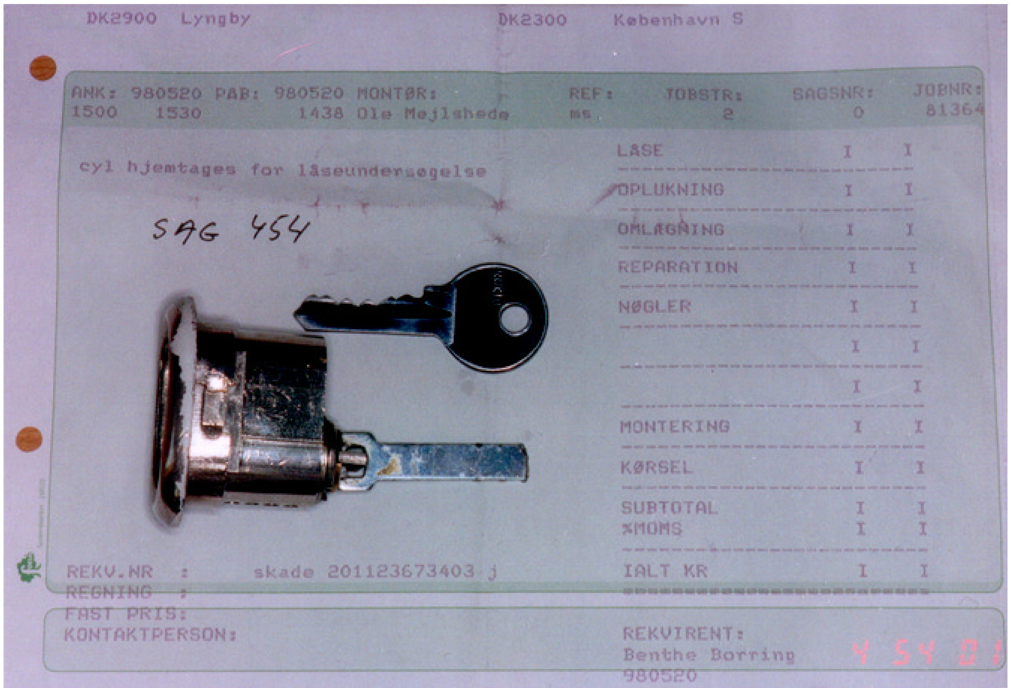
25_3.7 Forms and Reports



The following forms have been provided by I.A.I.L as a guide. As noted elsewhere in this text, complete documentation is required anytime that evidence is handled, analyzed, or stored. it is essential that the forensic locksmith or criminalist record all data regarding the identification, condition, test procedures, and alternations made to any key, lock, locking device, or other

item that has been submitted for evaluation.

Physical Security Device Worksheet
Forensic Inspection Request
Crime Scene summary form

The results of any forensic examination relating to locks and keys must usually be provided in written form to the court, investigative agency, defense counsel, or insurance company. It is essential that such reports be complete, well documented, concise, and accurate. Reports from several case investigations conducted by Hans Mejlshede have been reproduced. Note the form,

style, and content.

Dato: 5. July 1993 Vor ref.: 263/HM Deres ref.:

In this case we have on the 2. July received in our office by certified mail one Ruko cyl
with three keys. The received cylinder and keys are seen on photo 263 01. The front o
cylinder is shown in larger magnification on photo 263 02, and the keys on photo 263 03
263 04.

The cylinder is a seven-pin Ruko profile cylinder type 7102/K. The keyway of the cyl
is the standard keyway for Ruko's seven pin program, which means that keys can be co
everywhere without proof of ownership. Of the received keys two are original Ruko keys
one is a copy made on a Silca RU6 steel key blank. A cylinder of this kind always c
with three original keys. There is some wear on the cylinder and it is estimated to be bet
five and ten years old.

A cylinder like this one is considered by professionals to be difficult to pick. Picking
will with great certainty leave marks on the inner parts of the cylinder, marks that are
to trace with a microscope.
This cylinder has many marks. On the face of the plug, where the key is inserted ther
visible marks after a flat instrument, most likely a screwdriver, which has been pressed
seven millimeters into the keyway. The marks are shown on photo 263 07. This vi
treatment has produced some unevenness in the keyway that makes it impossible to
either of the original keys into the cylinder, while the slimmer non original Silca key sti
be inserted. With the Silca key the cylinder functions without problems.
On photo 263 05 the two first bottom pins of the cylinder are shown. There are marks
a flat instrument on the side of both pins and signs of some wear by using the keys, b
signs after any picking tools. The other pins have no marks from any tool.

It is my conclusion that it is extremely unlikely that this cylinder should have been pi
The marks that appear on the face of the plug and on the first two pins could have bee
there in order for someone to believe that the cylinder had been picked.

26_1.1 Introduction

LSS203: The forensic investigation of locks and keys, by Hans Mejlshede.

This chapter will concentrate on the most difficult aspect of the forensic analysis of locks: the search for evidence of surreptitious entry left by the manipulation of components. How marks are made by the different bypass techniques and detailed information regarding their appearance will be presented here. The material has been organized from general to specific types of evaluations. The goal is to develop leads and additional inquiries for investigators to pursue, anciliary questions that may be considered, and suggestions of supplemental forensic examinations that can be performed.

External indicia of non-destructive entry include tool marks, metal marking, and distortion of components. **Internal** evidence of surreptitious entry may leave tool marks, material transfer and debris, foreign materials appearing in the plug, and slight deformation of internal components. In analyzing external and internal components, the criminalist will search for the

following information:

- **Method of entry and whether it was destructive or non-destructive;**
- **Types of tools used to effect bypass;**
- **Whether there are any tool marks present, and how they got there;**
- **The skill of the perpetrator.**

The forensic investigator may also be looking for indicia of bypass of secondary locking mechanisms, such as latches and bolts. Loids or other techniques may have been utilized to circumvent the operation of these components.

An analysis of latches and bolts may be required. Courtesy of Hans Mejlshede.

Loids may be utilized to bypass latches and bolts. Courtesy of Hans Mejlshede.

26_1.2 Preparation and Dissection of the Plug for Examination

It is usually necessary to disassemble the lock and to dissect the plug in order to search for tool marks. The proper procedures for disassembly have already been covered in **Chapter 16.** Dissection of the plug will be detailed here.

Destructive analysis of locks is often required in an investigation. Courtesy of Hans Mejlshede.

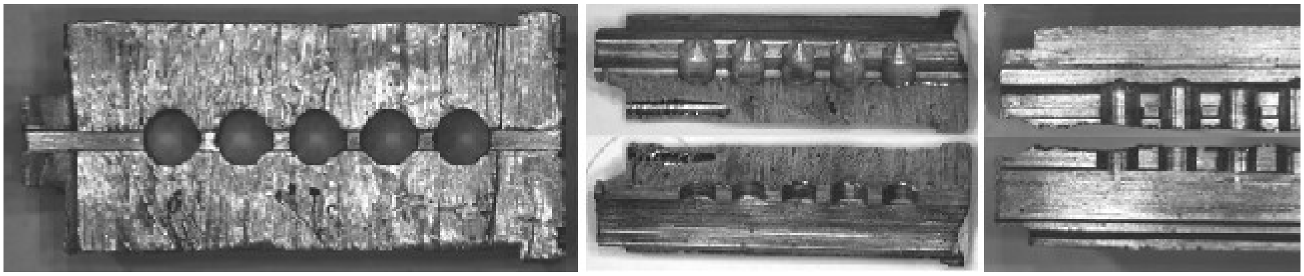
Analysis of marks within the plug after it has been cut apart. Courtesy

of Hans Mejlshede.

Prior to dissection, all internal components will be removed and placed in a setup tray or other storage container. Be certain to use plastic or nylon tongs to handle pins, so they will not be scratched. If a padlock is to be analyzed, it may have to be destroyed if no keys are available.

The tools that are required for dissection are a saw, plastic tweezers or tongs, a setup tray, modeling clay to hold the components for microscopic examination, and a zoom microscope with a range of at least 10X-40X. The author uses an Olympus binocular zoom microscope with a camera port. Generally, the keyway is analyzed before cutting the plug in order that evidence is not destroyed. The criminalist should be particularly alert to brass particles and tracks. If the lock has security components such as hardened pins to prevent drilling, then these must be removed first.

A plug must be examined internally, because there are areas where the key never encounters metal surfaces. This is due to the profile of the keyway and the reaming tool used in the broaching process. These "virgin" areas will yield information regarding bypass.



Virgin areas of the plug will provide an indication that the locks was picked. Courtesy of Hans Mejlshede.

The examiner is looking for places where no marks would be expected from normal operation, insertion, and removal of keys. The only way such marks could have been made is through the picking process. Once dissected, all surfaces can be examined.

The areas above the key and on the sides of the keyway will never be touched throughout the life of the lock, because the bitting is always lower than the top of the keyway. Consequently, corrosion in this area will be used as a control for comparison purposes. The only way to examine such evidence is to dissect the plug. Dust motes may also be present. These are surface particles of dust that will be visible under the microscope as round projections.

Dust motes, visible in forensic analysis. Courtesy of Don Shiles.

In practice, the plug is sliced horizontally, just below the top of the keyway, causing it to separate into three parts (left half, right half, and top section).

Exploded view of internal area of plug 1, 2, 3, 4.

The plug may be cut with a hacksaw or other fine cutting tool. The author uses a jeweler's hacksaw that has a thin wire blade. Care must be exercised to cut laterally and exactly perpendicular to the keyway. Compressed air may be used to clean the components once they are cut. Do not use cloth or any material containing fibers, as they are attracted by the rough surface of the brass and are extremely difficult to remove.

26_1.3 Forensic Analysis Protocol

Statistically, only one or two percent of burglary investigations actually involve lock-picking and other forms of surreptitious entry. That data is obviously based upon known cases of burglary, where a threshold determination has been made that in fact there was an entry or attempt. The problem, of course, is that there may be many cases of surreptitious entry or bypass that remain undiscovered and thus will not be included in any crime statistics. Such is the work of professionals in the business of espionage, sabotage, theft of information, and covert entry.

It is estimated that in approximately five to ten percent of the reported cases, apparent pick marks are present where perpetrators attempted to create the belief that picking was the method of entry. Attempts to cover fraudulent claims and destruction of evidence are much more common than actual lock-picking and other bypass techniques. For the uneducated public there is a perception that making the lock appear to have been picked will satisfy the police, and more importantly, the insurance company.

Both the criminal investigator and criminalist should evaluate the likelihood that the lock was picked or otherwise bypassed, based upon the intended target and local practice. Sophisticated methods will not be used where a small claim is involved. If a

method of bypass is common or popular in an area, that may of course be factored into the analysis.

Particularly in fraud cases, the insured will often use a hammer and screwdriver to make entry appear as if the lock was picked. There will be imprints, and generally many marks on the first and second pins. There will be no marks on the rear pins unless the lock actually was picked or the perpetrator was familiar with picking techniques. It is imperative that all marks be recorded on each pin for this correlation.

The thrust of this chapter, and indeed this text, is surreptitious entry and bypass. That is because high-value items such as cash, information, documents, and data are generally the targets of more sophisticated criminals. This is of heightened concern to criminal investigators, internal security, and intelligence officers. It is important that the criminalist is able to make a very educated guess as to what tools may have been used to effect bypass and entry. That information will provide clues as to the skill of the perpetrator and will form the basis for a more positive match in the case of tool marks. The criminalist must be aware of different bypass techniques for the specific lock or locking system that is being analyzed.

Bypass techniques must be known to the forensic investigator. Courtesy of Hans Mejlshede.

The forensic analysis of the plug, once dissected, may take less than five minutes. As detailed below, the examiner is searching for any unusual marks anywhere within the lock.

A forensic examination takes five minutes or less. Courtesy of Hans Mejlshede.

Generally, the lock is examined, according to the six primary evaluation phases, in the order listed below:

- **Lock specifications and data;**
- **Operation of the lock;**
- **Security of the lock;**
- **Indication of manipulation and bypass: tool marks;**
- **Material transfer;**
- **Keys.**

In the first two phases of the examination, as described earlier, a determination is made that the lock meets factory specifications, that it is operating properly, and the level of its security. Then, an examination of internal components is made through dissection of the plug. A search is conducted for the following:

- **Tool marks;**
- **Tracks;**
- **Deformations;**
- **Corrosion and oxidation in clear areas;**
- **Corrosion and oxidation over existing marks.**

It may be necessary to run tests in an attempt to extrapolate the time required to corrode or obliterate picking marks within a given lock for a given environment. Marks will be affected to differing degrees depending upon where the lock operates, i.e. inside, outside, salt air, or corrosive environment. After a search for tool marks, an analysis may be undertaken for additional evidence to determine:

- **Any material transfer within the plug;**
- **Security rating of the lock;**
- **Evaluation of the keying system;**
- **Any keys that may be involved in the investigation.**

26_1.4 Method of Entry

26_1.4.1 Analysis of Methods of Entry

Surreptitious methods of entry will vary widely, depending upon the lock, its location, and skill of the perpetrator. Information regarding methods of attack may be obtained from visual inspection of external and internal components and surfaces. Indicia may be present from tumbler, wafer, or lever distortion, caused by excessive application of force. Residue from tools may also provide an indication of the methods employed. For example, magnetic tracks on the face of a safe, made visible using magnetic spray, can provide clues as to the type of drill rig that was utilized. In other cases, depending upon the mode of entry, there will be no evidence. In the following instances bypass may be achieved without physical trace:

- **Use of keys;**
- **Power failure which cause electronic mechanism to open, as in the case of certain hotel locks;**
- **Decoding of pin-stack combination and production of a key.**

Investigators should also be alert to lock failures that may have been externally caused through criminal agency in order to cover up bypass. For example, an apparent simple sabotage of a locking mechanism that appears as a burglary attempt may actually have been orchestrated. This may have been perpetrated so that the lock and any evidence of tampering would be destroyed without giving a clue as to whether entry actually occurred. Power failure, dead memory batteries, lockout requiring picking or drilling, loss of internal memory, and logic failure may all be seen as potential abnormal events requiring further examination.

26_1.4.1.1 Queries Regarding Methods of Entry

- **Is there visual evidence of bypass, including tool marks, metal fragments or filings, distortion of the plug, broken keys in the plug or other marks;**
- **Are there any tool marks on the door, jamb, strike, or surface area of the lock;**
- **Is there any foreign material in the plug, including Freon residue;**
- **Are there any metal scrapings within the lock, in the keyway, or chambers;**
- **Does it appear that excessive pressure was applied to the plug, causing marks to be made between the plug and shell.**

26_1.4.2 Types of Tools Used for Entry

Many types of bypass tools are described in this book, most of which have been designed to open pin tumbler cylinders. Because of its prevalence, the conventional pin tumbler lock is the prime focus of forensic analysis. Some data will also be presented regarding the lever lock due to its popularity in countries outside the United States. Although this chapter examines most common forms of bypass and the forensic trail that such techniques leave, certain sophisticated tools will leave little or no trace or will imprint a unique signature when employed.

These devices are used to open lever and pin tumbler locks.

Certain procedures and devices have been developed for special variations of the pin tumbler and wafer lock. For example, there are decoding and picking tools for dimple locks, disc wafer locks (such as Abloy), for rotating tumbler mechanisms (Medeco), and for telescoping pin high-security locks (such as Mul-T-Lock). Some of these will leave very minute traces. The decoder/pick for dimple locks, for example, may only leave fine fragments of foil if the operator is not careful. Lubricant such as grease may also be present as the result of the use of this technique.

It is perceived that a security risk and potential compromise of intelligence operations would likely flow from the disclosure of certain bypass techniques and specialized tools developed for such procedures. Therefore, the author has presented only a summary of the principles of high-security bypass and their forensic implications in this chapter. A detailed description is included within the **LSS+/^{X} CD/ROM**, with restricted release to government agencies specifically dealing with high-security bypass.

26_1.5 Tool Marks Produced by Specific Entry Techniques

Marks produced by methods of entry, courtesy of Harry Sher.

In this section, we will be primarily concerned with marks produced by picking, impressioning, decoding, and 999 rapping techniques. Tool marks in many forms can be left by lock picks and impression tools and special manipulation keys (999 rapping). Minute traces of brass or other metal debris may also appear on the pins or at the bottom of the plug, as an indicator of manipulation.

For the purpose of this chapter, the author defines tool marks as any physical indication of bypass caused by the introduction of any mechanical implement or device into the keyway or locking mechanism. Physical indication is dealt with in detail later in this chapter. It includes scratches, striations, marks, tracks, alteration, scoring, cuts, compression, and debris. Tool marks may be found anywhere, on any surface of any internal or external component of the lock. Any unusual, irregular, or enhanced marking may be considered.

On any conventional five pin tumbler lock there is always a random chance that the cylinder was opened with a cross-key combination: a key made for another lock that also just happened to fit the suspect lock. The perpetrator employed no special techniques. A detailed listing of causative factors that will contribute to the presence or absence of tool marks is presented. The forensic examiner should consider each of these factors when initially looking at the lock. This will provide a better image of whether marks may be present, and if so how they may have been created.

Tool marks and evidence of bypass may be produced in many ways and are related to techniques and implements. They can be caused from, provide evidence of, or result from any of the following processes or conditions upon any internal or external lock component:

- **Application of torque or forward pressure to lock components;**
- **Use of bypass tools such as picks, tension wrench, nose puller or plug puller;**
- **Screw-marks from plug pullers;**
- **Drilling marks;**
- **Tolerance error from the application of force;**
- **Foreign material and lubricant, cleaner, grease or other matter in the keyway;**
- **Broken key or object in keyway;**
- **Non-working segments or parts;**
- **Application of heat or cold;**
- **Evidence of cutting the plug at a weak point to split in half;**
- **Evidence of drilling the plug for the introduction of a shim or to create a shear line;**
- **Deformity.**

26_1.5.1 Tool Marks: General Considerations

Normal appearance of pins and what type of marks appear. Courtesy of Hans Mejlshede.

What appear to be tool marks and thus indicia of bypass may in fact have been caused by the normal operation of the lock. The

examiner must be cognizant of and always consider the possibility that marks were in fact produced through normal use. How long marks have been present and if actual marks could have been masked or obliterated are of prime concern.

When keys are inserted into the keyway, there often will be shiny spots or marks on one side of the wards or plug surface. This may be caused by the way in which the plug is turned for opening. Therefore, the entire length of the plug should be examined. Usually, there will be no marks above the keyway on the chamber walls.

Tool marks may also be generated from the bypass of bolt mechanisms. Marks from a sharp pointed wire, ice pick, or other object may be present on secondary bolts or cams. So also, shim marks may be in evidence in certain sophisticated bypass applications involving pin tumbler locks and cylinders. See the discussion below relating to high-security applications.

Locks with well-designed keyways will be more difficult to pick and impression and thus will leave better marks during these processes. Angled rather than square wards will produce finer tolerances in the keyway and require more movement of the pick thus producing more marks.

The reader is also directed to Section **32_4.4** for a general discussion of tool marks.

26_1.5.1.A Methods of Examination of Tool Marks

Tool mark comparison. Courtesy of Hans Mejlshede.

The methods to compare and identify striated tool marks are different than will be employed with respect to impression marks. The tool mark examiner must demonstrate that the suspect object could produce striae that are identical to those obtained from a crime scene as evidence.

In order to compare a suspect tool or object with an evidentiary mark, the examiner must at the outset analyze and take into account several issues. These will include: could the tool have possibly made the mark, based upon its size, shape, structure, and material; location of edges or surfaces which are consistent with the hypothesis that a mark could have been made by a specific suspect object; how tests are to be conducted in order

to establish a comparison; and finally, the determination or conjecture as to which angles of attack are most consistent with the mark(s) in question.

The procedure and criteria for the selection of test materials is fairly straightforward. They must be sufficiently similar to the evidentiary material and surface to allow a valid comparison without potentially damaging the suspect tool or object. Lead is commonly used for such purpose.

In practice, the examiner creates a number of test marks, varying the attack angle, pressure, and speed. Not all tests are expected to produce useable marks, or perfect identification. Usually, fewer than a dozen tests are required, and often, between six and twelve.

The procedure for the examination of Ford locks and keys was detailed in a study by E. Lee Griggs, a technical advisor to AFTE, and published in 1999, are summarized here, to provide a protocol for forensic examination. An earlier study by **W.G. Plumtree(255)**, conducted in 1975 was cited, with regard to the analysis of pick marks on pun tumbler locks.

In the tests performed on Ford locks, Griggs employed certain definitions were are relevant to note, not only with regard to the tests that he performed, but to serve as a guide in all forensic examinations of locks and keys.

Proper Key: Prepared on correct blank and cut to the correct bitting depths to open the lock.

Improper Key: A key that has been cut to an incorrect code depth for any given tumbler, or cut on an incorrect blank.

Discs: All references to wafers, discs, tumblers are equivalent.

Active or working surface: Any surface that is contacted by the blade, bitting surface, or wards of the key.

Ford Lock: Six wafer configuration that are utilized in ignition locks. These mechanisms employ two sided keys, although, as noted elsewhere in this text, there is only one active surface. These are referred to as convenience keys.

Tests to be performed:

As discussed elsewhere within the chapters on forensic examination, extensive testing can be accomplished on all active locking components. It is critical to eliminate issues that can be raised by defense counsel to testing procedures. Thus, careful preparation of samples, and the development of a comprehensive protocol is essential to avoid challenges to identification evidence that may be derived.

In analyzing and testing disc tumbler or wafer locks, the following surfaces and components must be examined:

Keys:

- Lands forming ward pattern
- Bitting surface

Discs:
- All active surfaces that come into contact with the key

Plug:
- Active surfaces of discs that may be driven by irregular key, or improper usage

Springs:

- Normal
- Broken
- Fragmented
- Stretched or compressed

Complicating factors:

- Dirt or debris in keyway
- Broken spring in keyway
- Spring fragment in keyway
- Bent disc or wafer
- Deformed keyway

Specific testing procedure to be followed:

- **Obtain new original locks, plugs, and keys;**
- **Prepare photomicrographs of the discs and keys prior to any testing to document the condition of each component, and provide a standard for comparison;**

· Prepare some of the plugs with a broken or missing spring(256) in one or more chambers;
· Prepare some of the plugs with stretched springs in other chambers;
· Insert two-sided Ford keys into the keyways in a random fashion to simulate normal use of the lock
· Select an insertion sample rate that would be considered normal for the lock.
In the instant case, keys were inserted an average of 720 or more times to approximate one year's use of the vehicle, with two start-stop cycles per day.
· Utilize a factory-cut key to obtain wear data from both the key and lock;
· After all insertion-removal tests have been conducted, remove the discs from the lock plugs and reexamine them with a microscope to evaluate the presence of striae on the surface of each disc.
· Prepare photomicrographs of each disc and key for marks.

26_1.5.1.B Results of Testing

Test results will vary, depending upon many factors involving the condition of the lock, plug, key, and individual use characteristics. The findings in the Griggs tests can be summarized and provide a guideline to examiners as to expected indicia in similar examinations. The results are categorized by control sample and normal lock sample.

Control sample:

· **Keys:** No wear patterns on the operating surfaces (sides) or bitting surfaces;
· **Discs:** no wear patterns or striations;

Normal lock sample:

· **Discs:** wear patterns from the insertion of keys. An amount of material has been "rolled over" the edge of the lands of the key as it is inserted into the keyway and moves across the active surface of the disc.

· **Cylinders with normal springs:** wear on the lands is most pronounced on the first disc. It is least in evidence toward the far end of the cylinder, as would be expected. It should be noted that theoretically, the position of the discs could be determined by their wear pattern, if wear were constant for each disc, depending upon the number of root surfaces of the key come into contact with each wafer in an insertion and removal cycle.

It is not possible to determine an error factor, as the examiner has no way of determining if discs and springs were "always" in a normal operational condition.

· **Springs:**

· Extended or stretched springs can cause uneven wear on a particular disc associated with that spring.

· Broken, collapsed, or fragmented Springs: Wear patterns can be noticeably less than on other discs. If the spring is in the first or second position of the plug, the wear was less, but the error rate was higher in assessing the position of the disc.

· Complicating factors: Several factors may complicate the analysis of active components, and may skew wear factor, causing uneven or excessive wear. These include:

o debris in the keyway;
o broken springs;
o bent or damaged springs;

Microscopic Examination of Disc: Wear patterns were noted on the lands of the discs;

· No identifiable striations were in evidence to match the operating key for that specific lock;

· No identifiable marks were present on the lands of the discs and the side wards of the key;

· It was not possible to determine or match the side of the key that came into contact with a particular surface on the disc.

· Test marks made on new discs showed the same lack of identifiable characteristics as the tested discs: wear patterns without identifiable striations.

· As has been noted elsewhere in this text, the bitting surface of the key acts as an abrasive on the discs. This creates a wear pattern and striations without an identifiable pattern. Each time the key is inserted and removed, a tiny bit of material is removed from the disc. Movement of the key causes the discs to move in both vertical and horizontal planes (forward, backward, left and right, up and down).

· There can also be slight evidence of impressions upon the first disc, where the tip of the key contacts its surface.

· Examination of the lands of the discs upon removal of key: No identifiable striae could be linked to a particular side of a key, as it contacted the disc surface.

· Uneven bitting and non-linear surface: A key with a raised burr on one side of the wards, and an uneven (bent) longitudinal surface was inserted and removed from test cylinders. Upon examination, the burr left an identifiable mark on the first three discs. This was based upon the position of the burr on the surface of the key.

· The wear pattern on the first four discs was of a wider nature, due to the bent key and the attendant misalignment.

· The undamaged side of the key did not obliterate markings on the discs. The undamaged key key did not leave any observable or identifying marks.

· A different key without any burrs or other damage would, in time, obliterate any prior markings; thus, the one time insertion of a normal key will not provide any "last key used" marks.

· Discs exposed to high temperature: discs that have been damaged by fire will likely contain carbon deposits and oxidation of the material. These will show that the wear surface of the land cannot be examined for evidence marking.

· Key with Improper code: A key with an improper code and which will not open the lock will not produce observable striations to provide an indication that such a key had been inserted.

Summary of findings:

It is not possible to determine that a specific key has been

utilized with a specific lock, absent a deformation that will cause unique marking;

Wear patterns appeared as a single wear area on the land of the affected disc. "There are no obvious striated or impression marks on the tumblers of cylinders that have only been operated by the proper key."

Locks that are tested for "last key used" will not provide any comparable striations or impression marks that could be related to the last key that was used in the cylinder.

Although the literature is scant, the reader can find articles regarding forensic examination in the **AAFS(257)** and IAI journals, and in general literature(258).

26_1.5.1.1 Queries Regarding Keys

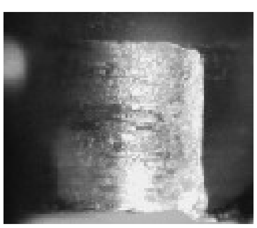
There are several inquiries involving the use of keys and their interface with lower tumblers that must be considered in assessing tool marks. The operation of keys described below must be compared against the use of properly cut keys having smooth bitting surface and ramps with no sharp edges.

Thus if the lock is operated with a key:

- **Made of steel, rather than brass or nickel silver:**
    - **Produced on a machine with teeth missing from the cutting wheel, thereby creating very jagged or rough bitting surface;**
- **With ragged ramps that act as an abrasive surface (file) against the tumblers:**
    - **How long will the lock continue to function;**
    - **What effect will there be on the lower tumblers;**
    - **What type of wear will be evident on lower tumblers;**
    - **How many passes of the key will be required to distort or obliterate pick marks (relevant to the determination of when the lock was picked);**
    - **When the key is inserted, are spots normally produced along the length of the keyway, based upon imperfections in the milling of the blank.**

26_1.5.2 Marks from Lock-Picking

The age of picking marks can sometimes be determined through the analysis of corrosion within the lock. Courtesy of Hans Mejlshede.

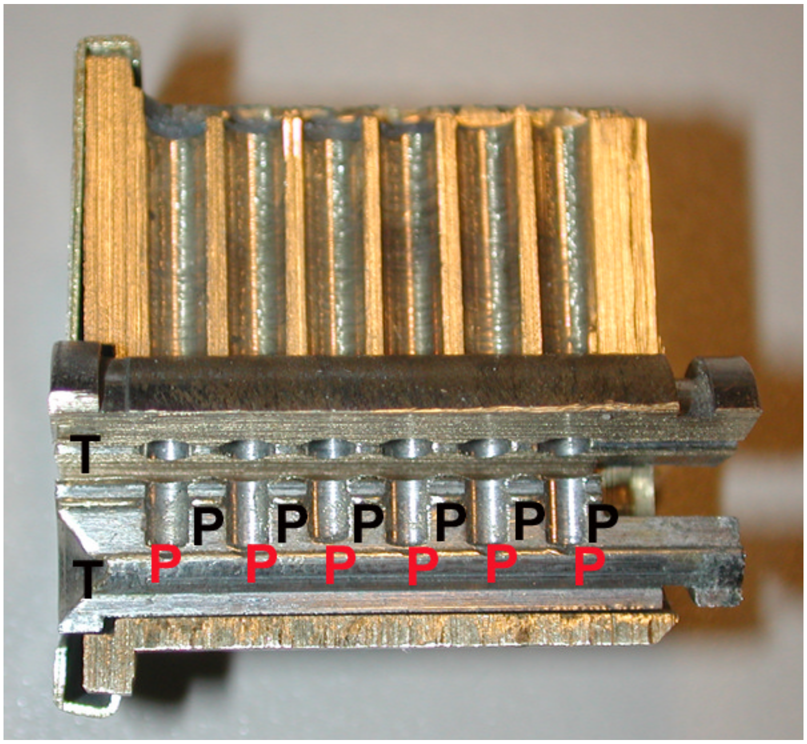


Different marks are created from various lock picks. Courtesy of Don Shiles.

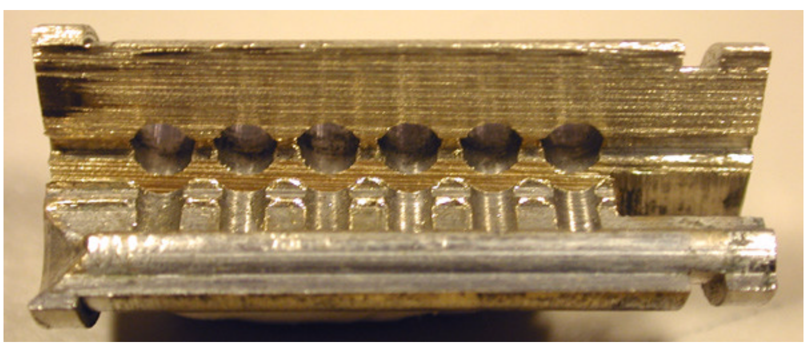
See **Chapter 29** regarding picking techniques. The underlying theory of lock-picking is simple and is based upon cumulative tolerance errors within the lock. Picking relies upon and requires that the plug and shell be not in perfect alignment; that a gap of a few thousandths of an inch exists between the two. As each pin tumbler is picked to shear line, this gap increases. Picking (whether successful or not) will generally require two distinct concurrent physical operations: raising each tumbler, and the application of torque and subsequent rotation of the plug. Each of these procedures can and generally does produce tool marks.

Forensic marks from the use of a lock pick. Courtesy of Hans Mejlshede.

Marks from lock picking: what do they mean? Courtesy of Hans Mejlshede.



During the picking process, each lower tumbler is raised until the top of the pin reaches shear line and is stopped by the alignment error between the plug and shell. It is generally unavoidable that marks will be created during the picking process, regardless of the tools used. This may not be true in the case of decoding procedures.



Tool marks appear from picks because there is friction and contact between sharp pick tools and soft brass or nickel silver component surfaces. The marks are created due to the resistance between pin and wall of the pin chamber and the pick. Force must be applied to move the pins, even if the lock is bypassed with only one rake action. The photographs below show the areas where

marks from picks (P) and a tension wrench (T) can be expected to appear.

Marks produced from turning wrenches are identifiable. Courtesy of Don Shiles.

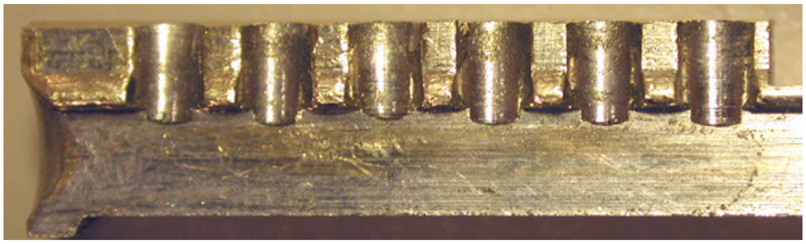


Figure LSS+2601 shows a cutaway view of a plug within a shell, denoting the areas where pick (P) and tension wrench (T) marks are likely to appear. Particularly examine areas between pin chambers, and at the base of each chamber. See the linked image view which denotes tension wrench in red, and pick marks in blue. The bottom photograph shows the mating half of the plug. Note that P (red) denotes marks within the chambers; P (black) shows where marks would appear between pin chambers.

The lower the skill level of the lock picker, the more pronounced will be the marking. The higher the security of the lock, the more difficult it will be to pick, often with corresponding additional indications of entry. Examiners should always check the back of the locking cam because often pick marks are left there also by an amateur.

The application of torque using a tension wrench will also produce marking of the plug, regardless of the design of the tool. There are many types of tools for applying rotating pressure. These include conventional turning wrenches, spring-loaded tweezers- type wrenches, plug spinners, and the Falle-Safe type adjustable wrench.

Turning wrench or torque wrench will leave identifiable tool marks. Courtesy of Hans Mejlshede.

Marks left from a turning wrench. Courtesy of Don Shiles.

The conventional tension wrench is inserted into the keyway at the bottom or the top. The tang or flat perpendicular portion of the wrench that is actually inserted into the keyway will often mark the sides of the plug. This will depend upon its size, material, stiffness, and thickness, as well as applied torque.

Marking will also depend upon the tension required to hold the pins against the shell, the skill of the lock picker, and the number of attempts required to pick the lock. In large measure, the varying application of torque is a personal preference, in

combination with the physical characteristics of the particular lock. Some locks require a large amount of pressure to retain the pins at shear line; others will open with a featherweight touch. Tweezers-type wrenches are made of spring steel, formed with two points that engage the very top and bottom of the keyway. Marking is problematical; it may or may not occur and can be very difficult to detect.

"Plug-spinner" type wrenches are round spring-loaded devices with wire pins protruding from the twelve and six O'clock positions. The center is hollow, much like a donut, allowing the insertion of picks into the keyway. The device, measuring about one or two inches in diameter, is pressed against the surface of the cylinder during picking; the two pins engage the plug and allow precise control of rotation. Their advantage is that they do not obstruct the keyway or block movement of picks. As with the tweezers wrench, marking may or may not occur depending upon the factors noted above.

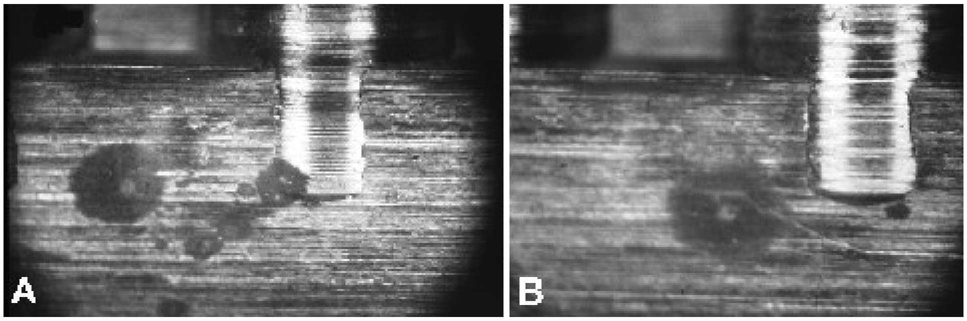
A special tension wrench has been developed by John Falle, (Falle-Safe Security) that is a modification of the plug-spinner. It is adjustable and inserts anchoring pins at the top and bottom of the keyway. It is operated perpendicular to the face of the lock for better control of plug rotation. Similar marks will be made by the plug-spinner or tweezers.

Tool marks from bypass will most often be caused for the following reasons:

- **High-security locks, making picking difficult and requiring many passes of the lower pins;**
- **Proper pinning of the lock, with differences in adjacent pin depths (high next to low cut);**
- **Use of security tumblers;**
- **Paracentric keyway, or keyway that makes manipulation of a pick very difficult;**
- **Lock parts made of soft metal such as brass, while the pick tool is made of stainless steel or hardened tool steel.**

The examiner is searching for unusual marks, spots, scratches, tracks, distortions, deformations, and tolerance errors caused by the application of force, non-working segments or parts, or other evidence of irregular operation. During the manufacturing process, certain patterns are created upon metal surfaces. When

altered by bypass techniques, these differences can also be visible. During picking, patterns created in metal surfaces during the manufacturing process will be disturbed in a different way than would be caused by normal wear. Other areas within the lock may be similarly affected.



Markings on components by manufacturers. Courtesy of Don Shiles.

Milling marks on pins during manufacture. Courtesy of Don Shiles.

Thus, indents from placing the turning wrench in the keyway may appear on the top and sides of the entry to the plug. There may be angled indents caused by heavy pressure from the torque wrench. There also may be markings on the sides of pins from excessive turning pressure, indicating impressioning. The most critical question for an examiner is whether marks or other indicia were caused by routine operation of the mechanism. In the alternative, were they created in circumstances not present in normal use of the lock or key. Any marks that would not usually occur are suspect.

One must be extremely cautious in defining the cause of marks. Thus, a poorly milled blank that does not precisely fit the keyway can leave markings that might be mistaken for the tang of a tension wrench. Repetition must be checked. If an improper blank is the culprit, marks may be created along the length of the keyway. A tension wrench would only create tracks over a very short area, and the marks would be at an angle. For example, scratches will never appear within pin chambers from normal operation. They can however, appear on the bottoms of tumblers, caused by improperly cut keys. Scratching will rarely be produced on the sides of the pins. So if there are such scratches present, then suspicion regarding picking must occur.

Because the key blade is always lower than the top of the keyway, such areas will never be touched except by picks and other bypass tools. Normally there will be corrosion or oxidation in this area and it can be used as a reference to compare with other areas in order to show changes. Generally, the corrosion or oxidation will cause very small bubbles to form on surfaces. They will be broken when touched by a pick or anything else. These areas are very sensitive. Once broken, they will remain in that state.

Normal insertion and removal of a key, over time, may create a track on the bottom of the tumblers, causing them to appear in horizontal alignment. That is, the bottom of each tumbler will be pointing in the same direction or orientation as the bitting of the key. This alignment may be disturbed during picking.

Forensic marks and their observation with proper lighting. Courtesy of Don Shiles.

Wear information and tests on pins. Courtesy of Hans Mejlshede.

Wear marks on pins. Courtesy of Hans Mejlshede.

Marks produced from keys making contact with pins. Courtesy of Don Shiles.

So also, the tops of the lower pins may wear at an angle, especially if the plug is rotated predominantly in one direction. If, for example, a lock were used on a door that was continually accessed by turning the key to the right, then the tumblers may wear more in one direction. If marks were made some time ago, then the oxidation will cover such marks, thereby offering an indication of age. Some marks may also be impacted with lint, dust, and grease.

Just as important to remember, marks may not be present but yet the lock was in fact picked or otherwise manipulated. For many reasons, marks may not be created, although it is most common that they will appear. Thus, picking cannot be ruled out as a means of entry in the absence of tool marks. Why would tool marks **not** be created during the bypass process? There are several reasons and they all relate to making the lock easier to pick:

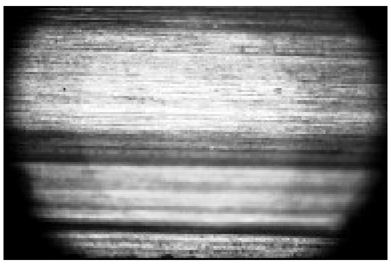
- **The lock is made of significantly harder material than the lock pick. Nickel silver pins or plug may not mark;**

- **The lock was decoded rather than picked; then a key was produced from the decoding process;**
- **The pin-stack configuration or combination may be extremely conducive to picking. That is, all tumbler positions may be close to the same depth or in a stair-step pattern;**
- **Maison keying may be in effect. There may only be two or three tumblers in the lock;**
- **Complex master keying may be employed with many cross-combinations available;**
- **The lock may only have three, four, or five tumblers;**
- **No wards or obstructions in the keyway;**
- **The tolerance between plug and shell may be quite sloppy. This may be due to poor manufacturing controls, the top of the plug was filed by an amateur locksmith, or due to wear;**
- **A key may have been run through the lock several times to obstruct evidence of picking, at least with respect to scratches on the bottoms of tumblers. The lock may also have been operated many times inadvertently prior to discovery of the surreptitious entry;**
- **The horizontal center-point alignment between chambers may be erratic, making picking easier. This means that not all of the pin chamber holes in the plug/shell are precisely in a straight line. When the lock is picked it will be easier to cause pins to hang at shear line;**
- **No security tumblers are used;**
- **The perpetrator may be very skilled in lock-picking;**
- **The perpetrator may have carefully picked in conventional fashion each tumbler, rather than raking;**
- **The suspect lock may be inherently easy to pick due to its design (especially if a wafer mechanism);**
- **The perpetrator may have been lucky and was able to pick the lock on the first attempt;**
- **The perpetrator may have raked the lock rather than conventional picking of each individual pin and may have succeeded on the first try;**

- **The springs do not present much tension, and thus low-pressure levels were required to lift them. Very light torque may have been applied;**
- **The perpetrator used non-metallic picks or pick tips;**
- **The perpetrator was able to open the lock by withdrawing a blank key while applying the correct amount of tension;**
- **The perpetrator was able to lift all tumblers using a pocket knife, because each depth was close to the same level;**
- **Rocker picks were utilized in a lock having a pin combination that matched the signature of the picks.**

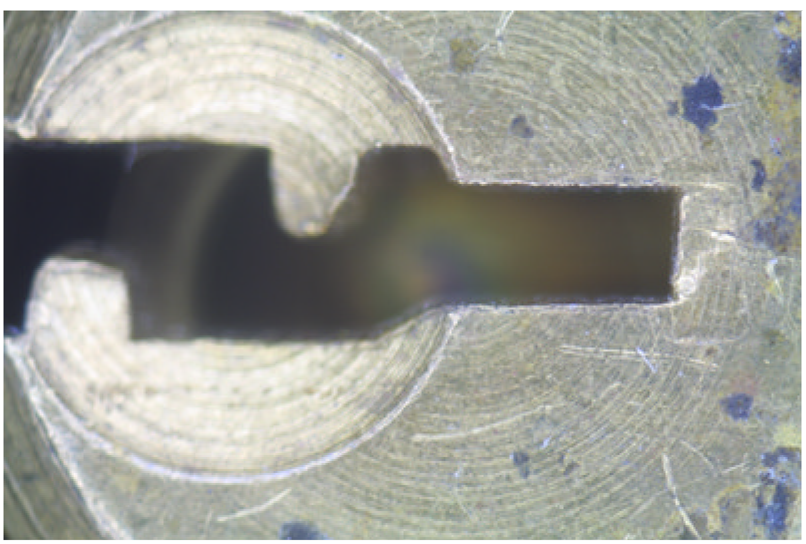
26_1.5.2.1 Location of Marks

Tool marks may remain as the result of bypass attempts in many locations within the lock and on surface areas. Examiners should thus consider the potential for finding such marks on the plug face, anywhere within the shell/chamber area, and on pins and springs, both bottom and sides.



With respect to the shell/chamber areas, marks may be produced within pin chambers within the plug or shell, between chambers in the plug, or around the opening between plug and shell. Marks may also be created on the front of the plug or shell during the impressioning process, discussed below. The marks are caused by the application of pressure against the front of the lock. If the color is scratched off the bottom pins or there are scratches on the bottoms of the pins, it may indicate that a new or jagged-cut key was used.

Other types of bypass tools may cause different tool marks. For example, chisel marks on the sides of pins may indicate the use of a 999 rapping technique. The examiner must also take into account the metal surfaces with which picks or other tools may come into contact. If ball bearings or nickel silver pins or plugs are employed, diminished marking may occur.

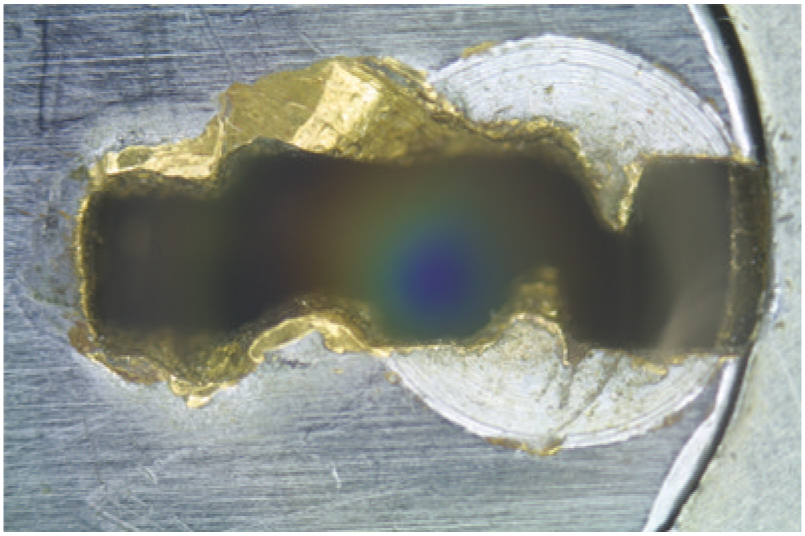


Note that all of the microphotographs of pins and cylinders in the following sections were taken by the author with an Olympus 10x-40x binocular microscope with a Canon D30 digital camera, lens adapter, and florescent ring light. The photographs were captured at 300 dpi, enhanced, and then reduced to 96 dpi.

26_1.5.2.1.1 Tool Marks in and on the Surface of the Plug

Tool marks may be found on the front surface of the plug, within the chamber walls, between pin chambers, and throughout broached areas. In addition, pick tracks may be evident within grease, oil, or plug lubricant anywhere along the keyway. Depending upon the type of bypass technique, there may be spreading, warping, denting, bending or distortion of wards within the keyway. There may also be tool or blank shoulder imprint marks on the face of the plug caused by the pressure exerted by an impression vice.

Examiners should also be alert to very fine holes drilled through the front of the plug at shear line. Some holes (which can be filled) are often imperceptible; yet, they will allow the insertion of a shim wire allowing the plug to be rotated. If tubular locks such as Abloy, Chicago, Ace, or Tubar are utilized, consider the possibility that the face was ground away and the entire lock replaced.



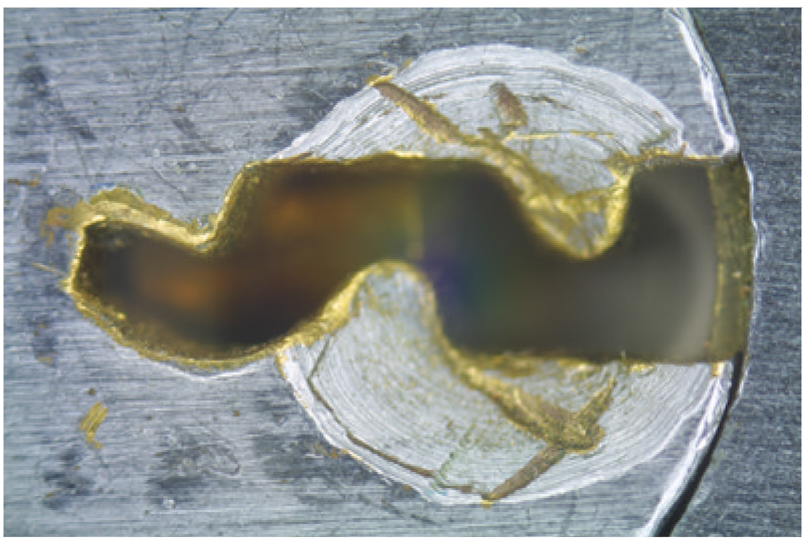


Figure LSS+2602 A cylinder that has been picked and raked (left) and picked, then a forced entry tool was utilized.

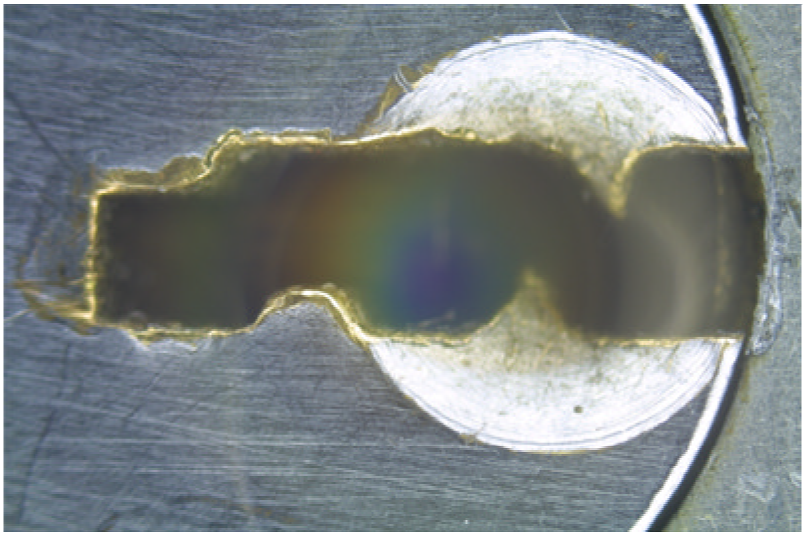

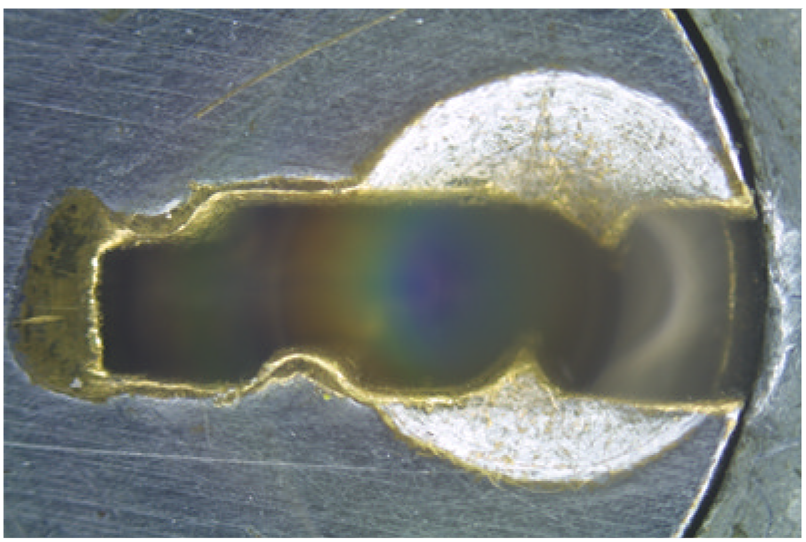

Figure LSS+2603 An electric pick gun was utilized to open the lock on the left; impressioning and picking was utilized to open the lock on the left.

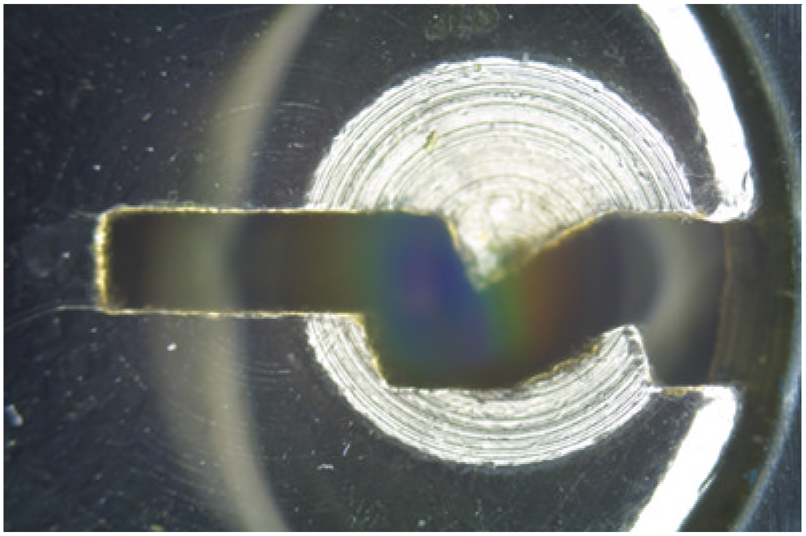

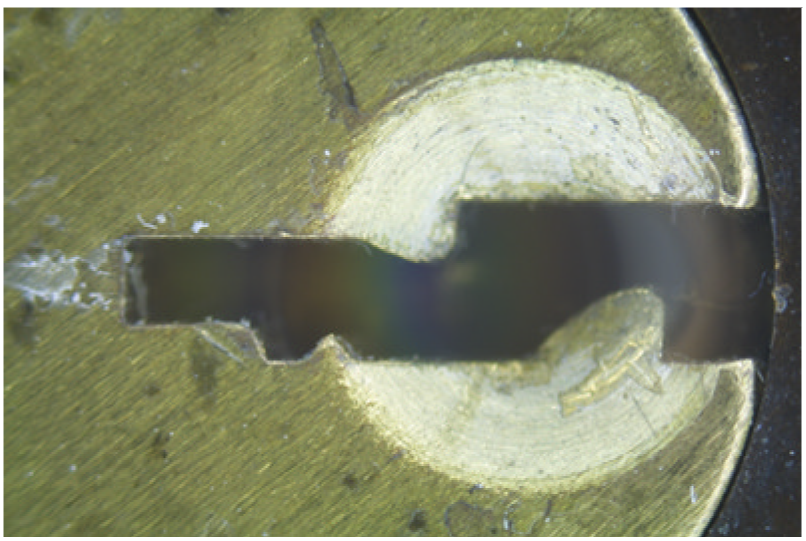

Figure LSS+2604 The cylinder on the left was opened by impressioning, raking, and picking. The cylinder on the right was picked by a left-handed person.

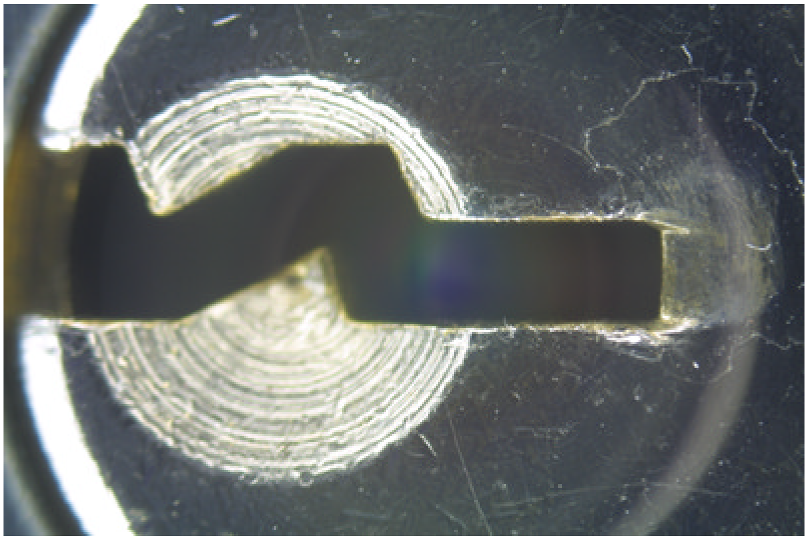

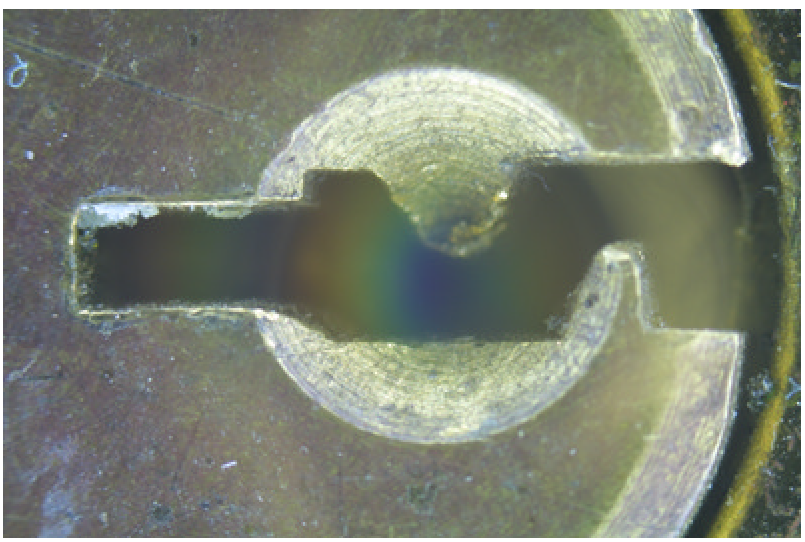

Figure LSS+2605 The cylinder on the left has not been bypassed. It shows normal wear marks from the use of a key only. The cylinder on the right was impressioned and opened by left turning.

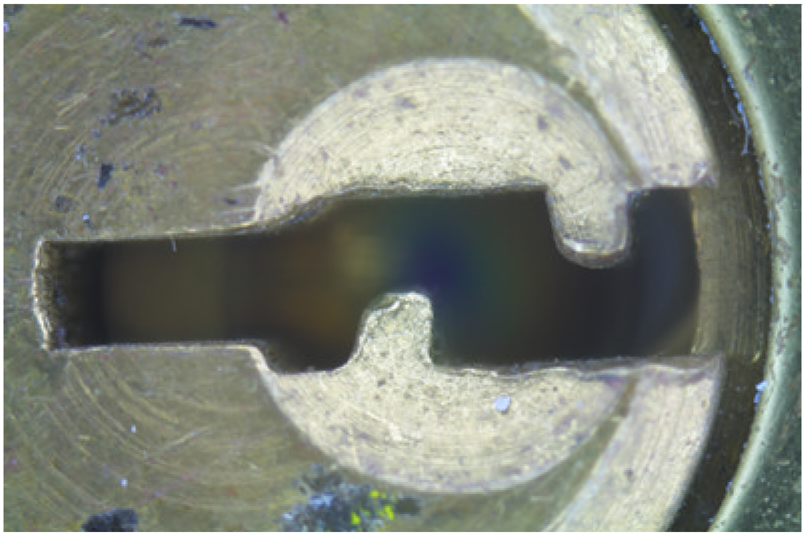

Figure LSS+2606 Both of these cylinders were opened by picking.

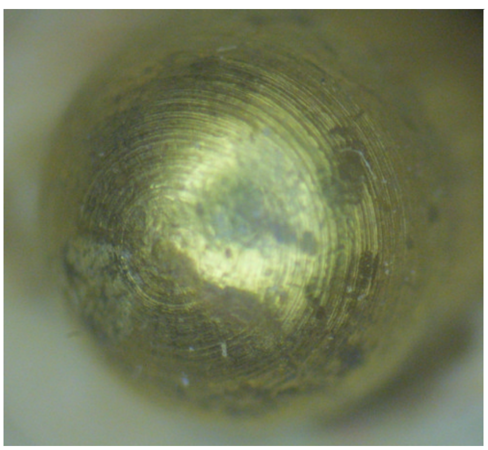
26_1.5.2.1.2 Tool Marks on Pins

Normal appearance of pins and what type of marks appear. Courtesy of Hans Mejlshede.



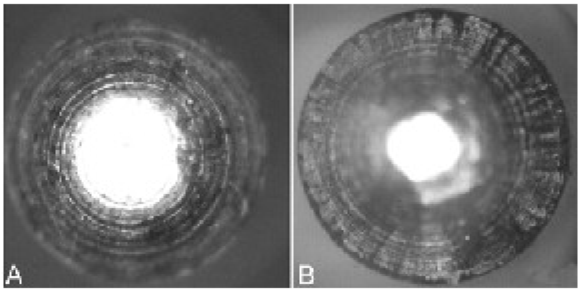


Figure LSS+2607 This normal pin shows factory machining marks, and has not been picked.

All pins and pin surfaces (bottom and sides) should be examined for evidence of tool marks and distortion. This is especially true for the pin that is the most out-of-alignment with respect to centering of pin chambers. This pin will be picked or impressioned first.

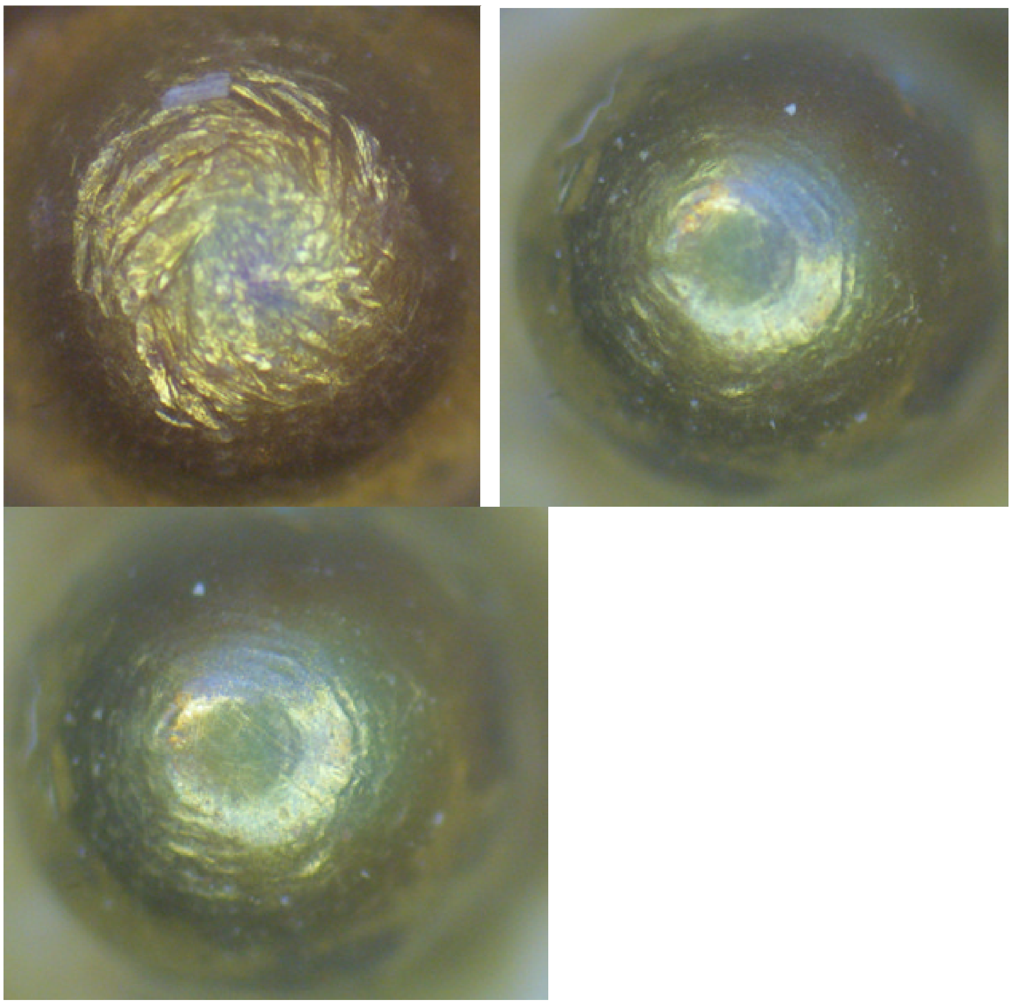

Figure LSS+2608 An electric pick gun was utilized on the pin shown in the left photograph.
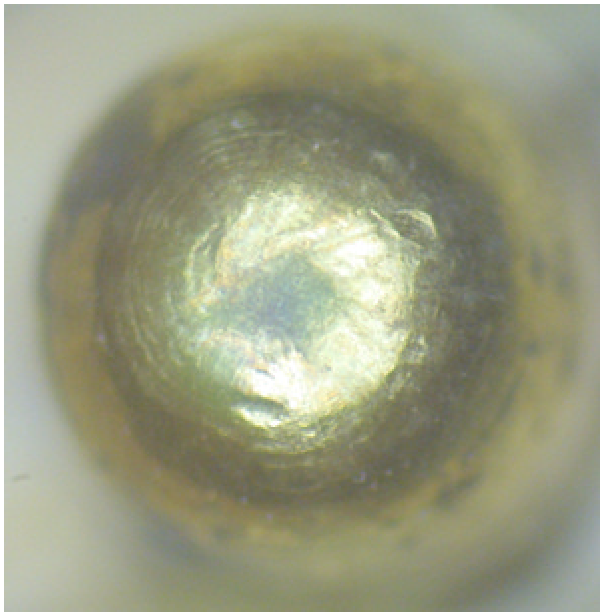
A snap pick was utilized on the other two pins shown.



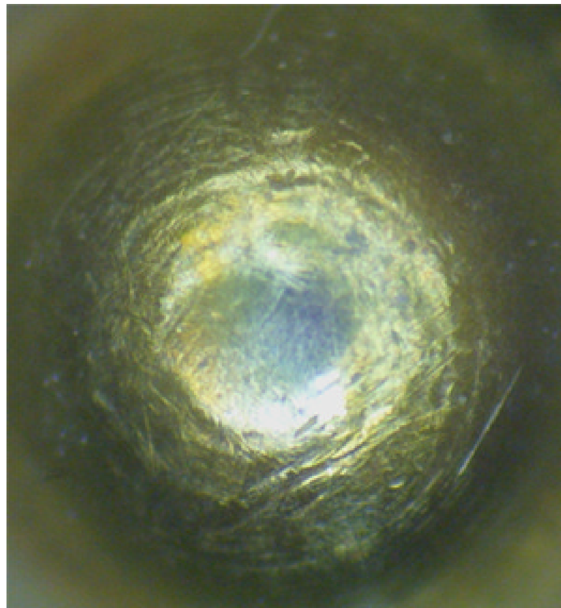


Figure LSS+2609 An impact tool was utilized on this pin. Note the deep impressions around the circumference.

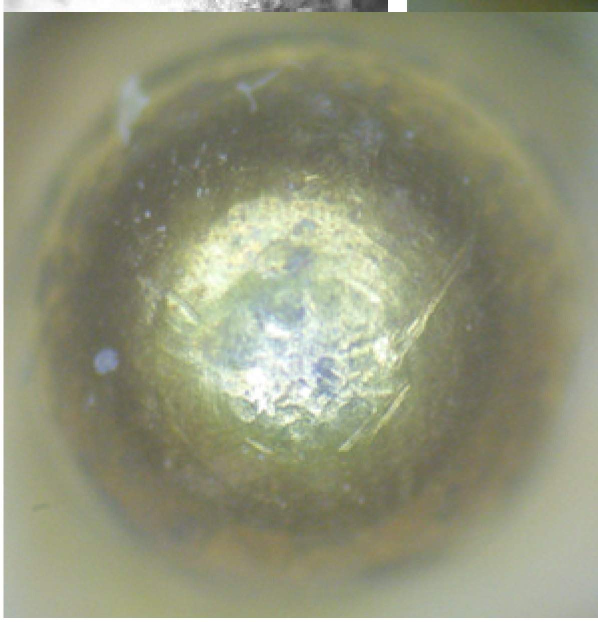
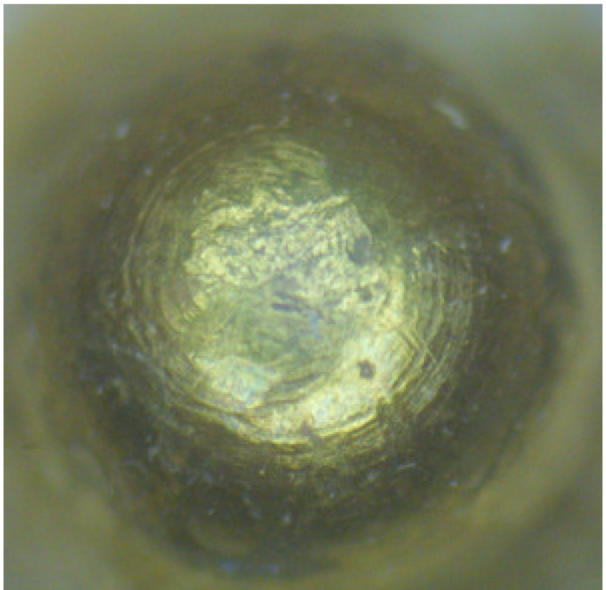
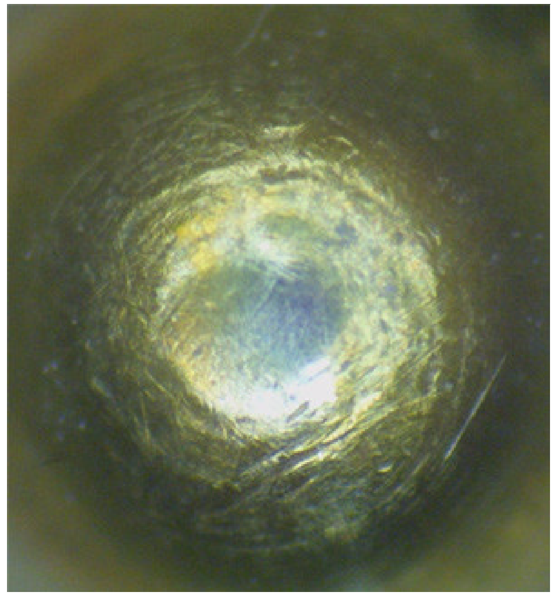


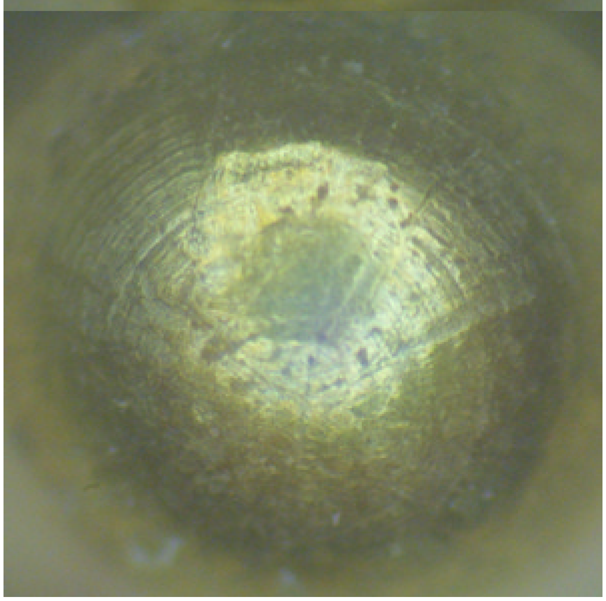
Tool marks may appear as scratches on the bottoms and sides of lower pin tumblers. The size of marks may indicate the type of pick. Marks on longer pins next to shorter ones will clearly point to picking with conventional tools; equal marks on the bottoms of all pins will indicate that a snap gun was used.

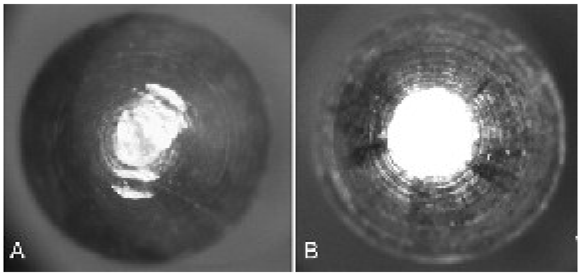


The location of the marking on pins will depend upon the keyway orientation. Methods of picking, especially with snap guns, must be determined so that an accurate estimate can be made as to where marks should occur. A test cylinder should be picked using various techniques to verify markings.



v





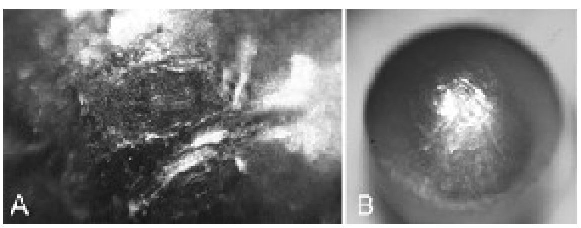


Figure LSS+2610 Examples of marks produced by different types of manual picks (above). In the photographs below, a Medeco Biaxial five pin cylinder has been picked using a probe to apply pressure against the edge of the pin. Although not a completely reliable means of opening, the technician reports that he could open this lock in between thirty seconds to one hour.

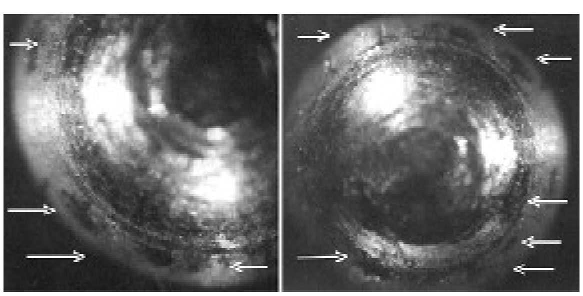
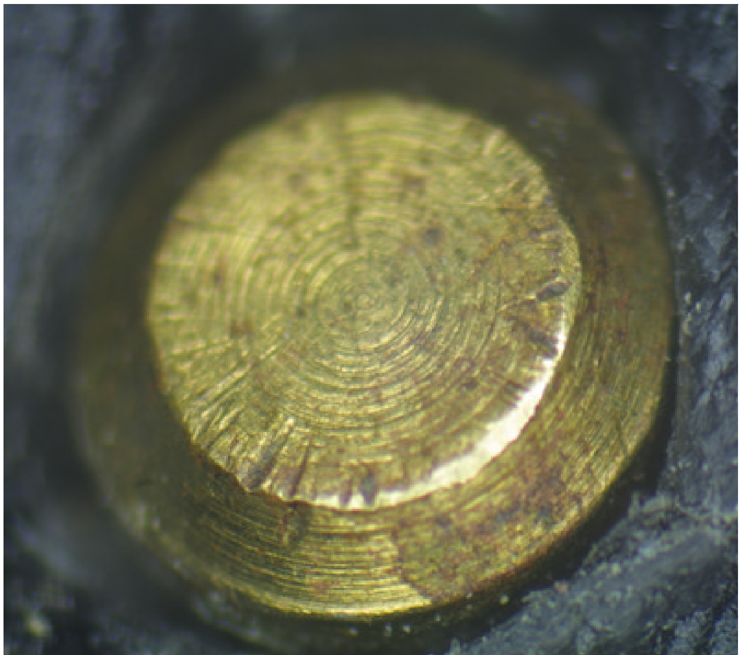
Indentation marks may be present on the sides of both lower and upper tumblers. This would indicate impressioning with the use of extreme torque.



There may be compression marks on the tops of pins, caused by the spring wire being exposed to the tumbler surface. This would offer evidence of the use of a comb pick, or substitution of lower pins for drivers. A comb pick requires that all pins be compressed into the shell. The force required to accomplish this can leave marks.



However, if markings are encountered, examiners must eliminate the possibility that such scratches were in fact produced from the bottom tumblers originally being used as driver pins, with the rounded surface oriented toward the springs. Sometimes, a locksmith will substitute bottom pins for drivers, especially when working on a lock in the field. If pins were substituted, generally the corresponding spring will be broken, with a jagged piece of wire contacting the pin. In such cases, the marks will appear to go around the dome of the pin. Examiners should also be alert to color coded pins with portions of the color missing.

Lower pins may slightly rotate during normal use, distributing wear until they are so worn that tracks are created on their base. Essentially, every time a key is inserted, the tumbler is contacted and marked. After many years, this will be quite pronounced. If a pin is hit at the same point many times, a flat spot will occur. In contrast, if the lock is picked, especially with a pick gun, the pin is rotated and marks will occur around the center-point of the lower pin. They will often appear like the spokes of a wheel.

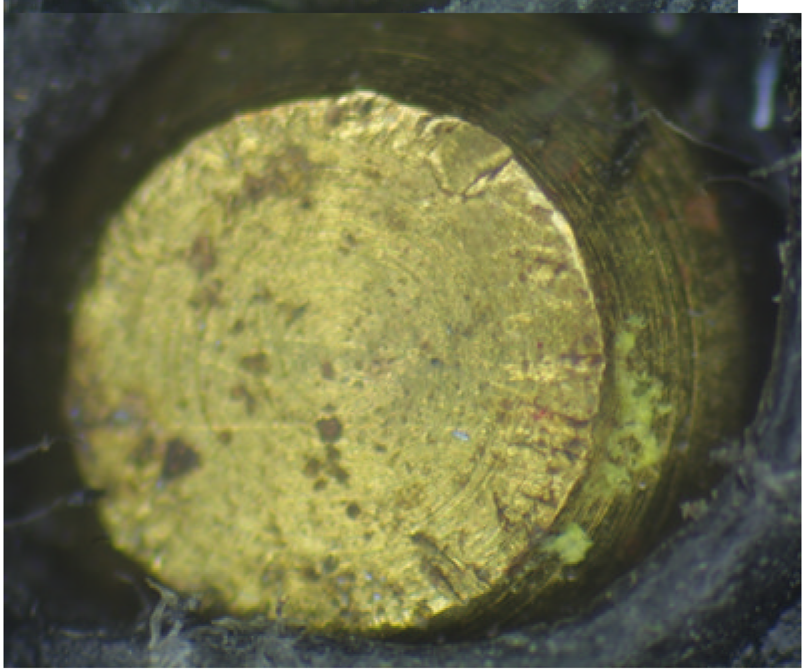


Figure LSS+2611 Marks produced by a pick gun (left) and rake pick (right). Note the multiple markings that are made by the pick gun around the circumference of the pin.

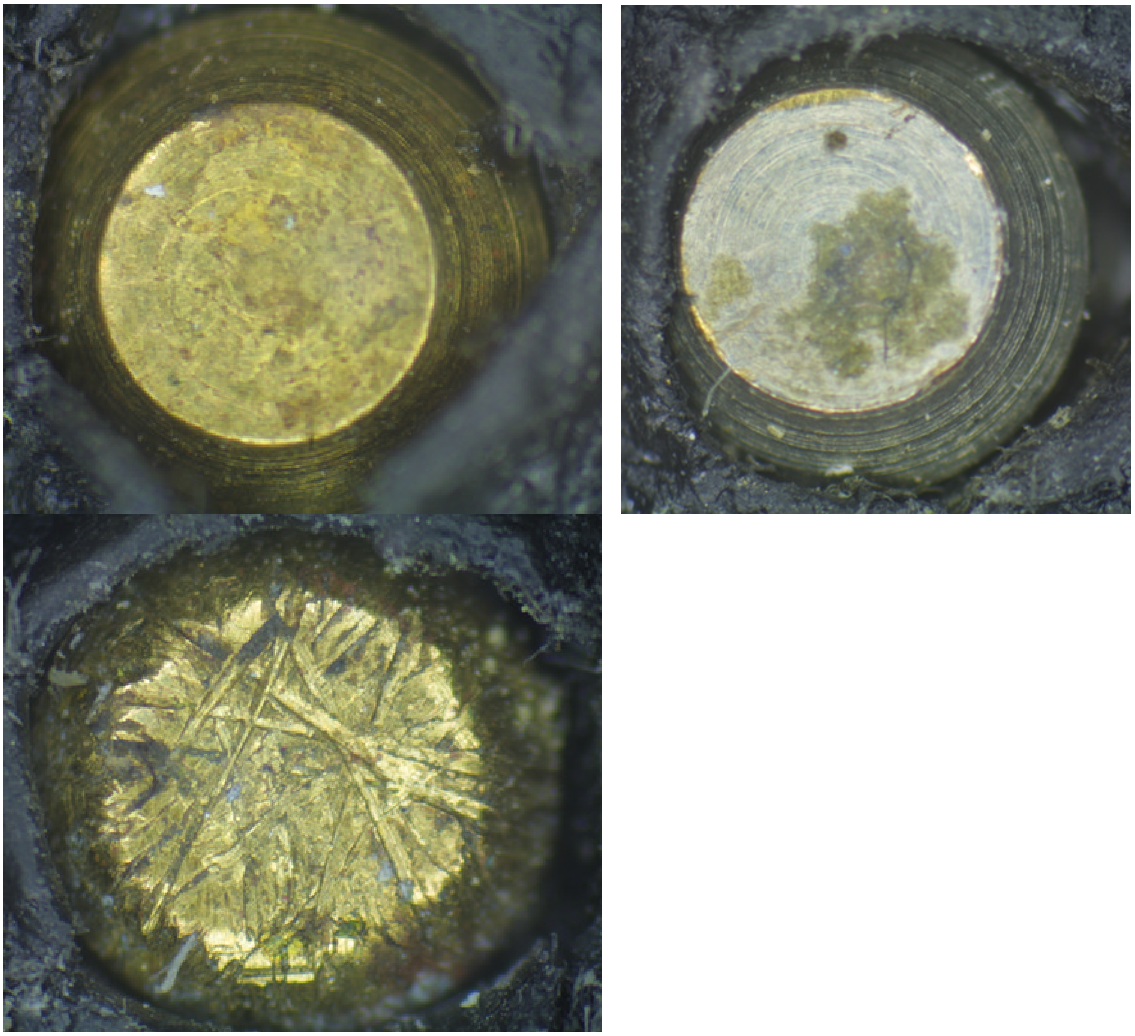

Figure LSS+2612 Marks produce by a pick (left, by a key only (center) and by an electric pick gun (right).

26_1.5.2.1.3 Marks on Springs

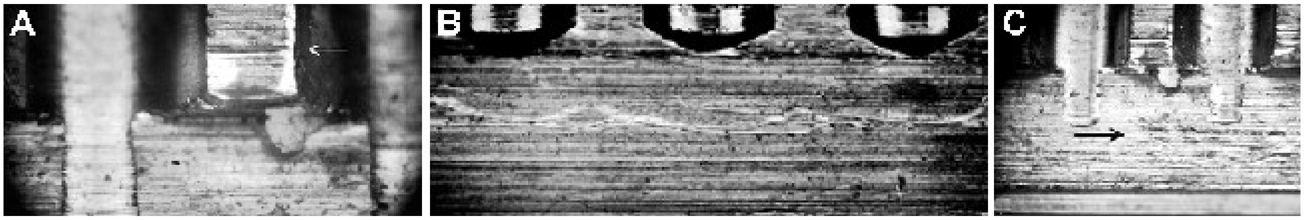
Sometimes, marks will appear on springs. This may indicate that a fine drill was used to create a shear line. Compression of springs may indicate that extreme pressure was applied with a comb pick.

26_1.5.2.2 General Queries Regarding Tool Marks from Picking

If it is determined that the lock was likely picked, then the following inquiries may be pursued:

- **Are there any tool marks on the surface components or within the plug;**
- **Are there pick or scratch marks on the top, bottom, or sides of any pin. Long marks may indicate that tumblers were raised improperly, caused by picking rather than normal key use. Marks will be created by applying torque to the plug while raising a tumbler. The friction of the pin rubbing against the chamber wall will cause discernible scoring;**
- **Are there tang marks (from the tension wrench) on the top, bottom, or sides of the plug;**

- **Are there scratch marks on the surface of the shell or plug, notably on the front escutcheon, keyway, chambers, or pins. This would be especially important in the case of dimple locks, because a different technique is generally used to apply torque;**
- **Are there apparent pick marks. If such marks were caused by picking the lock, how old are they. When were they made. Could normal operation of the lock cause the questioned marks. Are there alternative explanations;**



- **Was the lock picked by raking, conventional techniques, or pick gun;**
- **What type of pick tools were used;**
- **Have the tumblers been rotated by picking. This is why it may be important to maintain the exact vertical position of the tumblers when opening the lock, as noted earlier in the chapter. If the lock was picked, the tumblers may have revolved which would be indicated by misalignment with respect to normal key track wear.**

26_1.5.2.3 Marks from Conventional Picks

Marks produced by raking. Courtesy of Don Shiles.

Marks made by conventional picks may take many forms with respect to depth, length of track, and width. Picking with conventional tools has the same basic result: a scratching will occur as the

tip of the pick moves across pin and plug surfaces.

Optimally, the examiner will find locations within the plug where the key cannot encounter any surface. If marks appear there, it is almost certain that bypass occurred. Remember, picks may be sharp, rounded, sloping, angled, or of other design. Therefore, the marks created may be quite varied.

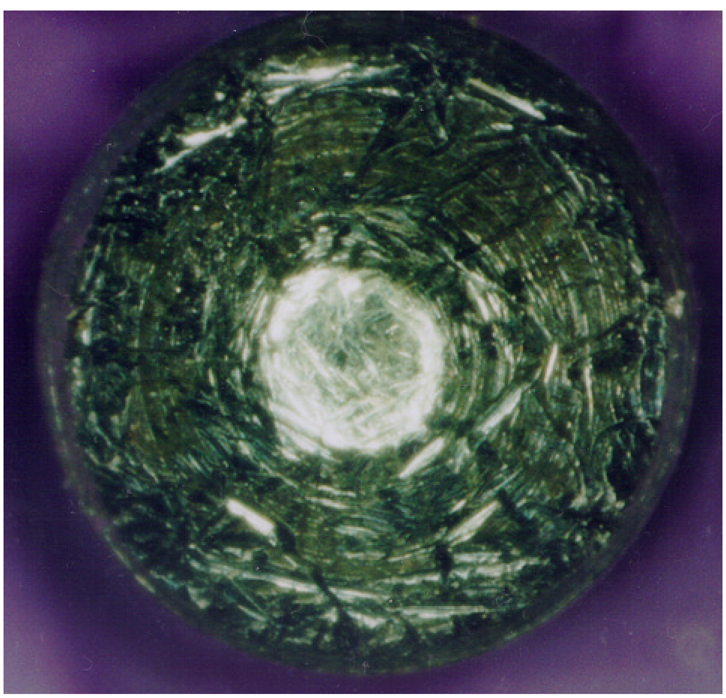


Figure LSS+2613 Marks produced from conventional picking tools are distinct, and will appear around the head of the pin as it is rotated during the picking process.

26_1.5.2.4 Marks from Pick Guns

Pick gun marks and order of picking. Courtesy of Hans Mejlshede.

Forensic indications of the use of an electric pick gun. Courtesy of Hans Mejlshede.

All pick guns, whether mechanical or electrical, perform the same function: to generate a rapid, focused shock wave applied to the base of the lower pins. Markings from the use of these tools can be quite pronounced because there is usually several attempts before the lock will open. Each time the tool is triggered, marks are created. The active end of the tool (the metal pick that meets the tumblers) presents a relatively hard surface against soft metal pins.

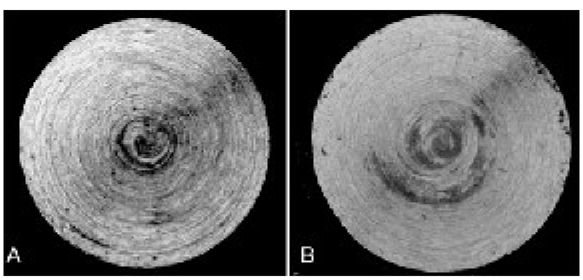
There are three types of pick guns: mechanical snap, electric solenoid snap, and electric vibrating. Each will produce markings on tumblers. The snap guns all work on the same principle and relates to Newton's theory of motion that for each action, there is an equal and opposite reaction.

Figure LSS+2614 Marks produced from pick gun.

Based upon the same premise as striking a pool ball with a cue, in turn striking another ball which is then moved to the pocket, the working end of the snap pick is the pool cue. It meets the base of one or more tumblers to create a shock or burst of energy. This energy is transmitted to the driver (upper) tumbler. The upper pin is moved as the "opposite" reaction to the force being applied to the lower pin. In principle and with the proper skill, **all** drivers will be simultaneously bounced above shear line for a few milliseconds. If during this very brief interval a turning force is applied to the plug, there will be nothing to stop its rotation.

The HPC mechanical snap gun described in **Chapter 29** is simply a device for rapidly cocking and releasing a long, straight piece of spring steel, formed to make contact with the base of each lower pin tumbler. For proper operation, the pick will be aligned with the bottoms of all tumblers at a perfect 90° angle. It is important that all pins be contacted at the same time and with the same force. To open the lock, the operator will repeatedly release the pick. Each time this occurs, a very brief force will be applied to the pins. With skill, the proper timing of shock and turning is achieved and the plug rotates.

The electric solenoid pick accomplishes the same function, except that the shock wave is generated by the action of a magnetic field rather than manual spring. The results are identical. The HPC vibrating pick is based on a similar theory as the pick gun. The tool generates rapid oscillations of the pick blade that may be adjusted to personal preference.



Each of these picking tools will cause similar marks to be

produced on the bottoms of the tumblers and perhaps on the sides of the keyway. The marks will be varied and often will be many in number, because the pins tend to rotate as the process occurs with multiple abrasive contacts. There will also be marks around the center of the pin. This is dependent upon the design of the wards and the freedom of the pick to move vertically. If the pick gun can be located directly under each tumbler, then all marks will appear in the center.

If a pick gun is triggered five times there will theoretically be five sets of marks, although this is not absolute. The angle of attack and the keyway will dictate where the marks occur. If there is a mark on one tumbler but not on others and there is corrosion present between chambers in recesses of the keyway or above it, then it is fairly certain that a pick gun was **not** used. Corrosion over the marks must also be checked and estimation made as to how fast picking marks would corrode in the specific environment where the lock is utilized.

26_1.5.2.5 Tool Marks from Comb Picks

A comb pick may be utilized in locks that are improperly pinned or which do not contain balanced drivers. Apparently many manufacturers are still not aware of this tool and thus do not compute the length of the pin stacks in their locks. The pick resembles the teeth of a comb; one for each pin. It will not work in any lock where the pin-stack (drivers and lower pins together) are balanced or longer than the upper pin chamber. The tool will function only when all lower pins can be pushed into the upper chambers above shear line. Then, the teeth of the pick form a new shear line allowing the plug to rotate.

This tool will leave marks on the bottoms of all tumblers because a fair amount of pressure must be exerted to raise them simultaneously, although such pressure is distributed. Springs may also be compressed as the result of such bypass. Examination should include the interior of plug chambers, both upper and

lower, for marks. Because of the design of the comb pick, marks may be quite symmetrical with respect to their relative location in each chamber. As remarked previously, the initial examination of the lock should also include verification of the length of the pin-stack for each chamber to ascertain whether a comb pick could actually work.

26_1.5.2.6 Marks from 999 Rapping

Cylinders may be opened by rapping them. Courtesy of Hans Mejlshede.

Rapping of a lock using a “999” style key is common in some countries, notably Denmark. The procedure involves the insertion of a specially cut key described in more detail in **Chapter 29**, followed by the application of rapping or repeated shocks to the end of the key using a mallet, plastic screwdriver, or similar instrument. The rapping motion is transmitted to all tumblers, (at a 45-90^{o} angle to the bottom pins) simultaneously. In theory, much like the pick gun, the forward motion of the key will momentarily cause the driver tumblers to be bumped upward above shear line. With the proper timing, a lock can be successfully rapped open in a couple of attempts.

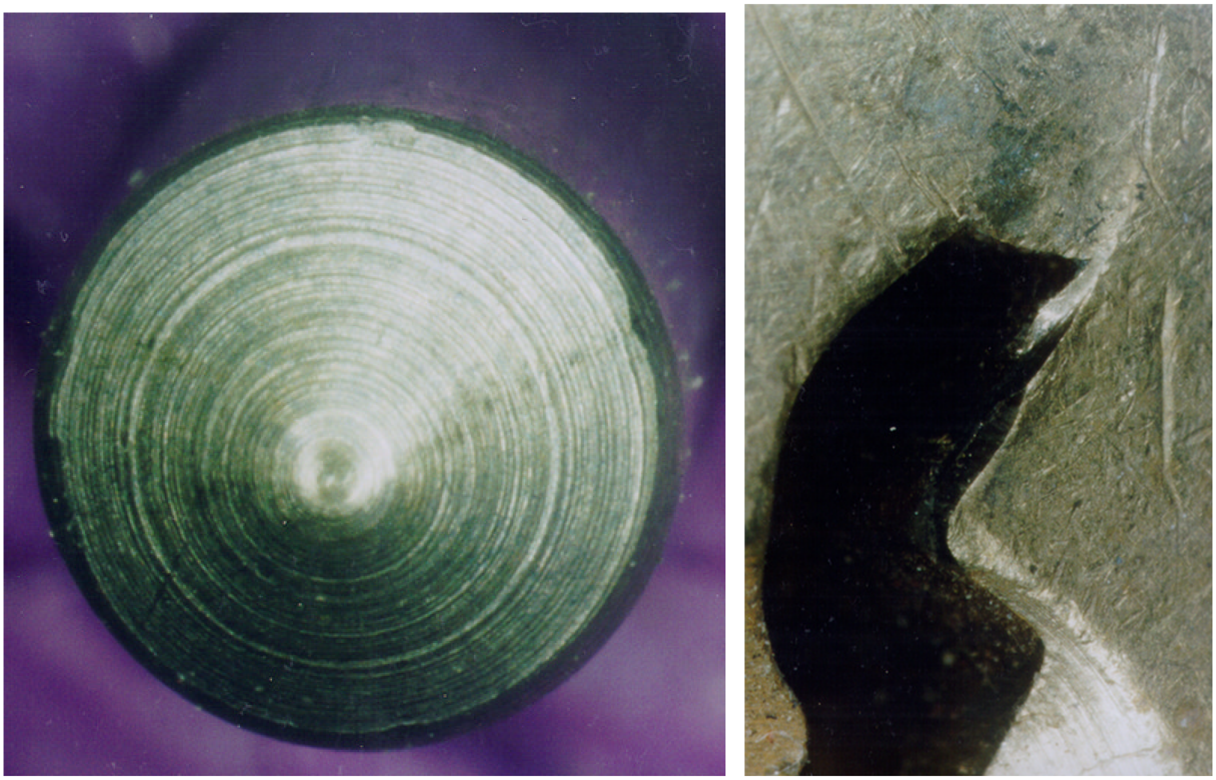


Figure LSS+2615 indicia of the use of a "999" or "bump" key. Note the tearing at the top of the keyway and the deformation of the pin circumference.

Forensic indication of the use of a ""999"" or "bump key," Courtesy Hans Mejlshede

The design of a 999 key would preclude its normal use. It would rarely if ever be encountered except in suspicious circumstances. Possession of such a key would warrant further inquiry. A 999 key will have all cuts at maximum depth and will often contain long ramps between cuts. These ramps will serve to catch each lower pin as rapping is applied.

The procedure will leave evidence in two areas: on the sides of all tumblers and on the plug. There will be marking where the shoulder strikes the face of the plug because the key is often hit too hard. If there is a visible indentation, the technique should be suspected. However, such could also represent a lock with heavy use. The pins should be closely examined; they will appear as if struck with a brass chisel. A radial mark will be present because the angle of the key is not the same as on the pin. Scratches on the sides and bottoms of the pins can show that a 999 rapping technique was applied, or that there was too steep

a ramp angle on a key that was forced into the lock.

26_1.5.3 Marks from Impressioning

See **Chapter 30** regarding impressioning techniques.

Impressioning requires that a blank key be inserted into the lock. Torque, in concert with a specific lifting motion, is applied in an effort to bind the lower pins until they are precisely at shear line. The underlying theory of impressioning (within the pin tumbler mechanism) can be simply stated. As torque is applied, pins that are below or above shear line will mark the bitting surface of a key when it is moved vertically. A pin will not bind when **at** shear line, if vertical pressure is applied to it. When the key is cut to the proper depth during the impressioning process, no marking will occur on the blank.

Various marks will be produced through impressioning techniques, depending upon the type of lock and the procedures employed. These generally will take the form of keyway distortion and marking on the walls of the keyway and chambers, on the sides of pins, and in other areas of the plug. Marking may also be seen at the bottom end and sides of the top pins. Side indentation may occur because of the rotational pressure of the plug that occurs just before the lock opens. Significant indentation may also be in evidence at the top and bottom of the plug, resulting from the heavy sliding action between the blank and the keyway. Angled indents on pins will be caused by the extreme application of torque and resulting pressure on the sides of tumblers.

Depending upon the age and use of cylinders, marks caused by impressioning will be different. Tests may be required on specific locks after all photographs and measurements have been taken. Impression marks may be left on lower and upper walls of chambers, caused by torque and vertical movement of the plug binding against the pins. The pins actually will scrape the chamber walls. Indicia may also be left on the face of the plug, both top and/or bottom, because of the application of pressure against the shoulder of the key.

Keyway wards may also be warped, deformed, or marked as a result of the interaction between the blank and sides of the plug. Spreading of the keyway can also occur. Marks on keyway wards may likewise be caused by an improperly fitting blank, generally a non-factory original. Elongated or distorted chambers may be found in the plug or shell because of the process. If a dimple

lock is impressioned, pins may be bent, distorted, or crushed, especially in the high-security mechanisms such as Kaba and Mul-T-Lock. In the case of plastic or nylon plugs, cracking can happen if too much torque is applied. In a forensic examination to determine impressioning, the following areas must be checked for marks:

- **On the front of the plug, from pressure caused by impression tool, vice grips, pliers, nose puller, screw marks, or other devices;**
- **On the face of the plug-top and/or bottom;**
- **Chambers, plug sides, and chamber spaces;**
- **Measurement of plug/keyway warping and spreading of keyway and of wards;**
- **Scraping of chamber walls, of driver and lower pins, and pin sides;**
- **Pins, on the bottom forward side, for impression marks that will indicate a hard pressure exerted against the blank. It may also indicate a poorly cut key with too deep of a slope angle, typical of hand cutting;**
- **Marks on the cam;**
- **Widening of pin chambers;**
- **Cracks or fractures of metal or plastic keyway.**

Forensic investigations involving locks that have been impressioned. Courtesy of Hans Mejlshede.

26_1.5.3.1 Queries Regarding Impressioning

- **Are there marks on all top surfaces of lower pins. This may indicate impressioning or a loose plug. Try to pull the key out. If it sticks, the cam-retaining screws are loose;**

- **Are there marks on the bottom of lower tumblers. This may indicate that the lock was impressioned or that a poorly fitting, worn, or improperly spaced key was utilized. Does the key have to be slightly withdrawn or jiggled to work;**

- **Examine the cylinder for scoring. This can occur if**

the key is improperly cut, causing tumblers to be raised slightly higher than shear line;

- **Are there multiple vertical tracks in the chambers or on pins. Markings on chamber walls, especially if they correspond in upper and lower chambers, can indicate impressioning or the use of comb picks. Vertical tracks in several chambers may also show impressioning;**

- **Are there spots on the bottom of tumblers. This may provide evidence of impressioning or that a poorly fitting key had to be lifted to raise the tumblers to shear line was utilized;**

- **Are there any tracks between the upper surface of chambers. This would indicate that the lock was picked, not impressioned;**

- **Is there any tracks or scoring on the interior radius of the shell, drawn in a circle or ring, that correspond with plug rotation. This would generally indicate that the plug was rotated using a key that was cut slightly high, so that the bottom pins scored the surface of the shell. It could, however, also provide evidence that a comb pick was utilized, although this is more remote;**

- **Are there narrow or wide tracks on the bottoms of tumblers. Narrow markings would indicate picking. Wide tracks would tend to indicate impressioning or extreme wear caused by heavy use of the lock;**

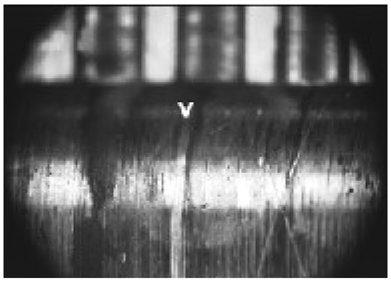
- **Are there spots on the sides of the keyway. This may indicate a number of conditions, depending upon the precision of broaching and the milling of the blank(s) used to open the lock;**

The spots can be caused by the interaction of a poorly milled blank that makes contact with certain points within the keyway, but not all points. Spots may also touch the keyway, especially if some pressure is required to insert the blank. A combination of the two errors may also contribute to spots. The exertion of

extreme pressure and torque upon a blank during impressioning can also cause them.

- **Are there shiny spots or indents on both the longitudinal surfaces throughout the length of the keyway, as well as vertical spots or distortions. Are there single or multiple spots or markings on the sides of the tumblers and chambers. Such would definitely be evidence of impressioning because both horizontal and vertical movement of the blank is required;**

- **Multiple vertical spots on one or more chamber walls would be highly suggestive of impressioning because of the procedure involved in making the key. Can a correlation be made between the number of spots within a single chamber and the depth of the tumbler cut.**



Thus, if the tumbler requires a deep bitting surface on the key, a corresponding number of samples would be required before a determination could be made of the correct depth. Each time the key is filed and the new depth is tested, a potential new marking will occur at a different position;

- **Are there distortions at the top of the plug chamber holes or the very bottom of the upper chamber holes. If so, this would indicate impressioning. The distortions are caused by torque being applied to the plug and the tops of the lower tumblers binding just above shear line;**

- **Are there marks on the bottom pins. These may have been caused by a poorly cut duplicate key. Excessive pressure and resultant marking can be caused by the insertion of the key, especially if ramp angles are too steep or there are jagged or sharp edges on the surface;**

- **Are there lateral marks that begin at the surface of the plug and extend inward a short distance (1-2 mm) along the keyway. These marks may appear anywhere, although usually they will be at the top, bottom, or against a protruding ward. Such markings would**

indicate the use of a tension tool. Remember that tang marks will generally not protrude past the first or second tumbler. If longer tracks are present, it may indicate the use of a flat-blade screwdriver, possibly to simulate picking. It may also be that such a tool was used as a turning wrench.

26_1.5.4 Markings on Lever Locks

Lever locks are popular throughout the world for all security applications. They are favored in Europe for safes and vaults as well as traditional uses. Almost all lever locks can be picked or decoded, even those promising the highest security levels and previously thought to be impenetrable. In the experience of the author, up to ninety-nine percent of all high-security lever locks employed on the finest safes and vaults in the world can be quickly compromised without detection or trace.

There are at least five methods for opening these locks, covered in detail in later chapters. Some decoding methods will leave little if any trace, while others may leave very tangible evidence. Marks will be present on the sides of levers. Although marks may also appear on the bellies (depending upon bypass methods), care must be exercised in their evaluation. Improperly cut keys or the insertion of the wrong key may leave marks that appear inconsistent with normal operation. In some instances, deposits of plasticine, type-correct solution, putty, nail polish, or carbon may be present because of impressioning attempts. Certain sophisticated decoders will leave virtually no trace. Their use is discussed in the **LSS+/^{x} CD/ROM.**

26_1.5.5.A Markings on Wafers: General Issues

The reader should also see **Section 32_4.4** for an introductory discussion regarding the different types of tool marks and how

they are produced.

Analysis of presence of grease on wafers in forensic investigation. Courtesy of Hans Mejlshede.

There have been few reported studies regarding the analysis of marks on wafer and disc tumblers, especially in vehicle locks, and the subsequent determination of factors regarding the use of specific keys within a given lock. In this regard, there are at least three significant issues to be considered by the forensic technician, and for which an examination may be conducted:

- **Can a determination be made with regard to the last key that was used to operate the lock;**
- **Can it be ascertained specifically which were the most recent key or keys that were used to operate a given lock;**
- **A determination if other than the authorized key has been used to operate the lock, through an analysis of internal components and suspect keys.**

An analysis of locks used in automobiles will further require the evaluation of keyways; marks left on wafers, discs, and pins from authorized and unauthorized production of keys; and exposure of internal components to extreme heat, as may be encountered in a car fire. In this regard, the deposit of carbon residue and potential oxidation upon component surfaces must be considered as a potential artifact to a valid analysis.

26_1.5.5 Markings on Disc Tumbler Locks

Disc or wafer tumbler locks are found everywhere and are used in low to medium security applications. They are an inexpensive substitute for pin tumbler locks. See **Chapter 15**. All critical components (springs and tumblers) are self-contained. Locks can be configured as single, double, or triple bitted.

Disc tumbler locks are used in desks, cash drawers, money bags, alarm panels, key cases, access control, display cases, and hundreds of other applications. Because of their popularity,

they may be the focus of surreptitious bypass in burglary investigations or where covert penetration is suspected.

Disc or wafer tumbler mechanisms can be easily identified by the appearance of the wafers viewed from the front of the lock and by the relative diameter of the plug and shell. Wafers will appear flat, rather than rounded, when examined from the outside of the keyway. The diameter of the plug is large in relation to the diameter of the shell. Very little space is required above the plug in contrast to the pin tumbler lock that must have sufficient room for driver tumblers and springs.

An experienced lock picker can bypass these mechanisms in seconds, leaving little if any trace. Generally, keys will make marks on the bottoms of the wafers. Any scratches or marks on the sides of the wafers should be cause to suspect picking. Many varieties of disc tumbler locks are also utilized in automobiles, and will be discussed in the following section.

26_1.5.6 Markings on Sidebar Locks in Cars

Briggs and Stratton developed the original sidebar lock in 1935, for use in automobiles. They are essentially the same design today and have been copied in many forms of high-security locks. General Motors continues to utilize sidebar locks as do other manufacturers. There have been several keyway changes since the original mechanism was introduced in 1935. Today, the locks contain six discs with five depths: a “1” depth is a no cut and a “5” is the deepest.

They are difficult to pick but can be decoded and opened with special tools. They are often drilled; a small hole is made directly above the sidebar so that pressure can be exerted as each tumbler is raised to shear line. On certain sidebar locks, a borescope or ophthalmoscope may be used to read the depth coding number stamped on the face of each tumbler.

In the laboratory, key codes may be determined by disassembling the lock and examining each tumbler in the order installed. Remember that the combination of a sidebar lock can be easily changed or the lock removed and replaced. It may be wise to verify the code number of the lock as shipped from the factory with the vehicle in order to determine if it has been altered or replaced.

26_1.5.7 Markings on Dimple Pin Tumbler Locks

When certain dimple-style pin tumbler locks are impressioned, visible damage may be caused regardless of the method employed. This is especially true in the case of some of the high-security mechanisms that utilize telescoping pins or tumblers with extremely thin walls. Kaba and other locks employ such pins. They are easily warped, distorted, or crushed if too much torque is applied during the impressioning process. The reader is directed to **Chapter 30** and the **LSS+/^{x} CD/ROM** for a more detailed discussion of the techniques for impressioning these locks.

26_1.5.8 Markings on Axial (tubular) Cylinder Locks

Axial locks, such as Chicago Ace and Fort, are used primarily in vending and access control. They may be picked, impressioned, and decoded. For this reason, it may be useful to perform an analysis to determine surreptitious entry, although conclusive results may be difficult.

They are generally configured as cam locks, offering low to medium security. They are pin tumbler mechanisms with all pins positioned in a 360^{o} radius. The numbers of tumblers vary, generally from six to nine, and they may be exposed or recessed. High-security pins, including telescoping and mushroom, may be employed. The standard key measures .375" OD; the most common cross-reference blank is Taylor 137 or Ilco 1137S. Regardless of design, all axial pin tumbler locks will have one or more shear lines resembling conventional devices.

There are a number of different methods to open these locks, including conventional picking, decoding, impressioning, and manipulation with special pick tools. These locks may be forcibly opened using the HPC "**lock killer**" or special hole saw. Although normal pick tools may be used, the process can be awkward due to the difficulty in locating and securing a torque wrench in the keyway guide slot. An Allen wrench may be used as a tension tool, or a small hole may be drilled in the center of the lock for a tension tool to be screwed into the plug.

Conventional picking of axial locks requires several rotations to achieve one revolution of the plug. Also, the lock may be left in a partially picked state. This will provide direct and generally indisputable evidence of attempted bypass. It will also render the lock inaccessible for normal use because the key will be blocked from entry into the plug. The criminalist should be alert for such condition.

The preferred method of opening is to utilize one of the specially designed pick tools sold by HPC and other vendors. These are designed for specific locks, taking into account the number of tumblers, their spacing, diameter of the plug, and other characteristics. These tools generally have sliding steel shims embedded axially; their position to correspond with the pins. To open the lock, the tool is pressed against the tumbler, and with torque applied, rapidly inserted and withdrawn. The action resembles traditional impressioning: the tumblers bind until reaching shear line, and will cause movement of the shims. The advantage to using decoding/impressioning scheme is that once the lock is opened, a key may be generated directly from the tool.

One must be very cautious in drawing a conclusion that a lock has been bypassed or that an attempt has been made simply from the fact that the plug is rotated to a partially picked position. If the top guide-pin on the key has been removed, the key may be withdrawn in any position. See **Chapter 29** for a detailed description of picking these locks.

26_1.5.9 Markings on Abloy and Abus Disc Wafer Locks

Abus (German) and Abloy (Finnish) each manufacture high-security disc wafer locks that appear quite similar in their design. Disc wafers, resembling the wheel pack in a traditional combination lock, are rotated so that their gates are aligned, thereby allowing a sidebar to retract and the plug to turn. Each company produces a series of extremely popular cylinders and padlocks employing this design.

These locks can be decoded and opened using highly specialized tools. Evidence of such decoding can be quite pronounced in the form of scratches and gouges on the surface of discs and potentially on the spacers between the discs. See **Chapter 31** for detailed information on bypass of these locks.

26_2.0 Material Transfer and Residue

Trace materials found within locks may link tools, keys, suspects, and remote locations to crime scenes. They can provide valuable evidence that a bypass (or attempt) occurred, as well as techniques, expertise, and identity of perpetrators.

Transfer may occur between keys, bypass tools, or anything that has been inserted into the plug. Materials that may be deposited or produced will include dirt, lint, tobacco, clothing fiber, lubricant, cleaner, graphite, oil, grease, wax, metal foil, wood, and metal fragments. Trace elements may be left from tools inserted into the questioned lock after being transferred from other locks prior to bypass, or picked up from materials with which such tools came into contact. These may include carrying cases, pockets, toolboxes, and work areas.

26_2.1 Trace Evidence: Foreign Material in Plug

Materials found within locks may be significant, or they may simply have been deposited, created, or transferred through normal use. Trace materials and their possible origin and significance are listed below. Metal fragments or particles may be found within a plug, often on wards or other areas that are exposed to keys. Materials may also be found in recessed areas. It is important that a preliminary determination be made as to the probable means by which the material was created or transferred and if normal use of the lock could have caused such transference or creation.

Materials may be transferred, deposited, or created for a variety of reasons. The criminalist or investigator may therefore wish to eliminate as many causative factors as possible, especially since each may be potentially raised by a defendant to create reasonable doubt. These include:

- **Remnants of original manufacturing process;**
- **Normal use of the lock;**
- **Routine maintenance by a locksmith;**
- **Transferred from a newly cut key;**
- **Abnormal or unusual actions, circumstances, or conditions of authorized access person in handling or storage of keys;**
- **Random act of vandalism or sabotage;**
- **Intentional act of vandalism, sabotage, or planting of evidence;**
- **Earlier bypass attempt, undetected;**
- **Current bypass attempt;**
- **Bypass attempt by more than one perpetrator;**

- **External environmental conditions that may cause chemical or metallurgical changes within the lock, such as humidity, temperature, particulate matter in air, or unintentional introduction of chemicals into the lock or its proximity.**

26_2.2 Specific Trace Evidence and Causation

Following is a list of common materials that may be detected or found within a lock and their probable source, origin, or cause.

26_2.2.1 Maintenance and Transfer of Materials from other Locks

Lubricants and cleaners including graphite, WD-40, oil, grease, Cosmoline and gasoline.

26_2.2.2 Impressioning

Carbon, metal foil, cellophane tape, electrical tape, wax, plasticine, grease, type-correct solution (White-Out), nail polish, paper fragments, putty, Vaseline, soap, broken key or fragment thereof, broken key extractor, or parts.

26_2.2.3 Impressioning of Dimple Lock

Grease, wood fragments, metal foil, cellophane tape, and electrical tape.

26_2.2.4 Impressioning and Molding of Keys

Clay, silicone, epoxies.

26_2.2.5 Impressioning and Decoding of Locks

Plasticine, paint transfer on wards.

26_2.2.6 Recently Duplicated Key by Machine or by hand operated in the Lock

Brass filings on bottom of pins, oil.

26_2.2.7 Picking

Brass fragments or particles, steel or stainless steel fragments or particles, gun-blue material transfer, metal particles at bottom of plug, dissimilar metal fragments present in plug.

26_2.2.8 Vandalism, Interruption of Entry Attempt, Sabotage

Toothpicks, paper, glue, other foreign materials, broken key.

26_2.3 Contact between Bypass Tools and Lock Components

Two primary sources of evidence may be available to prove that bypass tools were used. Metal transfer to or from pick tools may occur, resulting from the interaction between sharp hard points on the tool and the relatively soft surfaces within the lock. It may be possible to retrieve and identify such metals, especially if completely dissimilar elements are present. For example, a spring steel pick tool may leave a trace on brass. Normally, steel would never be present, especially if it can be identified within pick tracks. Both spectral analysis and a scanning electron microscope may be employed to develop such evidence.

Difficulties regarding the presence and analysis of different metals to prove the introduction of bypass tools may be varied. They can raise many questions that should be anticipated in any defense. These would include:

- **What metals and alloys are present in the plug, shell, and tumblers;**
- **Are dissimilar metals incorporated within the lock, such as in chamber sleeves and security anti-drill pins;**
- **From what materials are the suspect bypass tools constructed;**
- **Can a positive match be made between bypass tool materials and metals found within the lock;**
- **Can a lock manufacturer and specific lock be identified from the materials transferred to bypass tools;**
- **Can foreign materials found within a lock be identified as to content and source.**

It may also be possible to match striations or irregularities in the tip of the pick tool on surfaces of impressioning tools or blanks, with corresponding marks on interior areas of the lock. There can be a great deal of pressure exerted on internal components during the impressioning process that may be transferred to the keyway or other areas of the plug. If available, they should be examined closely. Marks may be left on pins and chamber walls that can be matched under a scanning electron microscope or other high- magnification technique. Metal may also be transferred to tips of picks.

26_2.4 Use of Scanning Electron Microscope

LSS101: Scanning electron microscope Part I: Michael Platek

LSS101: Scanning electron microscope Part II: Michael Platek

LSS101: Scanning electron microscope Part III: Michael Platek

A scanning electron microscope (SEM) utilizes electron beams, rather than light and lenses to magnify objects. The author has utilized a Jeol 5900 for testing of locks and picking tools. This is one of the more sophisticated systems that is available, and allows the magnification of images up to 1000x. These systems also allow for the targeting and analysis of materials with respect to elemental content. As can be seen in the accompanying video, specific metal composition can be easily displayed.

Figure LSS+2616 A Jeol 5900 SEM system and a specimen container for placing a small amount of material in the chamber to be analyzed. This system is in operation at the University of Rhode Island Forensic Laboratory.

An SEM is especially useful in cases where non-destructive testing of materials is required. A sample can be analyzed without destroying the material, as is the case with other forms of testing. In addition, as can be seen in the photographs below, there are no depth of field issues as encountered with traditional microscopy. All areas are in focus, because light is not utilized as the source of illumination. Although a conventional microscope with a 10x-40x zoom will suffice for most forensic analysis of locks, the SEM can offer options not otherwise available in cases where an analysis of metal content is required, or extremely high resolution tool marks is needed.

An SEM may be employed in certain instances to make the following determinations:

- ***Identification of pick marks on pins, keyway, or chamber walls;***
- ***Identification of impressions or distortions on pins, wards, and keyway;***
- ***Identification of tool marks on keyway wards or plug walls, produced from blanks used during impressioning;***
- ***Presence and identification of dissimilar metals***

within the plug in order to prove entry of a specific key or bypass device. Such metals may include brass, nickel silver, steel, iron, aluminum, or alloys such as Avional, lead, and zamak. It should be noted that manufacturers will cease to use lead in the future due to environmental concerns. Thus, the presence of lead in a cylinder may provide additional identification criteria for certain keys;

- **Presence of metals used within a plug, shell, pin, or chamber sleeve upon a bypass tool or key in order to prove entrance by such tool or key;**
- **Tool marks on surface of pins, plug, or keyway that are produced from a specific bypass tool such as a pick;**
- **Introduction of a specific key into a lock, evidenced by tool marks produced on bottom pins.**

Additional sources of evidence of surreptitious entry may be developed and will depend upon many variables. These include lock design, metal content of components, keyway, methods of bypass, construction of tools, what metals are present in the tools, the physical shape of a tool, and the competence of the perpetrator.

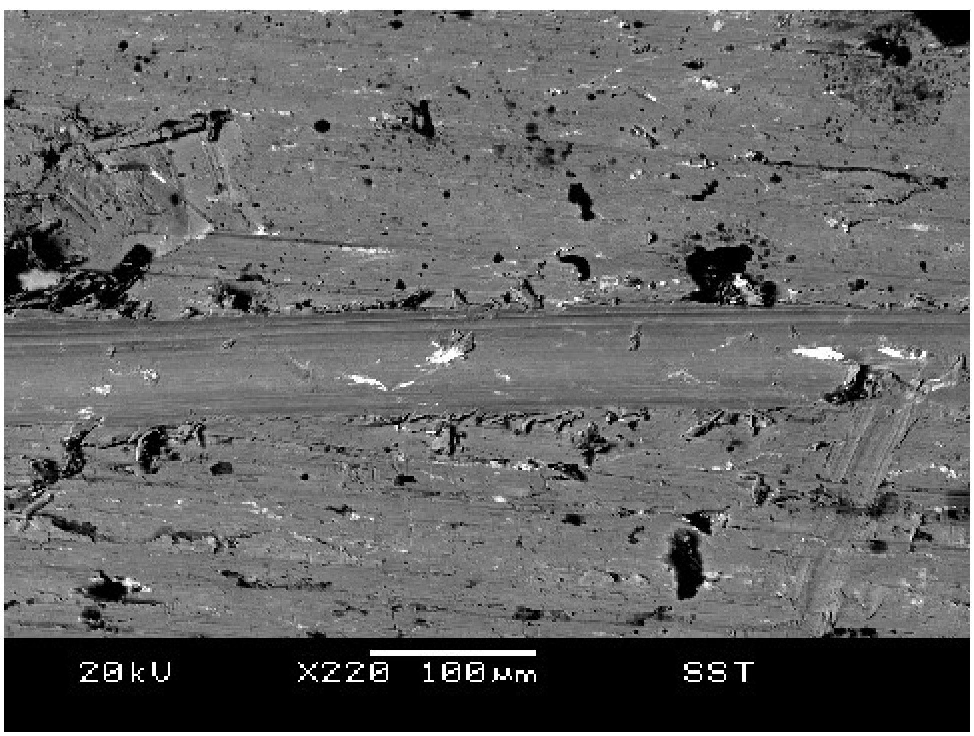

Figure LSS+2617 220X SEM photograph of lock, using backscatter, showing pick

track.

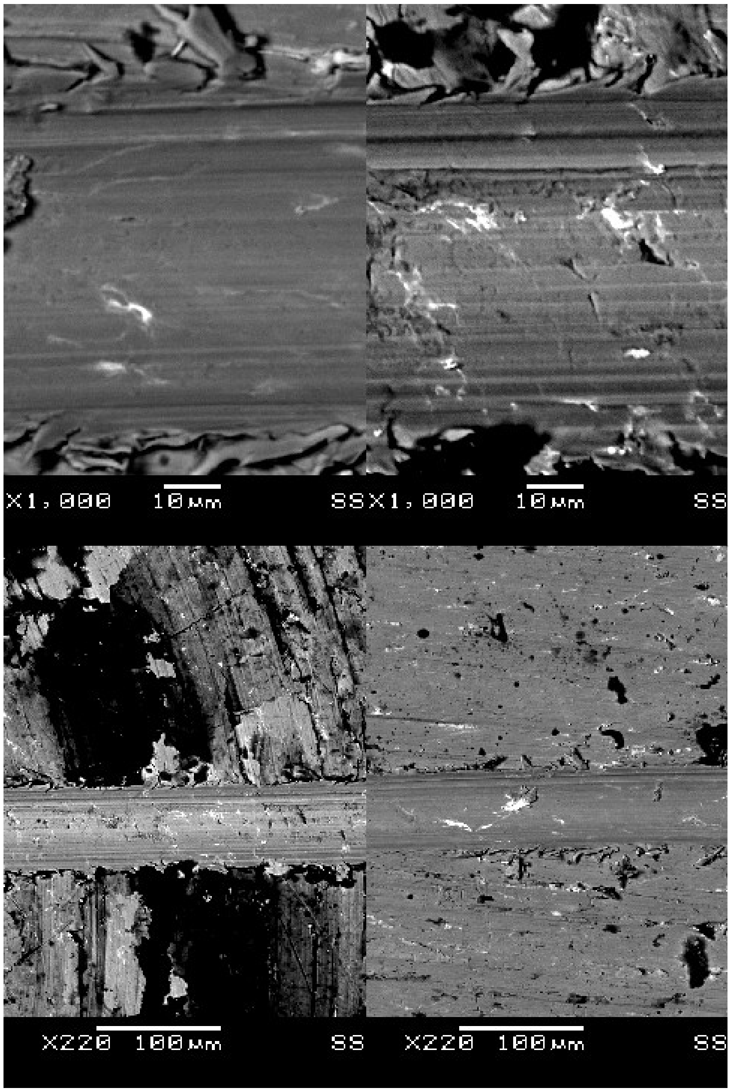

Figure LSS+2618 Composite photograph at 1000x (left) and 220x (right) of pick tracks on known sample and suspect lock. These marks were made by the same tool.

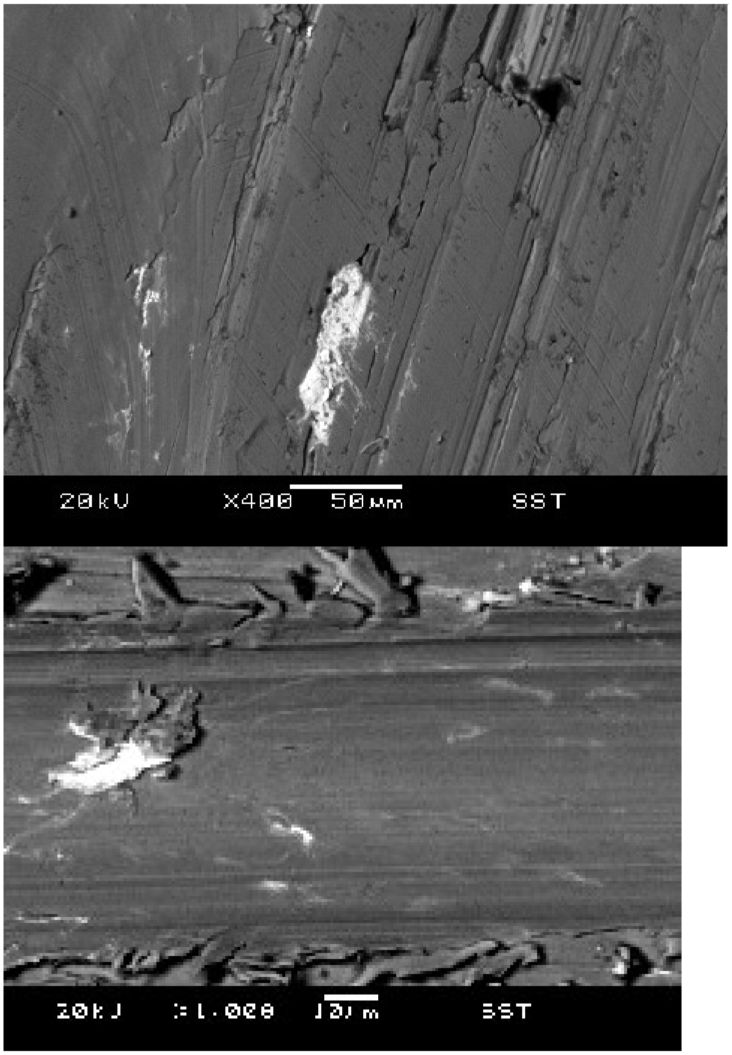

Figure LSS+2619 Photograph of internal surface at 400x and the same material at 1000x showing pick track.

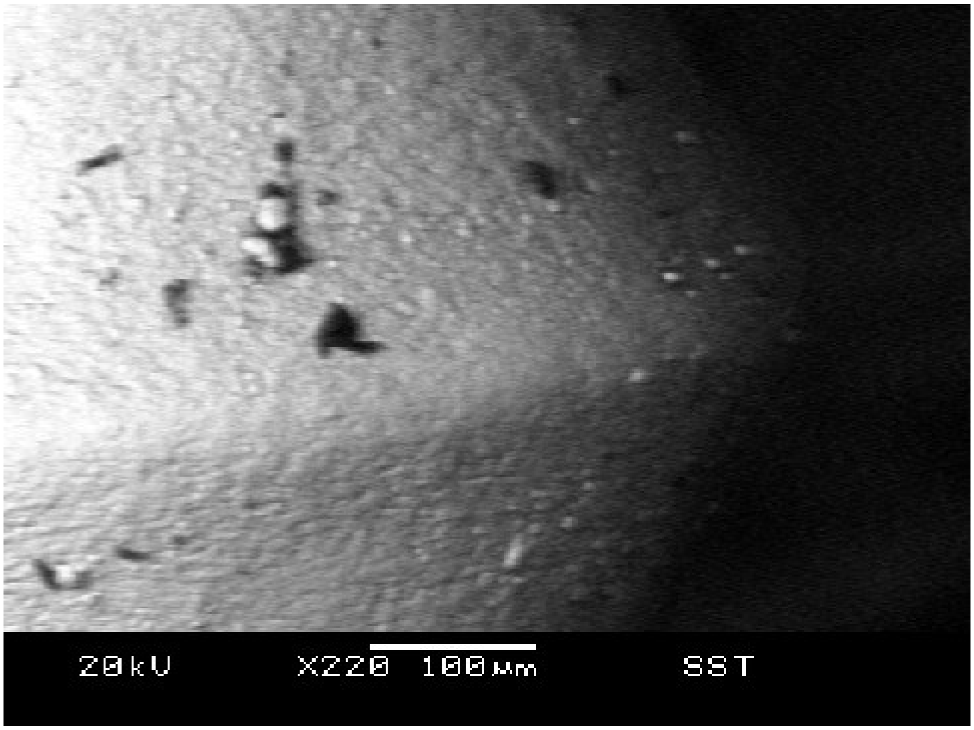

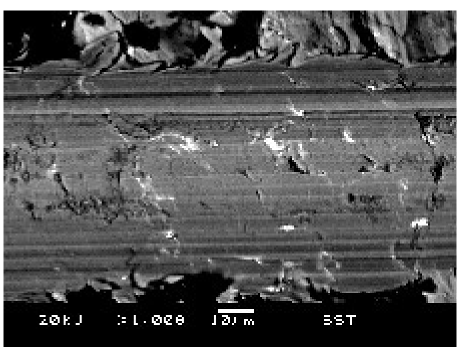

Figure LSS+2620 Photograph of the surface of the pick that produced the marks in all of the photographs, taken at 220x using backscatter. Note the curved surface. This pick was produced by acid etching of stainless steel.

Figure LSS+22 Photograph of plug with pick marks and comparison with known sample made from the same pick.

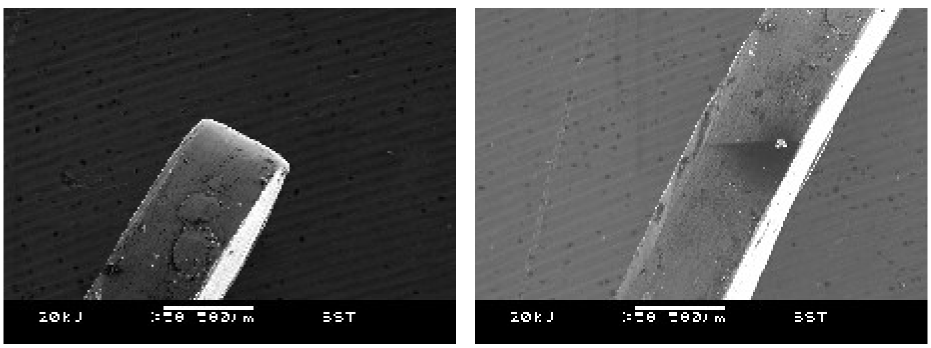

Figure LSS+2623 Photographs showing the surface of a pick at 50x using backscatter (left) and secondary illumination (right).

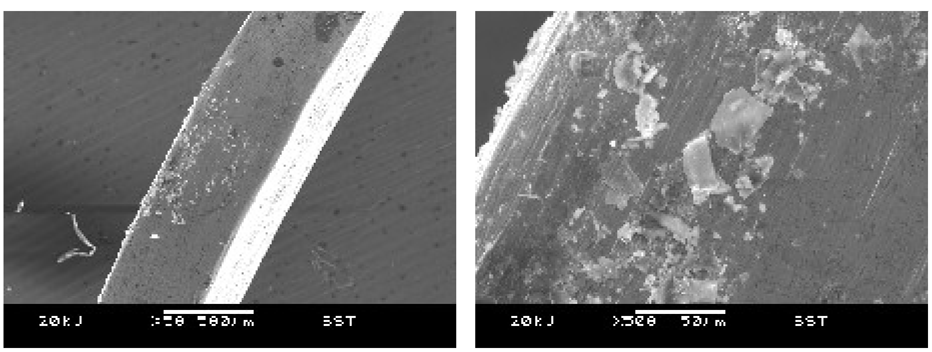

Figure LSS+2624 Photographs of pick at 50x (left) and 500x (right).

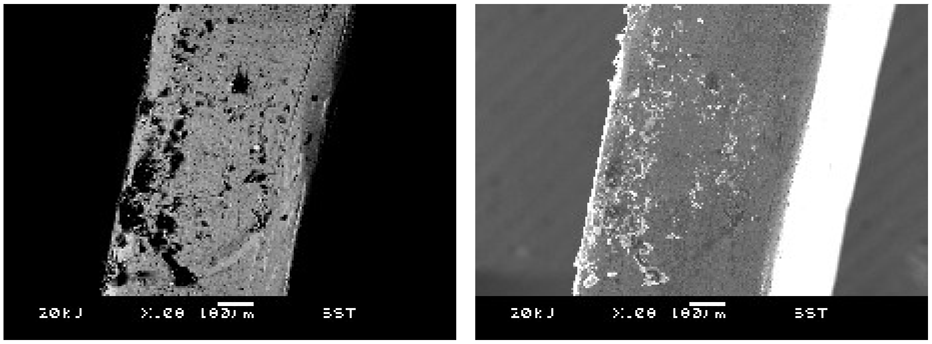

Figure LSS+2625 Photographs of surface of pick at 100x utilizing backscatter (left) and secondary (right) illumination.

26_2.4.1 SEM Issues Regarding Analysis of Pick Marks

There are a number of issues that will affect and control the ability to use a scanning electron microscope effectively, regarding the analysis of pick marks within a lock. These include:

- **Size and shape of the pick;**
- **Materials that the pick us made of;**
- **Materials that the plug are made of;**
- **Process used to produce pick: acid etch, stamping, grinding;**
- **Shape of pick and whether it is flat or rounded;**
- **Contact surface of the pick: curved, rake, ball, and how much contact with tumblers;**
- **How the pick us utilized: rake, individual pins, and possible obliteration of marks;**
- **Is it likely that the pick would rotate the tumblers;**
- **Skill of technician utilizing the pick;**
- **Amount of tension applied to the plug;**
- **Amount of upward pressure applied to the pick;**
- **Any aberrations on the pick surface;**
- **Any special coatings on metal within the plug or on the pins;**
- **Differing pattern of tumblers within the lock, which will control torque and necessity to apply pressure to each pin;**
- **How many times the pick contacted other surfaces;**
- **Skill of the technician in moving the pick vertically and horizontally across the pin surface;**

- **Special coating materials on the surface of the pick, such as teflon to diminish marking by bypass tools;**
- **Differs would affect number of passes required for picking;**
- **Use of mushroom or security tumblers;**
- **Use of master pins;**
- **Number of pins in the lock;**
- **Angle of attack of the picking tool, and whether that varies as the lock is picked;**
- **Whether the pick is utilized at 90 degrees or other angle, or the side of the pick makes contact with the pins;**
- **Geography of contact surface: flat, curved;**
- **Relative hardness of pick as opposed to pins or plug;**
- **Sharpness of point of contact of the pick;**
- **Prior lock picking attempts;**
- **Age of pins and wear patterns;**
- **Multiple techniques utilized on the same pins: raking, picking, snap gun;**
- **Have marks of different technique obliterated other markings;**

26_2.4.2 Issues Regarding Metal Transfer

There are several critical issues that will affect whether metal particles will transfer between the target lock and suspect pick tool. The issue becomes one of matching the specific characteristics of metal from an individual plugs and whether this can be isolated to one sample, or is generic to a type of brass form which most locks are constructed. Significant testing is required to determine if differentiation between locks could occur.

Although the likelihood of metal transfer is high between the lock and tool, the problem becomes whether the metal will remain on the pick surface long enough to be present for analysis. This is affected by the type of metal from which the tool is constructed, how it was stored, the amount and type of contact between the tool and internal components, and the geometry of the tool surface. Normally, one would expect fragments to be deposited on the pick. This is especially true in the case of a vibrating pick. Also, there may be metal fragments outside of the lock that can be matched to the pick tool.

Additional issues include:

- **Size of pick and type of contact surface: curved, rake, ball, diamond;**
- **Metal and polish;**
- **Relative hardness of the two metals;**
- **Whether metal fragments were deposited on the face of the pick;**
- **Whether there is any oil or grease which would retain fragments**
- **Pressure applied on the pick during bypass attempt;**
- **Angle of attack, digging out material from the plug;**
- **Would it be expected that material from the pick would be deposited on the plug;**
- **How the tool is stored;**
- **How the tool was carried;**
- **Was the tool wiped clean, either intentionally, or based upon how it was stored or carried;**
- **Is there a nickel or other coating or plating on the plug or the lock;**
- **Is there the possibility of plating deposits being left on the tool that transferred from the lock;**
- **Is there a potential of paint or dye transfer from pins to the surface of the pick;**
- **Is there lead or other foreign substances deposited on the pick from the lock, based upon irregularities in the manufacturing process;**

27_1.0 Introduction

Keys can provide extremely valuable and complex information about suspects, perpetrators, victims, connected locations, how they were cut, and the locks they fit. The criminalist or investigator may be called upon to conduct a forensic analysis of locks and keys for many reasons. These are classified according to primary information that can be developed and are discussed in detail throughout the chapter. The following checklist provides an outline of issues.

Keys and how they were Cut

- **Determine if keys have been recently cut;**
- **Determine if a key was cut by hand or machine;**
- **Determine if a key is a factory original or duplicate;**
- **Determine if a key has been copied;**
- **Evidence that a specific key machine produced a given key;**
- **Evidence that a generic type of key machine produced a given key.**

Keys and Tool Marks

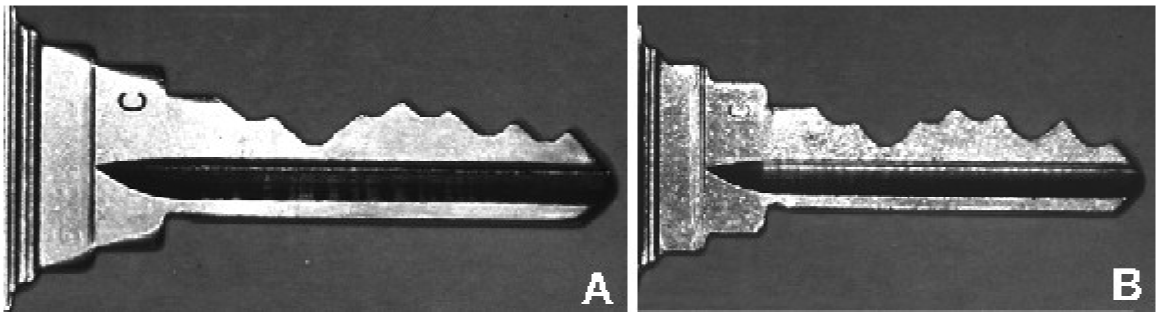
- **Determine if a specific key could have been used, based upon tool marks within a lock;**
- **Determine if a duplicate key was used to enter a**

lock;

- Determine if a key opened a specific lock;
- Determine if a key was used to impression a lock;
- Identify metal transfer between key and lock;
- Identification of stamped letters, numbers, or logos on face of key;
- Identification of key used as abrasive on other materials;
- Identification of key as causing marks on other materials.

Identification of Locks, Keys, Suspects, Victims, Locations, Vehicles, and Property

- Identification of victims from keys;
- Identification of co-conspirators from keys in their possession or from common locks that they fit;
- Identification of possible suspects for a certain crime from keys in their possession;
- Location and identification of contraband, stolen property, evidence, or fruits of a crime;
- Tracing keys to specific locks;
- Matching suspects and keys with specific locations;
- Matching a key to a lock;
- Identification of illegally possessed keys;
- Identification of vehicles;
- Tracing and identification of locks;
- Identification and recognition of disguised keys;
- Identification of universal keys;
- Identification of foreign material on key to a lock;
- Trace unique, old, or rare blanks to vendor;
- Identification of metals transferred between suspect key and key ring or other materials with which the key came into contact;
- Identification of fingerprints, oil, blood, tobacco, paper, cardboard, paint, dirt, lint, fiber, hair, metal filings, salt, airborne particulate or other foreign substance on key surfaces with which the key or its bearer may have come into contact.



27_2.0 Keys and How They were Cut

In certain investigations, it may be important to know how keys were cut and to identify the cutting machine that produced the suspect key. Certain preliminary questions arise which follow:

27_2.1 Preliminary Questions

- **Is the key hand cut, machine cut, or stamped code cut;**
- **Is the key a duplicate or factory original;**
- **Are there sharp cuts on the key;**
- **Does it appear as if the bitting surface of the key would cause marking on lower pins;**
- **What are the ramp angles for each cut. Do they appear to follow industry guidelines as detailed elsewhere in this text;**
- **Are there steep cuts with sharp peaks, indicating that the key may have been cut by hand;**
- **Is each cut centered in the proper position directly under each tumbler. If not, hand cutting may be indicated. The key may also have been cut by hand during the impressioning process. Often, keys produced by impression will be irregular with respect to the center-to-center spacing between cuts and the width of each cut. Generally, a round file is used, often resulting in adjacent cut overlap;**
- **Was a factory original, original duplicate, or improperly obtained or produced duplicate used to open the lock;**
- **Are there scratches, shiny spots, or sharp edges on the key. This will generally indicate a recent duplicate;**
- **From what metal was the key produced;**
- **Is the key produced on a knockoff or original blank. Although a factory- original logo may appear on the key head, this may not be dispositive that the blank actually was manufactured by the vendor owning the logo. The author has seen many cases of counterfeit blanks that copied trademarked logos as part of the design;**

- **Is there any evidence as to the type of cutting wheel that was used to cut the key;**
- **Is there any data available as to what the factory used to cut original keys at the time the lock was shipped;**
- **Does it appear that the key was cut by code, or simply duplicated from another key.**

27_2.2 Manufacturing Process

It is useful to understand how key blanks are initially produced, cut, and identified by a typical manufacturer. The subject is also examined in **Chapter 8**. Keys and most domestic cylinders are usually made of #58 brass with up to a 99% content. Nickel silver, aluminum, Avional, and steel are also used. Brass is probably the most popular metal for wafer and pin tumbler locks because it is inexpensive and self-lubricating for longer life. Plastic polymers and other composite materials will become more prevalent in the future.

Nickel silver is favored for the more expensive locks in order to achieve high tolerance and security. The advantage is strength and hardness. Because it is a dissimilar metal to brass, it will experience less wear when used in conjunction with a brass plug. Some manufacturers use aluminum or an alloy of aluminum such as Avional (Silca). Avional is stronger and lighter than brass. Iron or soft steel that is cold-pressed and forged is also popular. Zamak, for poor quality locks such as mailboxes, is also used.

In the manufacturing process, keys are cut or stamped from strips of material with dies. They are then plated. In the future, the author believes that keys will be produced on small milling machines controlled by computers. Maintaining an inventory of thousands of blanks for each keyway and lock will be outdated.

Locksmiths will simply insert a piece of special composite material into the mill, enter the keyway design or optically scan a keyway, and the computer-controlled mill will produce the proper blank.

Factory cutters produce striations on OEM keys that are different than those on keys cut at the local hardware store. Cutting wheels are either single or dual sided. Angled cutters are also used for certain locks such as Medeco. End-mills and special drills are also utilized to cut certain keys, such as laser track.

An analysis of tool marks may identify:

- **How keys were cut;**
- **That a specific key machine cut a suspect key;**
- **That a key was cut by hand, by code punch, by manually operated key machine, or by an automated key-cutting system;**
- **That a certain key was inserted into a specific lock.**

Striations left by a cutter may remain for a very long time, depending upon the above- noted factors. See the discussion below for methods of identification. Striations may differ on the bitting surface of a key depending upon the following factors:

- **Whether the key is single or double-bitted;**
- **Number of active rows of tumblers;**
- **Position of the bitting on the key;**
- **Relative smoothness of the pins;**
- **Force exerted by the springs;**
- **Frequency of use of the key.**

27_3.1 Identification of Locks, Keys, Suspects, Victims, Locations, Vehicles, and Property

Keys, and the information they may provide, can be used in the identification of locks, suspects, victims, locations, vehicles, and property. Often, keys may be found on victims or suspects, at crime scenes, in vehicles, during the course of a search, or

in relation to other apparently non-connected cases. In each of these scenarios, a key may provide valuable leads. Sometimes, it is important to trace a specific lock from a recovered key. It may be necessary to know what type of lock the key fits, if it is a unique lock, and if the factory can provide any detailed information about its owner.

Perhaps a key is found on a suspect that might fit a storage locker. Information derived from that key may help identify a particular installation, which in turn will lead to its location. Keys for locks used in special industry applications should be viewed as suspicious when found on suspects or at crime scenes. Although these locks are prevalent in many industries, their keys are still relatively rare. Keys for the following applications should cause additional inquiry:

- **Banking;**
- **High-security safe and vault change-keys or long profile key;**
- **High-security lever lock keys;**
- **Mail and postal;**
- **Safe-deposit;**
- **Public locker;•High-security padlock (Chubb, Abus, Abloy);**
- **Vending (Ace, tubular, Tubar, axial keyways);**
- **Alarm control;**
- **Telephone;**
- **Secure key control and storage (real estate, automotive, and building lock boxes);**
- **Hotel dual-access or bypass (such as VingCard and Winfield);**
- **High-security (Medeco, Abloy, Assa, Evva, Schlage, DOM, Ikon, Mul-T-Lock, Sargent Keso).**

Many agencies maintain a criminal association and terrorist index to match keys to locks, suspects, location, and offense through the following criteria:

- **Lock manufacturer;**
- **Keyway type;**
- **Generic mechanism type;**
- **Code numbers;**

- **Keys that fit particular locks, especially those of victim;**
- **Evidence of replacement of lock;**
- **Broken key identification and match by:**
  - **Keyway;**
  - **Analysis of sections;**
  - **Code numbers;**
  - **Markings, logos, and other identifiers.**

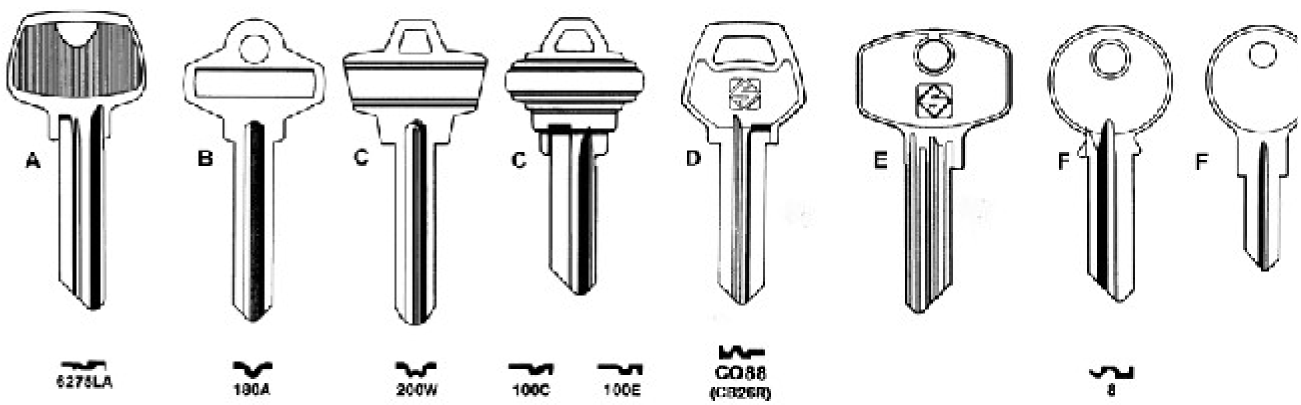
27_3.2 Queries Regarding Identification

The following lines of inquiry will assist in the match of a key to its lock:

27_3.2.1 Basic Key Design

- **What type of locking mechanism does the key fit: warded, wafer, lever, pin tumbler, hybrid, or axial;**

- **Is the key single, double, triple, or quad-bitted. Is a special technology employed, such as rotating tumbler (Medeco), sidebar, laser track, magnetic, infrared, induction, or transponder;**



- **Does the blank number identify a particular lock;**

- **Has the derivation of all stamped numbers on blanks been obtained, including blank identification, code numbers, and internal numbers.**

If it is a steel flat key for use in padlocks, letter boxes, lockers, cash boxes, cabinet locks, lever locks, or safe-deposit locks, they are quite easy to duplicate, leaving little evidence to trace their origin. Blanks not intended for the suspect lock can be modified to work by cutting to size. A flat piece of metal may suffice. The length must be correct, the thickness and height close to the original. Generally, a 6” warding file can be used to cut these keys. An analysis of metal filings embedded in files or cutting wheels, if seized as the cutting instrument, may be helpful.

27_3.2.2 Lock Manufacturer

- **Who manufactured the lock. Does a specific manufacturer popular in the geographic area produce locks. Are the locks available. If so, from whom. Have many manufacturers produced locks of the same keyway. Does the key head provide any information, such as the lock manufacturer and keyway identification.**

In the above illustration (Figure 6-10), the key heads of different manufacturers are shown.

27_3.2.3 Key Blank Manufacturer

Certain vendors may carry OEM blanks for lock manufacturers. Thus, Silca produces original blanks for Medeco and many other lock producers. The blank manufacturer may point to the local vendor.

- **Who manufactured the blank. Generally, a manufacturer will stamp an identifying number on each blank, as well as offering a distinctive key head or logo;**

- **How many tumblers are in the lock for which the key fits. Is the lock turned to the left or right to open. Wear may increase in one direction;**

- **Was the key recently duplicated, determined from the wear on the serrations caused by the cutting**

wheel of the key machine.

This information may be derived based upon measurement of the suspect key against a factory original. This analysis may be difficult, but is possible.

Keys can also be evaluated to determine if they are cut following factory-established depth coding and spacing. This can serve to identify the key to a given manufacturer by looking up the difference between depths and consulting an HPC or Silca reference table. This information will also indicate if the key was code cut by machine originally, or by hand, and if the lock was pinned to factory standards. Perhaps a locksmith altered the pin-stack during rekeying. The ramp and valley angles for each cut can also be evaluated. This will provide strong indication of hand cutting, and may lead to the conclusion that the key was produced by taking the lock apart and cutting individually for each pin position.

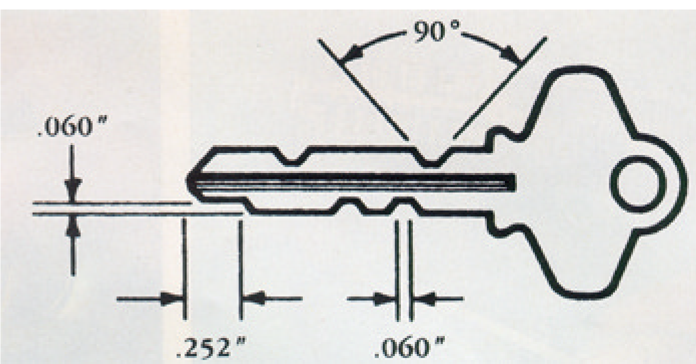
Certain keys, especially for storage lockers, are very distinctive. American Locker, for example, has utilized a standard lock for at least forty years that is a hybrid conventional pin tumbler and axial mechanism. Guardian, Illinois, Chicago, and DuoLock are likewise very easy to identify.

27_3.2.4 Mechanism

- **What kind of lock does the key fit in terms of generic mechanism: warded, wafer, lever, or pin tumbler. How would the lock most likely be used: door, drawer, file cabinet, access control, padlock;**
- **Could the lock be an interchangeable type, such as Best removable core;**
- **Does the lock utilize a unique mechanism or principle of operation, such as a sidebar, rotating disc, dimple, or programmable function;**
- **Is the keyway special or unique.**

27_3.2.5 Keyway

- **How common is the keyway. When was it introduced, and by whom. Are there knockoff keyways. How old**



might the lock be;

- What is the potential number of keys that might be in existence, based upon the age and popularity of the lock, the number of pins, and total available depths (differs);

- Is a special keyway utilized. Is it restricted. What is the availability of blanks and key cutters for the keyway. Can any locksmith, hardware store, or vendor reproduce keys. If a restricted keyway, is it registered to a specific user, locksmith, or geographic area. If a special cutter, die, or procedure is required, who has that capability in a given area. This is especially relevant in the case of dimple, laser track, and sidebar keys that require special cutters;

Perhaps a key can be traced back to a specific locksmith in an area who sells very old series of locks. For example, the Schlage series 922 is fifty years old, but there are still millions in service. This is a very distinctive key, but not all locksmiths support the lock.

Bypass of a Schlage 922 series wafer lock. Courtesy of Don Shiles.

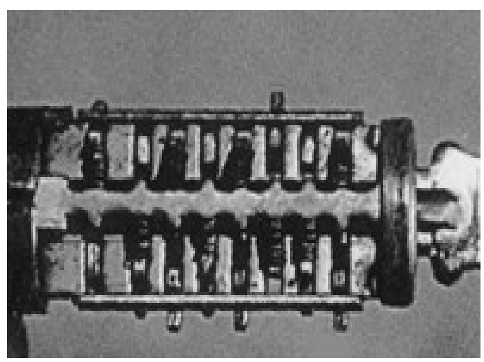


Figure LSS+2701 A Schlage 922 key is distinguished by its pattern of "cuts" and "no cuts." The lock utilizes a series of wafers of three different configurations.

Many shops will be able to identify locations where certain locks are used. They may also provide leads as to who may still stock such blanks. Certain locks are primarily used in business applications, such as Medeco, ASSA, Schlage Primus, and Sargent

Keso. Restricted use may provide a lead as to who services such locks.

27_3.2.6 Stamping on Key Head

- **Are there any letters, numbers, or warnings on the key head, such as "do not duplicate." If so, a check of locksmiths may identify where the key was cut.**

27_3.2.7 Key Code

- **Are numbers stamped on the key. If not, once the manufacturer and keyway is determined, an HPC or SILCA reference can be consulted to derive the direct coding for a particular key. That code can be given to the manufacturer, who may be able to determine who purchased the lock.**

Equally important, the direct code for any given lock can be determined and matched to a suspect key. If a burglary occurred at a given location and the keys to a specific lock were taken or cannot be located, then the lock can be disassembled and a key produced and entered into a database by code number.

If the lock utilizes a restricted keyway and the key still has factory-original coding, a manufacturer may be able to determine who the lock was sold to, in what system it is used, and other valuable information. This also applies to safes that are furnished with factory set codes. The following example is illustrative.

In one homicide investigation in which the author was involved, a wall safe was found at the victim's residence. The make and model was determined, and the factory was consulted. The preset combination was obtained that opened the lock. Use of factory-default numbers indicated that the safe had been recently replaced. The factory was able to advise that that model safe had been shipped to the victim's address. It was determined that the perpetrators had killed their victim, then burglarized the original safe, removed it, and replaced it with a new one, not bothering to change the factory combination.

27_3.3 Copy or Original

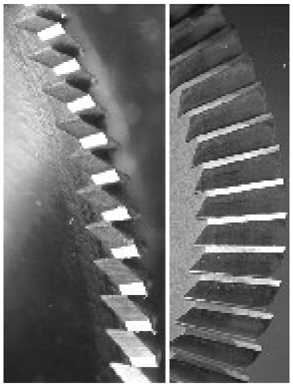
It may become relevant to determine if a key is a factory original or a copy. In certain instances, it may be equally important to learn if an original key has been copied. In one case, the author examined evidence involving the theft of Mercedes automobiles from rental car agencies. It was important to learn if the car rental keys had been copied in order to facilitate the thefts.

Investigations may require a determination of whether a key has been copied. Courtesy of Hans Mejlshede.

In that case, the original keys were examined for tool marks on the laser track surfaces for evidence of an automated key machine stylus moving across copied areas.

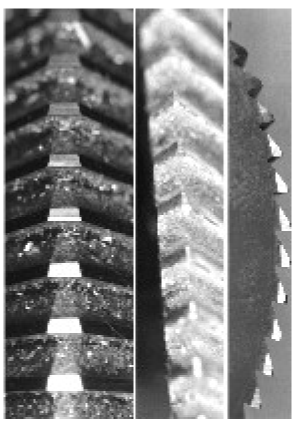
Key-cutting machines, as discussed in **Chapter 8**, will have certain unique characteristics. Each will have slightly different tolerances and tolerance errors in the duplication process. These errors may help identify a specific key machine as having produced a suspect key. Initial criteria to consider in making a determination if a key is a factory original or duplicate include:

- **Was the key produced on a factory-original blank;**
- **Is there easy availability of original key blanks used to produce a duplicate;**
- **Are original keys routinely supplied by the manufacturer, or are the locks keyed in the field;**
- **Does the manufacturer plate factory-original keys. If so, does the plating occur before or after the key is cut. If any remnants of plating are found on the bitting, the key is a factory original. Check the back slope of the bitting surface for such indication, especially on the cut closest to the bow;**
- **What characteristics of surface texture are present in the bitting surface. Of particular interest to the examiner will be the roughness or primary texture of this area. Texture is defined as the number of peaks per unit length and their average height. The examiner will see this as perpendicular striae running along the longitudinal axis of the bitting. Production processes, defined below, will**



be closely related to the degree of roughness and visible striae.

Relevant production processes affecting key cutter characteristics and bitting striae will include:



- **Machining operations;**
- **Production rate and quantity;**
- **Quality control;**
- **Cooling and lubricating during cutting;**
- **Movement of the key in relation to the cutting tool;**
- **Method of clamping the key;**
- **Positive or negative vertical cutting error;**
- **Skewed copying;**
- **Error in clamping angle;**
- **Broken or missing teeth in cutting wheel;**
- **Number of teeth in the mill cutter or cutting wheel per centimeter;**
- **Diameter of the cutting wheel;**
- **Alignment of guide;**
- **Speed of travel of the key;**
- **RPM of the driving motor for the cutting wheel;**
- **New or old cutting wheel and sharpness of cuts;**
- **Loose or unstable cutting wheel.**

27_3.3.1 Examination of Striae to Determine if Original or Duplicate

Examination of bitting surface will focus on the striae left by the cutting mill. Such striae will be directly related to the diameter of the wheel and teeth per centimeter. Assuming constant cutting speed and feed rate, a large diameter will result in higher cutting speed, and a greater number of “peaks” produced for a given area, or a finer resolution between cuts (less peak center-to-center distance).

The more teeth on the wheel, the less material will be removed by each during the cutting process. This will result in shorter amplitude for each peak. The result: there will be a finer cut pattern in the factory original key. If the examiner has a known factory original key to compare with the questioned duplicate, the determination can be made easily.

If a suspect key machine is examined, it is important to determine tolerances maintained during the cutting process. Silca, a leader in key machine manufacture, will maintain a minimum tolerance of .0075-.003”. A .02 mm variance per copy is acceptable. Silca will adhere to a tolerance of .001-.003” in producing blanks. Silca key machines can run ten generations before keys will fail to operate a lock.

Wear statistics for a given key and lock is very difficult to determine for many reasons. Wear will depend upon:

- **Metal used to produce the key;**
- **Material used in the plug;**
- **If the metals used in the key and plug are the same;**
- **Precision with which the blank was manufactured;**
- **How well the key fits in the lock;**
- **Whether there are foreign materials in the plug;**
- **If the lock is regularly lubricated;**
- **If the pin-stack opens precisely at shear line;**
- **How much torque is required to turn the key;**
- **The individual habits of the users of keys;**
- **Spring bias on each tumbler.**

Critical information to determine in such evaluations will include the following:

- **Does the key (or copy) appear to be handmade or machine cut. Good indication that the original was code cut, or produced by machine, is the accuracy of the depth of each cut corresponding to manufacturers specifications, the centering of cuts, and their shape. Indications that a key was cut by hand include irregular angles, too steep angles, multiple angles (such as two vertical ramps of differing angles), and differing widths of cuts. A hand cut key may be difficult to insert, remove, or operate in a lock, because ramp angles are too sharp.**

- **Are there stylus marks running laterally across the surface of the key, essentially in a straight line. Such markings will be present when automatic feed machines are utilized. A tracing stylus may be required when cutting high-security keys;**

- **Examine the key to determine how it was cut. By**

doing so, it may also be possible to extrapolate wear patterns on the bottom set of tumblers and whether a suspect key might have created them. This may be especially relevant where keys have jagged or sharp edges that may mark bottom tumblers;

- **Can an assessment be made as to whether the key has been recently duplicated and if the key is in fact an original, or a duplicate, or a duplicate original generated by code. Looking at two keys, it is always a question as to which was copied from which. This can be determined through precise measurements to determine subtle changes in ramp angles caused by errors in the accuracy of the tracing guide;**

Marks from key duplication. Courtesy of Don Shiles.

- **Are there clamp marks or distortions on the suspect key. Depending upon the location of such marks, this would indicate duplication rather than hand copying. An analysis of such marks may lead to a match between a key machine clamp, vice, or other securing device;**

- **Was the key burnished with a wire brush. This generally indicates machine cutting;**

- **Is the key an inexpensive knockoff, factory original blank, or blank produced by a licensed or high-quality vendor. Silca, for example, produces superior blanks, both as factory originals for certain lock makers, and as an individual blank alternate source for many locks throughout the world. Silca may, for example, produce slightly thinner blanks for certain locks, in order to insure a proper fit in the keyway. In contrast, cheap knockoff blanks, such as may be produced in Taiwan, China, and other Asian factories, will maintain poor tolerances, have profile errors, use more lead, and cause misalignment between blank and keyway. If a vendor does not maintain precise tolerances for its key blanks, then there may also be a greater possibility that the blank will score the sides of**

the plug when inserted, especially during impressioning. It is also more likely to break under the stress of normal use or impressioning.

- **Does the cutting machine use a single angled cutting wheel, or "V" angle;**

- **Do cuts appear to be made straight into the valleys of the key, thereby forming both sides and the ramp angles. This indicates factory code cutting;**

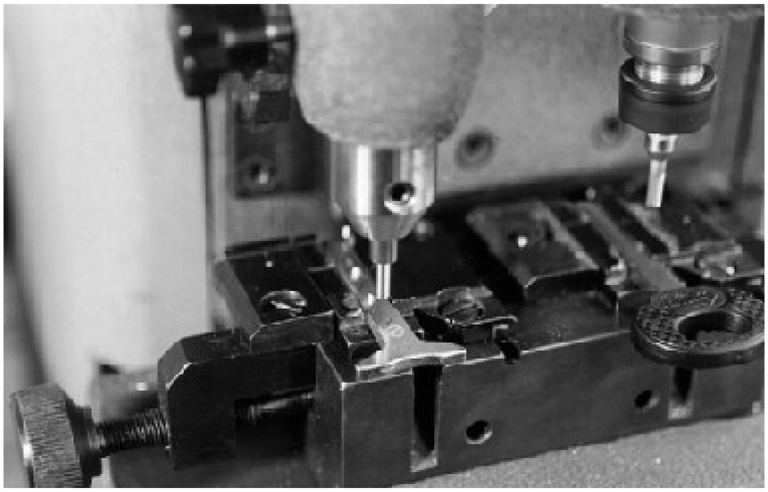
- **Has a key been simulated to meet depth and spacing requirements from metal, plastic, or other material. Remember, keys may be made to look quite different than the actual profile that fits a given lock. In the Falle variable key system, for example, keys are made from acid-etched stainless steel having only a few thousandths of an inch thickness. They may resemble the original key in depth and spacing only; there will be no keyway. These types of keys must be jiggled within the lock to work; they cannot simply be inserted as with a normal key. Remember that peaks, valleys, and ramp angles may all be altered, so that the key appears differently. If this is suspected, correct depth and spacing can be determined for a specific lock and the key evaluated against this criteria.**

- **What material was used to produce the blank: brass, steel, nickel silver, aluminum, or an aluminum alloy. Some manufacturers, such as Silca, have developed their own special metal alloys. If these can be identified, then so can the manufacturer;**

- **Does it appear that there is a tracing error on the suspect key. If there is a misalignment on the key machine between the tracing guide and the cutting wheel, then all cuts will be off by a certain dimension. It may be possible to determine if such an error has occurred and match such error with a suspect machine;**

- **Was there an alignment error in the way the original key was secured in the key machine that would either create an upward or downward angle in the copy. If the source key is clamped in the guide track improperly or there is an alignment error in the machine, then cuts will be stair-stepped, either up or down on the duplicate. This would result in a poorly fitting key;**

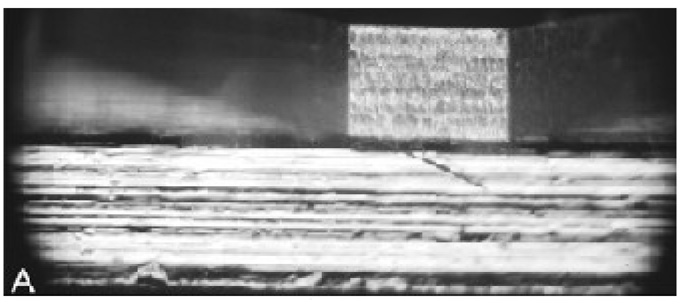
- **Is it possible to determine how many generations of keys have preceded the suspect key from the factory original. Are ramp angles or peaks wider, more rounded, less distinct, or disfigured. This would indicate several generations. Some key blank manufacturers have sophisticated equipment to read keys, regardless of generation, and produce a first-generation original. Silca, for example, has equipment that will laser-read a key, then correct any errors when generating a new one. These services would be available, if necessary from Silca.**



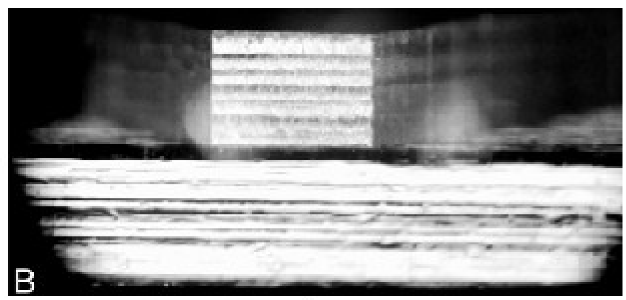
- **What is the surface appearance and texture of cuts. Depending upon whether an automatic or manual cutter was used, the surface at each cut may appear even or uneven. If a manually operated key machine made a duplicate, there is more likelihood of unevenness in cutting pattern on the bitting. This requires a comparison of the entire bitting surface, evaluating each tumbler position against all others.**

- **Can it be determined when metal plating of the key occurred. Sometimes keys are cut and then plated by the original manufacturer. Blanks, of course, are plated prior to the bitting being cut;**

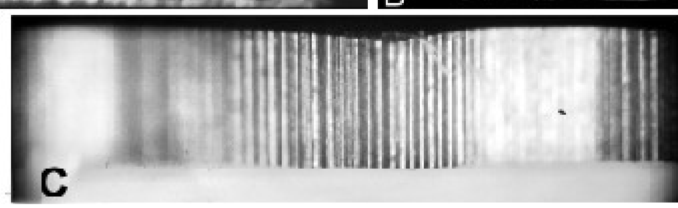
- **Did the operator of the key machine align the two blanks correctly prior to cutting;**

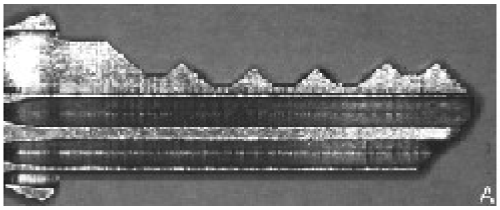


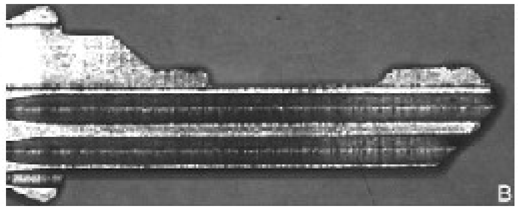
- **Do cuts appear smooth. If so, this would indicate a high RPM rotational speed of the cutting wheel and code cutting of the key. Silca, for example, cuts factory keys by code at 2200 RPM, in contrast with a**



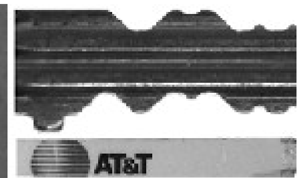
normal speed of around 800 RPM for conventional key machines used for cutting brass keys.







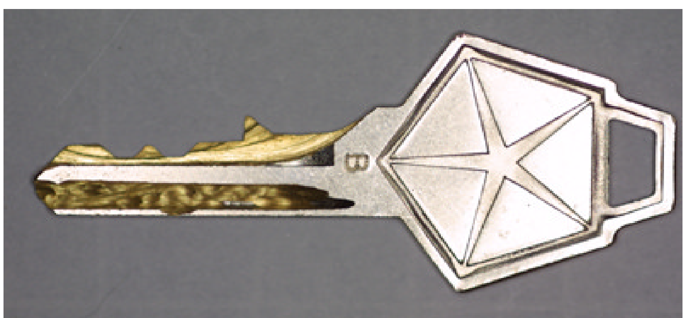
27_3.4 Keys: Substance over Form

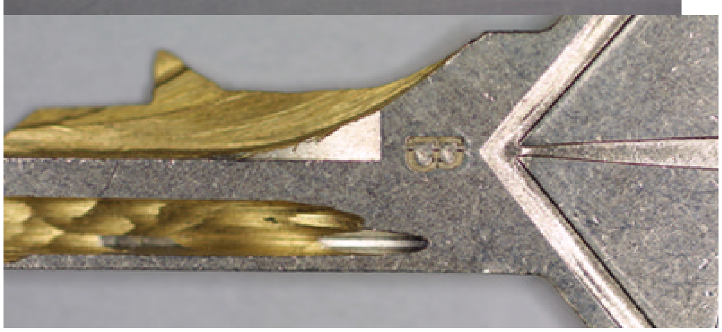


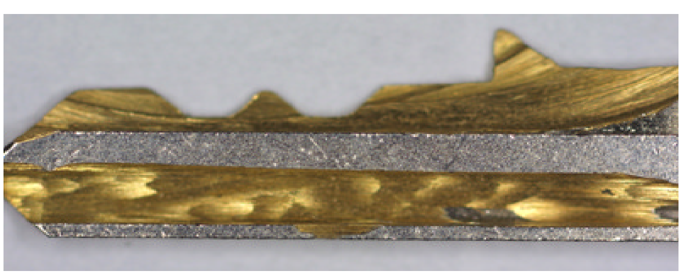
A working key is composed of four essential elements: keyway, bitting, depths, and spacing. **The correct simulation of these four elements will open a lock.** It is thus imperative that whenever keys are evaluated, substance must take precedence over form. That is, what the key looks like may not be as important as what the key does, functionally.

A key may not appear at all like the factory original. Keys can be made of any material, including metal, wax, metal foil, epoxy, thin stainless steel that has been specially cut or acid-etched,

wood, plastic, or clay.







Exploded view.

Keys may have no distinguishable valleys or ramps. The position of valleys may be changed, causing the tumblers to ride on ramps. Extra cuts may be interspersed on ramps, making the key appear more complex than it actually is. There may be more cuts than there are tumblers within the lock. Cut order may be altered: there may be six cuts on a key, but only the first or last five are active. The keyway milling may be altered or a different sectional keyway may have been used.

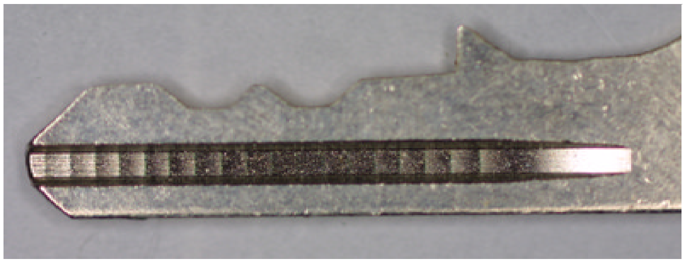


Figure LSS+2702 A Chrysler blank has been milled to fit a keyway on wafer locks that are used on hundreds of computers within a banking center. This altered key will open every computer in the system. Security officers were unaware of the problem.

27_4.0 Case Explanation from Beginning of Chapter 24

At the beginning of **Chapter 24**, seven relatively simple cases were presented. These demonstrate the diverse problems and evidence that may be encountered during the course of an investigation, where locks are an integral part of access. Other examples have been provided by experts in forensic locksmithing. Each of these scenarios will be briefly reviewed. They are not all-inclusive of course, but indicative of simple to complex indicia of bypass.

Case #1: Money is missing from an inner locked drawer that is contained within a safe during business hours. There are no signs of forced-entry. A day-lock keeps the combination lock from being opened.

There are two approaches: the lock on the dial may have been picked, if a standard wafer mechanism. However, often Medeco cam locks are utilized, making picking more difficult. A key may have been copied and used by the thief. However, often the simplest solution is to inquire where the key for the combination lock is kept. In many cases, it is left in a nearby desk. It is then a simple investigation to determine who had access. The other possibility is that the dial was rotated a few digits clear of the last number in the combination, never actually resetting the wheel pack. With the key for the day lock, the dial is simply turned back to the correct number and the safe can be opened.

Case #2: An apartment has been broken into. Property, including jewelry, is missing. A large insurance policy covers the loss.

There are tool marks on the face of the lock and within the keyway. Upon closer examination, it is noted that the marking of internal tumblers occurs on the first and second pin only. This is indicative of a fraudulent claim, where a screwdriver was inserted into the keyway and struck with a hammer to simulate picking.

Case #3: A lock shop has been burglarized in Paris, France. The insurance company believes that the burglary report by the owner is false, based upon the fact that the high-security locks could not be bypassed. In this matter, the Chief Forensic locksmith in France was consulted to buttress the premise that the locks could not be bypassed. He was able to demonstrate that in fact they could be picked. The claim was allowed. The owner was vindicated, notwithstanding that the manufacturer stated that their locks could not be bypassed.

Case #4: Property is missing from an office in a large complex. All employees who were thought to have had access to the area were polygraphed with negative results. A key system analysis was then conducted, pursuant to the material presented earlier in this chapter. It was determined that based upon the complexity of the master key system and the attendant cross-key combinations, that a key assigned to an employee in a different section would open the lock. He was confronted and subsequently confessed to the theft.

Case #5: Confidential information has been compromised from a computer. The keyboard is always locked at night or when not in use. An employee is suspected. Upon being polygraphed, the employee is cleared. It is verified that keys for other computers in the adjoining offices would not unlock this computer. The author was summoned to conduct the investigation. It was noted that the locks that blocked access to the keyboard were axial in design. Although it was obvious that they were a knockoff of the Chicago Ace, their security level was not immediately ascertainable.

Upon close examination, it was determined that in fact there were no tumblers in these locks. They were a simulation, made to **appear** as if they had pins. What they actually used were hard protruding pins that formed a crude keyway. The author demonstrated that with two paper clips the entire core of the lock could be depressed and rotated. A night janitor was identified as the culprit.

Case #6: Upon opening the store on Monday morning after a three-day holiday, there is money missing from the safe. There is no sign of forced-entry. The safe was located in view of the front window to discourage burglary attempts after closing.

The theft obviously occurred over the weekend; the manager is the prime suspect because he was the only individual having the combination. The lock is a Sargent & Greenleaf 6730, three number combination, with 1,000,000 permutations. After a long investigation it was determined that the lock was opened using an automatic dialer. The thief had learned the third number in the combination sequence. The TTI dialer will open one of these locks in less than an hour when one of three numbers if known. Although theoretically there are 1,000,000 permutations, in reality, there are only approximately 240,000 useable combinations.

Case #7: A theft of jewelry occurred in a hotel room safe at a very exclusive resort. There were no signs of forced-entry, either in the safe or door lock. The guest has been polygraphed, verifying the theft. Although these safes are not known for their physical security, they are utilized in rooms to protect valuables.

The particular safe had an electronic lock that utilized any commercial bank credit card to set the combination. The card was swiped through the magnetic stripe reader, and the account number on the card became the code to which the safe was locked. A magnetic card lock, utilizing barium ferrite spots, protected the door to the room.

It was determined that the burglars were quite sophisticated. The door lock was easily compromised through a decoding process of reading the location and polarity of the magnets. Once inside the room, the thieves had already determined that this particular type of safe utilized a security bypass scheme in case of lockout. They determined the combination for the bypass card, which would open any safe in the hotel. A duplicate card was created with a laptop computer and portable card encoder while the thieves were registered in the hotel.

27_4.1 Master Evidence Search Checklist

The following compilation summarizes covert methods of entry and trace evidence that may be encountered.

27_4.1.1 Methods of Entry

- **Picking of the lock;**
- **Decoding the lock;**
- **999 rapping of the lock.**

Presence and Transfer of Materials from other Locks

- **Impressioning (in general);**
- **Impressioning of dimple lock;**
- **Impressioning and molding of keys;**
- **Impressioning and decoding of locks;**
- **Recently duplicated key, by Machine or by hand, operated or inserted within the lock;**
- **Picking;**
- **Vandalism, interruption of entry attempt, sabotage.**

Additional Sources of Trace Evidence

- **Contact between bypass tools and lock components;**
- **Forced-entry techniques.**

27_4.1.2 Indicia of Entry

- **Lubricants and cleaners, including graphite, WD-40, oil, grease, cosmoline, gasoline;**

- **Carbon, metal foil, cellophane tape, electrical tape, wax, plasticine, type correct solution (White-Out), paper fragments, putty, Vaseline, soap, broken key or fragment thereof, broken key extractor, or parts;**

- **Wood fragments, clay, silicone, epoxy;**

- **Paint transfer on wards;**

- **Brass filings on bottom of pins; Brass fragments or particles, steel or stainless steel fragments or**

particles, gun-blue material transfer, metal particles at bottom of plug, dissimilar metal fragments present in plug;

Metal filings at the scene of a safe burglary. Courtesy of Don Shiles.

- **Toothpicks, glue, other foreign materials.**

PART B: General Introduction to Bypass

Silent Non-Destructive Entry

"To open one takes skill and knowledge, sensitive fingers, inventive ingenuity to contrive tools that will circumvent mathematics. This gives the locksmith the intoxicating feeling of using his skill to the utmost. When I confront a drillproof safe with dynamite triggers and the most exacting mechanism that has been contrived, I feel a shiver of expectancy down my spine, waiting for the moment when the bolts fly back and the door opens. Whatever may be inside--and the contents are often fabulous--it is never as stirring to the imagination as the moment when the lock gives."

In Unlocking Adventure, by Charles Courtney
CHARLES COURTNEY was a fellow countryman of A. C. Hobbs.

LSS303: Analysis of bypass techniques, by John Falle

LSS204: Brian Chan on the disassembly of a lock and derivation of the TMK

28_1.0 Introduction

This chapter surveys non-destructive covert methods to bypass locks, including picking, impressioning, decoding, and other forms of manipulation. The material in Chapters 28-31 has been organized according to bypass technique, rather than by specific type of locking mechanisms in order to minimize duplication of information. Certain materials in chapters 28-31 are restricted and only available in the Government edition for authorized law enforcement, government, and security services. This database provides detailed information of a sensitive nature. It includes instructions on the use of certain high-security bypass tools that have an extremely restricted availability, primarily to intelligence agencies. The Electronic Infobase provides complete patent information on picking, impressioning, and decoding tools described in this book.

The information contained in the following four chapters is directed to forensic investigators, intelligence and special operations units, locksmiths, and security specialists. The material will also be highly relevant for legal counsel that is charged with the responsibility of assessing the security of a lock and the liability for its failure. The data has been gathered over the past thirty years. It reflects not only the personal experience of the author but of the most skilled craftsmen and technicians worldwide. Some are in the business of covert entry, primarily involving government operations. Material has also been gleaned from thousands of patents reviewed by the author in the United States, England, Japan, Germany, Taiwan and other countries relating to bypass and manipulation tools and techniques. Many of these patents are referenced and contained in

the electronic edition.

Concerns regarding the printing of sensitive information in this book and other publications has always been seriously considered and evaluated by the author and others. That such knowledge may allow a person to bypass a lock and commit burglaries or other acts is outweighed by the need to know for those involved in the law enforcement, forensics, and intelligence communities. The dissemination of information regarding lock-picking, impressioning, and other bypass techniques is surely nothing new or unique. Books in the early nineteenth century provided detailed information on lock-picking and other forms of bypass. Notably, John Chubb (1850) and George Price (1856) wrote very revealing works.

What this book does is to provide the reader with the information needed to understand both traditional mechanisms as well as the most modern and sophisticated security technology incorporated into locks and how to bypass them. The text within the Government edition has a restricted distribution and is available to those with a need to know such information. To commit a burglary or otherwise use the information in this book to break the law can subject the reader to severe penalties. In a free society, liberty means choice. If the reader chooses to utilize the data herein for unlawful purposes, that is a personal choice that carries potential sanctions.

Locksmith supplies, videos, and extremely detailed manuals on every subject relating to locks may be purchased from a variety of sources. There is a great deal of information presently available regarding the bypass of locks, if one knows where to find it. This is especially true of patent offices worldwide. Lock picks and books do not make an expert in opening them. Practice, experience, and knowledge however, do. Even in England, where patents and the information they reveal are considered as state secrets, detailed data on the highest security locks may be found in Chancery Lane.

It is the author’s belief that publication of the information in this book will improve the security of products available now and in the future. Professional law enforcement and government agents, locksmiths, and security personnel should have the means to thoroughly evaluate a lock to assess its security. There is in fact very little information in this text about specific products and their bypass. Such information is included in the Government version where appropriate safeguards to distribution can be

imposed.

The modern locksmith is a skilled technician who understands the various technologies incorporated into today's locks. Unfortunately, there has often been an antagonism and protectiveness between the locksmith community and law enforcement regarding the release of information about bypass. Locksmithing is a full-time profession of experts. Lock-picking and covert entry is a specialization that does not make one qualified to fix locks. There should be no competition between the two disciplines.

The main purpose of this book is to tell the story of locks and how they are opened. They are utilized everywhere and in almost every culture. Their security is a constant concern because they protect every facet of society: its inhabitants, their property, and institutions. In the following chapters, we will learn how to circumvent that security.

28_2.0 Historical Perspective: The Development of Security Locks and Bypass Techniques

As has been noted elsewhere in this text, methods for bypassing locks are as old as the lock itself. The very nature of a lock invites its circumvention. It is the one single device that protects valuables from access by unauthorized persons. The art of lock-picking and those who have developed such techniques have always been the catalyst for the invention of countermeasures by the manufacturer. It should be no surprise that they have always outpaced such innovations.

Throughout modern history, lock-picking and safecracking contests have attracted world attention and competition between the pioneers in the business. During the eighteenth and nineteenth centuries, London and Wolverhampton were the centers for research, commerce, and industry involving locks and safes. Bramah, Chubb, Hobbs, and many others were the main participants in the quest for security and those that could defeat it. Their efforts, and of many of the other pioneers in this industry, contributed to the high level of technology available today.

Until fairly recently, making secure locks was quite a challenge. Prior to the convergence of many modern technologies such a metallurgy, high-tolerance manufacturing processes, electronics

and computers, this was especially difficult. Lock inventors had to start from nothing but a 4,000-year-old concept that originated in Egypt. The task was truly awesome. Bypassing each new mechanism was equally daunting for the lock picker. It has been a game of inventiveness, innovation, engineering, research, and wits. As will become evident in the next few chapters, that game will continue. Perhaps even at an accelerated pace.

Locks have been in existence prior to the time of written history. More than 4,000 years ago, a fresco discovered in an ancient temple pictured a lock. The Egyptians provided the basis for the modern pin tumbler, now the most popular security device in the world. Until the eighteenth century, locks offered little security and merely provided complicated inconveniences to burglars. As we shall see, until 1778 all locks could be bypassed.

Recent developments during the past quarter century have eclipsed all of the security enhancements occurring during the previous 4,000 years. The introduction of microprocessor technology and the inductive coupling of energy to make smart keys and locks have revolutionized the basic mechanical lock, and its ability to protect. There have been commensurate developments in the technology of bypass. Modern tools and devices are just as sophisticated and complex and utilize computers, radiographic technique, sound-signature analysis, space-age drilling materials, and extremely advanced metals and metallurgy in their design and operation. So, the technology of locks and their bypass continues.

There are certain pioneers, both early and modern, in this profession. Primarily in England and the United States, they are credited with revolutionary ideas in the both design and bypass of locks. A. C. Hobbs, Jeremiah Chubb (and the Chubb group), Joseph Bramah, Linus Yale (Sr. and Jr.), and James Sargent provided the foundation for current bypass technology. Modern pioneers, innovators, and inventors in this industry include Jerry Hoffman (HPC), Harry Miller (S&G), John Falle (Falle-Safe), Martin Newton, Bennie Wells, Nick Gartner (LaGard), Roy Spain (Medeco), S.A. McClean, Clayton Miller (Lockmasters), Mark Bates (MBA), Ken Dunckel and Skip Eckert (safe penetration and manipulation), and the design team at Mas-Hamilton. There are of course many others, but these are perhaps the best known for their contributions.

28_3.0 Introduction to Bypass

The art of lock-picking and the development of bypass techniques are as old as the first lock. The purpose of any lock is to restrict entry; it is axiomatic that someone will have a desire to do just the opposite.

What is a lock? Moreover, what is a key? As we have learned, a lock is a mechanism that comes in an infinite variety of sizes, shapes, and configurations. Its chief element is a bolt that can be shot into a staple or other recess. It is retained there until withdrawn by properly activating the locking mechanism. A key, in whatever shape and size, is simply a device for operating the mechanism within the lock in such a way as to control the bolt.

Locksmiths, from the time the craft first came into existence, have always been fascinated by the problems of security. The basic challenge has been to present the would-be thief with the most difficult obstacles to entry. There are many myths about opening locks. A very interesting book about Houdini entitled Believe (by Michael C. Tobias) may be of interest to the reader. Among the myths: that a blank key can open a lock; that wax or soap can be inserted into the lock to make an impression of the key; that all of the tumblers can be lifted to open the lock, that a special tool may be inserted, and by magic the lock is opened; that there is a universal master key or instrument for opening all locks; that there are skeleton keys; and that there is a universal picking tool.

These and many more tricks shown in the movies, make the whole process appear quick and simple, requiring little talent. Rarely is that the case. The author has picked thousands of locks, sometimes in seconds, more often requiring minutes. Sometimes, the simple locks will offer more difficulty than high-security bank locks. Then again, one may repeatedly attempt to pick a lock to no avail. After a five-minute rest, another attempt is made and the lock is opened in seconds. Bypassing locks is an art and a science that requires considerable practice, skill, and patience.

There are many labels to define the process of opening locks and safes in a manner not intended by the manufacturer, or in contravention of the "normal" mechanical activation. **Bypass** and **neutralization** are perhaps the most popular terms. In this text, the term "**bypass**" shall denote any process or manipulation that is employed to open a mechanical or electronic lock by tools, devices, and procedures other than intended or designed by the

manufacturer.

28_3.1 Security: A Simple Premise

The security of modern mechanical key and combination locks is primarily based upon the double-acting detainer principle. This requires that all discs, levers, or tumblers be lifted, rotated, or moved to precisely the correct level or position in order that the mechanism may be actuated. In addition, keyways, guards, wards, and other techniques may be utilized to block entry to the lock components by all but the correct key.

There obviously have been many variations. This involves the use of rotating tumblers, sidebars, telescoping pins, magnetics, optics, infrared, and the integration of other new technologies including induced fields, digital transponders, electronics, and computers. In essentially all mechanical locks, bypass requires that the action of the key or other actuating device be simulated or replicated. The ability to bypass a particular lock will depend upon nine primary factors:

- **Type of mechanism and inherent tolerances;**
- **Physical construction and measurements of the container holding the lock;**
- **Material and method by which the lock is affixed: If the lock is mounted on wood or other material that does not offer sufficient structural integrity, then it can be easily bypassed with force;**
- **Bolt-actuating mechanism, and capability of externally manipulating the active components to open the lock;**

External bypass of a solenoid using a magnetic field. Courtesy of Don Shiles.

- **Incorporation of special security devices within the locking mechanism that are designed to frustrate bypass, such as anti-drill pins and security tumblers;**
- **Number, structure, and design of tumblers, levers, wafers or discs: This is perhaps the most important information that can be developed in order to determine the best method of bypass. Such details will allow a determination of whether the lock is**

most susceptible to picking, impressioning, decoding, or drilling, and the likelihood of success. This information will also provide a means to visualize the internal components in order to translate touch and hearing into physical action;
- **Design of the keyway;**
- **Design and functionality of the key;**
- **Number of differs.**

Whether a lock can be bypassed depends on many factors, including its security rating. A comprehensive list of such factors can be found in **Chapter 29**. A detailed analysis of bypass potential is presented in the next three chapters and in **Chapters 24-25-26-27.**

28_3.1.1 Physical Components and Designs to Prevent Bypass

Within the lock, there are several principal components and designs to prevent or frustrate bypass. Although covered elsewhere in this text, these are summarized here. There are two primary means to make bypass more difficult: keyway profile, and the design of the device or means for obstruction or blockage of rotation of the plug or other bolt-actuating device. These are commonly described as wafers, levers, discs, or pin tumblers.

28_3.1.1.1 Keyway Design

The purpose of the keyway is to require the correct key to have identical properties, so that it may enter and turn inside the lock. The keyway wards prevent entry for all but the proper key.

28_3.1.1.2 Implements to Block Rotation

Locks with many mechanical designs have emerged during the past two hundred years, all with one common objective: to block rotation of a plug or other bolt-actuating device until the proper key is inserted. These have taken the form of levers, discs, wafers, and pin tumblers. Regardless of their size, shape, thickness, or number, they prevent movement of components until properly set by the bittings of a key.

28_3.2 Methods of Bypass

Discussion of different bypass techniques. Courtesy of Don Shiles.

LSS303: Analysis of bypass techniques, by John Falle

There are three primary methods of covertly bypassing all mechanical locks: **picking, impressioning, and decoding.** Other forms of manipulation may also be employed. Certain bypass techniques require disassembly of the lock; most do not. Understanding bypass procedures and the underlying theory of each method, coupled with sufficient practice, will allow almost anyone to become proficient at opening most locks.

In general terms, a lock may be bypassed or opened by the manipulation of active components, or by producing a key. In this text, techniques for bypass have been divided into three primary categories: **picking, impressioning, and decoding**, although impressioning and decoding are often in fact so closely connected so as to be indistinguishable. Although there are many techniques and procedures that can be employed to open a lock, all of them can be said to be subsets of one of the three categories listed above.

The following techniques, or subsets of them, are explored in detail throughout this text, and constitute the methods by which a lock or locking system can be compromised covertly. The summary does not include methods of forced entry.

- **Picking;**
- **Key picking;**
- **Impressioning;**
- **Mechanical bypass of security mechanism (such as comb pick or spiking);**
- **Injection of spray into the plug to freeze the top pins, then use heat to release bottom pins below shear line;**
- **Core shimming;**
- **Pin and cam technique;**
- **Pick and form technique;**
- **Stack probing of pin stack (length of pin stack determination. This can be done visually with an otoscope, and by viewing color coded pins);**
- **Sac probing (break point on short pins, visible decoding);**
- **Basic decoding of tumblers;**

- **Electronic decoding;**
- **Extrapolation and decoding of top level master key (TMK);**
- **Plasticine reading of levers;**
- **Automatic impressioning using pressure responsive materials;**
- **Step key and count back techniques;**
- **Shim wire decoding;**
- **Radioscopy (x-ray and Gamma ray imaging);**
- **Endoscopy (Use of borescope or otoscope);**
- **Belly reading;**
- **Scratch reading for levers (Use of borescope to view the length of wear marks on bellies of levers);**
- **Vibration techniques;**
- **Automatic manipulation of components by computer technology;**
- **Utilization of standardized access and control keys or combinations to enter other secure areas. Elevators, power panels, telephone company panels, alarm consoles and similar locations may employ standardized locks and keys. For example, all elevators in New York city are keyed alike, and all elevators in New York state, other than in New York, are likewise keyed alike;**
- **Combination of techniques.**

28_3.2.1 Picking

Picking involves a process of manipulating each moving component in a manner that simulates the action of a key or other actuating device. Many techniques are available to pick a lock, as well as a wide array of tools to accomplish the task. Picking is accomplished through the manipulation of individual pins or groups of tumblers using mechanical or electromechanical means such as conventional picks, rakes, pick guns, and “999” rapping keys.

All picking techniques rely upon cumulative tolerance and alignment errors between moving parts in a lock. As the gap between active components decreases, the difficulty of picking increases. All locks have a certain amount of space between plug, pins, shell, wafers, or levers. These gaps, coupled with slight misalignment of parts resulting from the manufacturing process, will allow a lock to be bypassed. The optimum exploitation of these errors differentiates amateur from expert.

28_3.2.1.1 Survey of Bypass Techniques: Picking and the Manipulation of Active Components

The following list provides a comprehensive summary of picking techniques:

- **Using a skeleton key;**
- **Using a mechanical vibration pick;**
- **Accomplish physical bypass of bolt mechanism;**
- **Pinning error, use of comb pick;**
- **Prying or defeating bolt by spreading, such as with desk lock;**
- **Rake picking;**
- **Key picking (jiggling of keys);**
- **Raking with a set of tryout keys or rocker picks;**
- **Rapping the lock;**
- **Rocking using computer picks;**
- **Use of snap-pick tool;**
- **Traditional picking;**
- **Use of tryout keys;**

Forensic analysis of gang, jiggle, or tryout keys. Courtesy of Hans Mejlshede.

Marks on Ford wafer locks produced by gang, jiggle, or tryout keys. Courtesy of Hans Mejlshede.

- **Use of a special pick tool to open and decode the lock, such as with tubular locks;**
- **Use of brush pick;**
- **Use of control key for removable core or interchangeable core lock;**
- **Use of shim to bypass lock mechanism;**
- **Use of vibration after removing springs, such as with the Briggs and Stratton sidebar lock;**
- **Utilize a cross-key combination;**
- **Vibration of special key inserted into the lock;**
- **Add wafers or pins to lock for later picking or entry;**
- **Celluloid to get around secondary bolt;**

- **Use of ice pick to manipulate the actuating cam or bolt.**
- **Electronic signature analysis;**
- **Radiographic imaging.**

28_3.2.2 Impressioning

Impressioning allows keys to be produced for locks without disassembly. The original technique was developed hundreds of years ago and involved the insertion of blank keys coated with wax or covered with carbon to sense the resistance of levers. Today, the process is essentially the same, except that the materials have changed. There are many ways to impression a lock. These include traditional techniques or the use of a special brass, lead, latex key, or hybrid key surface. Some rely upon the use of special substances to enhance tumbler marking. Materials such as carbon, metal foil, cellophane tape, electrical tape, wax, plasticine, grease, type-correct solution (White-Out), nail polish, putty, Vaseline, and soap may all be utilized. The technique depends upon the particular mechanism and personal preference.

Impressioning is a combination of picking and decoding. The process relies upon tolerance errors, and the ability to decipher information left on the bitting surface of a key. During the impressioning process, a blank key is inserted and manipulated. This allows a reading of the tolerance between plug and shell, and the position of a specific pin, wafer, disc, or lever. The advantage of impressioning is that a working key is produced at the completion of the process.

28_3.2.2.1 Impressioning Techniques

There are two primary methods of impressioning:

- **Tactile impressioning tool, such as foil and wax;**
- **Tactile impressioning of lock itself.**

28_3.2.3 Decoding

Decoding envisions and encompasses many techniques and procedures. It involves the acquisition and deciphering of data about active moving components within the lock that control configuration of the shear line. Both the lock and its keys can be decoded and compromised. Data for a given lock may be obtained

by various means, including:

- **Gaining physical possession of the key and copying it;**
- **Visually decoding the bitting, then utilizing that code for creation of a duplicate key at a later time;**
- **Viewing code numbers stamped on the key;**
- **Obtaining codes from an internal system list, from the locksmith who installed the system, or from the manufacturer;**
- **Impressioning;**
- **Use of a borescope to read the wafers, levers, or tumblers;**
- **Visual external decoding of the tumblers, especially if they are color coded by the pin manufacturer. There is no standardization of color coding, but an educated guess may be made as to pine length from its color;**
- **Use of a change key to extrapolate the top level master key;**
- **Disassembling the lock and measuring each pin;**

LSS204: Brian Chan on the disassembly of a lock and derivation of the TMK

- **Shim wire decoding.**

28_3.2.3.1 Decoding: Creating a Key for the Lock from Data

The following sources may provide direct code information that will allow a key to be produced by:

- **Code cutting after deriving the code by one of the following techniques:**
  - **Copy a key;**
  - **Decipher the key code from lock or tumblers;**
  - **Decode master key for entire system;**
  - **Decode combination using a depth gauge or key;**
  - **Extrapolate a composite master key in a positional system;**

- **Obtain factory or dealer data regarding codes;**
- **Make a silicone impression of the original, then decode or produce a molded copy;**
- **Measure the key with a micrometer;**
- **Trace the outline of a key for later reproduction;**
- **Obtain master key system listing or extrapolate the code for the TMK;**
- **Obtain or borrow a key;**
- **Obtain the code list for the lock;**
- **Photograph the key, then reproduce it;• Pick the lock, then examine with borescope to decode;**
- **Remove one lock, decode, and replace;**
- **Employ specialized decoding systems, such as magnetically reading the signature of the lock or measure tumbler lengths;**
- **Use of foil for impressioning;**
- **Visually decoding of the key or tumblers;**
- **Visually deriving code from one or more keys;**
- **Visually observe master key, then decode.**

28_3.2.4 Other Forms of Manipulation

Manipulation takes many forms and encompasses those techniques not constituting traditional picking, impressioning, or decoding. Manipulation is generally mechanical in nature and involves the alteration, exchange, addition or removal of active components. Modification of the pin-stack is a favorite technique, and generally involves two principal procedures: addition of master pins or the removal of pins. Both are designed to reduce pick resistance.

The removal of one or more tumblers and the exchange of security tumblers for conventional pins will make the lock easier to pick. The addition of one or more master pins, thereby increasing the number of shear lines, will also reduce pick resistance. Alteration of cams, removal of cylinder retaining screws, removal of springs, and similar actions can also make a lock more susceptible to bypass. Another technique involves the compromise of conventional master key systems by obtaining a change key and then decoding the TMK by sampling each chamber for each depth.

29_1.0 Introduction

This chapter is about covertly bypassing locks, using techniques commonly referred to as **picking**. Principles of picking, checklists for analyzing potential problems, various bypass techniques, and a description of general and special pick tools are presented. Information regarding warded, lever, wafer, disc, and pin tumblers locks is detailed so that the reader can become proficient at opening most mechanisms. Data will also be presented for certain types of hybrid locks such as sidebar, magnetic, rotating disc, tubular, and dimple, due to their wide acceptance. The majority of the discussion will relate to pin tumbler locks because of their popularity. However, most principles will be equally applicable to the disc, wafer, and lever. The differences in mechanisms and opening techniques will also be explored.

Although television and the movies have portrayed lock-picking as within the grasp of the common criminal, it really is not. For high-tolerance locks, it is a precision art requiring skill and practice. There are few universal rules: some locks are simple and some are exceptionally difficult. Others, including electronic, magnetic, laser-track disc, and sidebar, are virtually impossible to open. My intrigue with locks and picking began at age 15, when I opened my first pin tumbler mechanism and had my first key cut by code. From that time, it has been a continuing fascination and learning process. One has to marvel at the developments in the industry during the past quarter century. It is impossible to imagine what the next century will bring.

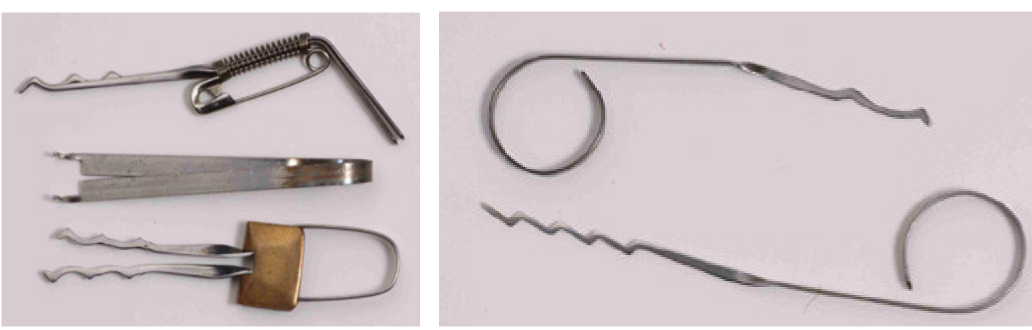

Figure LSS+2943 Special pick sets that can be concealed during covert operations, and thrown away if necessary. Courtesy of Barry Wels.

Modern locks, and specifically high-security locks, provide an extraordinary measure of security against many forms of bypass.

Having said that, one must take heart because most locks can be picked or decoded. It just takes a little more time, skill, and effort. From over thirty-five years of experience, I can attest that there is only one means to become skilled at the art: pick many locks of all kinds and in every possible situation. The only way to learn how to recognize and exploit defects within a lock is to practice.

This means practicing many times on the same lock as well as practicing on many different locks. Anyone can learn how to open desk and filing cabinets, but the ability to open a quality lock in under thirty seconds is a talent that requires a great deal of skill. It is gained through practice, coupled with mechanical sensitivity, physical dexterity, visual concentration, and the ability to think analytically. This chapter will teach that there is no "one" way to do it. Everyone develops preferences. Every instructor teaches slightly different methods, based upon personal experience. We all do things differently. If the basic premise of lock-picking is understood for each type of mechanism, then the reader will be able to succeed, albeit with persistence.

Many manufacturers have conducted the proper research and development necessary to produce secure locks. Although **all** manufacturers will represent their products as secure, in the author's personal experience, many have been quite the opposite. Just because the lock "looks" like it will be difficult to pick provides no barometer to its true security. A properly designed lock has the requisite security to make picking difficult and time consuming. That is what research and development accomplishes. Security tumblers, sidebars, magnets, false notches and gates, serrated levers, keyway curtains, and other refinements are all utilized to frustrate the process described in this chapter. Such devices and technologies are the product of research and development.

Manufacturers have been quite surprised by latent design defects that have not been found until years after a product is introduced and patented. Until discovery by a locksmith, government expert, or criminal, such defects are not obvious to anyone. Once discovered, of course, they often are so obvious as to be laughable. The author has always maintained that design engineers are skilled at making things work but not at breaking them. The issuance of a patent for a particular design does not guarantee security.

Finally, in the author's perspective from within the law

enforcement community, it is observed that there have been very few instances of dishonest locksmiths. It is indeed a noble profession of protection; it should receive the accolades it deserves. Few other groups of specialists are charged with such a responsibility and given such a wide array of tools to fulfill their mission. It is now a complex business, requiring the ability to open many different locks, sometimes in very difficult circumstances.

SECTION 1: Bypass and the Characteristics of a Lock

29_1.1 Locks Have Personalities, Too

Although skill and luck can play a significant part in bypassing a lock, there are many technical issues that will allow or preclude a successful opening. Certain characteristics will make a lock easier to pick, and others will present serious obstacles. Each lock has its own physical personality, resulting from differing mechanical features and defects that can help or hinder bypass. These traits can often be used to advantage during picking. To open a lock, its characteristics must be correctly assessed, responded to, and exploited using the proper remedy or technique.

The following discussion summarizes physical, setup, and mechanical characteristics that can affect how a lock responds to bypass attempts. Many common issues and problems can be remedied with skill, the correct tools, and proper techniques as outlined below. Consideration must be given to each of the following factors to assess whether a target lock can be opened and with what level of expertise and difficulty.

29_1.1.1 What Makes a Lock More Conducive to Picking

- **The suspect lock may be inherently easy to pick due to its design (especially if a wafer mechanism);**
- **The pin-stack configuration or combination may be extremely conducive to picking. That is, all**

tumbler positions may be close to the same depth, or a stair-step pattern may have been used;

- **Maison keying may be in effect. There may may only be two or three tumblers in the lock;**
- **Complex master keying may be employed, with many cross-combinations available;**
- **The lock may only have three, four, or five tumblers;**
- **No wards or obstructions in the keyway;**

- **The tolerance between plug and shell may be quite sloppy, due to:**
  - **Wear;**
  - **Poor manufacturing controls;**
  - **Because the top of the plug was filed by an amateur locksmith;**

- **The horizontal center-point alignment between chambers may be erratic, making picking easier. This means that all of the pin chamber holes in the plug/shell are not precisely drilled in a straight line. When the lock is picked, it will be easier to cause pins to set at shear line;**
- **No security tumblers are used;**
- **The perpetrator may be very skilled in lock-picking;**
- **All tumblers can be pushed, using a pocket knife, because each depth is close to the same level;**
- **Rocker picks can be utilized in a lock having a pin combination that matched the signature of the picks.**

29_1.1.2 Pick Resistance of a lock

- **Are high-security locks used. Does the lock carry a UL 437 or equivalent rating;**
- **What is the tumbler orientation of the lock (vertical or horizontal) and how does this affect pick resistance;**
- **Are security pins (serrated, mushroom, spool) employed. Are telescoping pins used for extra security;**

- **Does the lock utilize a paracentric keyway for added pick resistance;**
- **Have special pick or decoding tools or procedures been developed for this type of lock. Are there known picking or bypass techniques;**
- **Do locks utilize high tolerance components, factory original keys, and incorporate anti-pick features;**
- **Are high tolerances maintained between the plug and shell;**
- **Does the lock resist tumbler manipulation;**
- **Does the lock resist decoding techniques. Any chamber that allows slight lateral movement of the plug before pins are lifted can permit decoding of bottom pin lengths with a key blank;**
- **Does the lock resist impressioning;**
- **Will key jiggling be ineffective, due to high tolerances. Wide tolerances at shear line will facilitate jiggling, impressioning, and cross-combinations;**
- **Does the lock resist progressive compromise.**

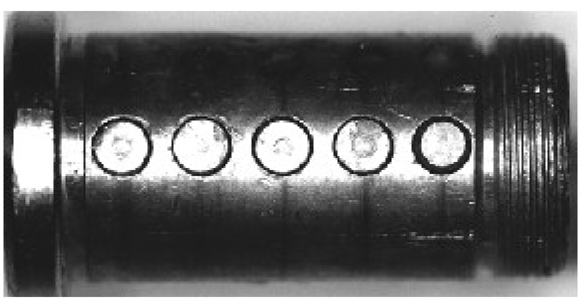
29_1.1.3 Information from the Keyhole

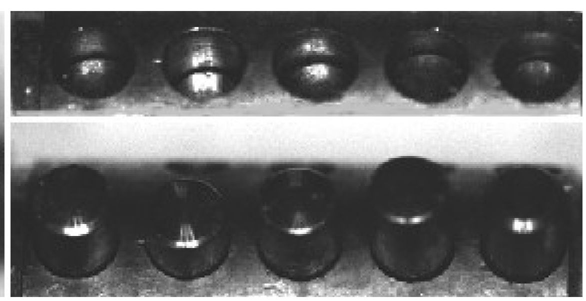
The keyhole will provide some valuable information that can make picking easier and faster. The following observations should be made when planning an entry:

- **Type of mechanism (pin tumbler, wafer, lever);**
- **Possible number of tumblers;**
- **Design of keyway;**

- **Potential for visual decoding of tumblers;**
- **Special security features.**

29_1.2 (RESERVED)





29_1.3 Lock-Picking and the Theory of Bypass

29_1.3.1 Introduction: the Basics

We begin our discussion of lock-picking by reviewing the most basic questions: **How does a key open a lock, what keeps the lock from opening, and why is it difficult to pick a lock?** If these concepts are thoroughly understood, then the actions of the key can be duplicated to effect the same result. The very essence of lock-picking, and indeed all forms of bypass, is an understanding of how a lock responds to manipulation and simulation of the use of the proper key.

29_1.3.2 How Does a Key Open a Lock?

A key is first inserted into the keyway. The protrusions on the side of the keyway are called wards. They restrict the set of keys that enter the plug. A cylinder can rotate when the proper key is fully inserted. The non-rotating part of the lock is called the shell. The proper key lifts each pin-stack, wafer, disc, or lever until the gap between the bottom pin and the top pin (or equivalent) is located at and forms the shear line or clearance. When all the pins are at shear line, the plug is free to rotate, thereby allowing the lock to be opened. An incorrect key will leave some of the **detainers** protruding between the shell and the moving component, thus preventing rotation.

29_1.3.3 What Keeps the Lock from Opening

Although the mechanisms of each classification of lock differ in

their operation, the theory of all mechanical locks is inherently identical. Regardless of design, the active internal components that control some form of boltwork are maintained in a locked position until some mechanical action or series of actions removes the obstruction and allows rotation or other movement. The obstructions are formed by the pins, levers, wafers, or discs. Removing this blockage involves the insertion of a key that rearranges and moves each of the obstructions to a common point, called a "shear line."

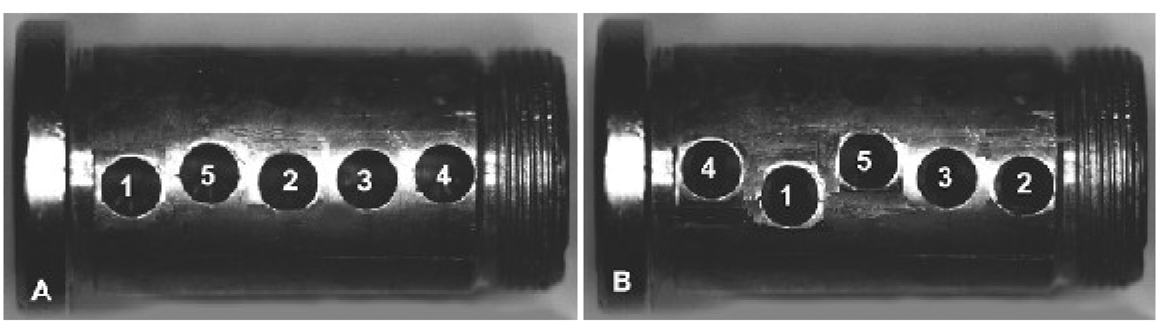
29_1.4 Cumulative Tolerance Errors

29_1.4.1 Introduction: Why is it Difficult to Pick a Lock?

Why locks are easy or difficult to pick is covered in detail later in this chapter. The short answer primarily involves tolerance errors. If a lock and its moving components (plug and pins) maintain a very high tolerance, meaning little space between parts, then the lock will be more resistant to manipulation. If all chamber holes have very close to perfect centerline alignment, ever more difficulty will be encountered. If security tumblers are added to the equation, the mechanism may present a serious obstacle to bypass. As the reader will learn, the question involves many complex issues. Understanding them will provide the maximum opportunity to successfully open a lock.

29_1.4.2 Tolerance

Tolerance errors are cumulative in effect, resulting from many factors. In high-quality security-rated locks, the plug and shell is made from brass bar stock or nickel silver. The pin chambers are drilled individually and reamed for a close fit. In contrast, poor quality knockoff locks such as produced in Asia are less expensive with commensurate poor tolerances. Maintaining tolerance is costly; there are no shortcuts. Cheap locks will generally display the following characteristics:



- **Have too much chamfer on the top and bottom of the pins;**
- **Use die-cast plugs and bodies with poor chamber alignment;**
- **Have oversized pinhole diameters;**
- **Allow too much clearance between the shell and plug;**

- **If brass is utilized, it will be of inferior quality to #58, (which is typically used in quality locks).**

The following tolerance errors are typical in a pin tumbler mechanism and will contribute to the ability to pick or impression the lock:

- **Plug and shell >.005”;**
- **Loss of bottom metal of keyway due to broaching <.0005";**
- **Flat at top of plug .005”-.015”;**
- **Chamfering pin chamber with a reamer or drill bit;**
- **Chamfering a pin;**
- **Pin chambers not all same diameter;**
- **Pin chamber centerlines not equal;**
- **Concentricity of chambers: roundness;**
- **Pin diameter and concentricity of tumblers;**
- **Master keying can create up to 2,000 or more shear lines because of cross-keying.**

Locks can be picked due to cumulative tolerance errors resulting from required clearance between moving parts. The poorer the tolerance between moving components, the greater the opportunity for setting pins at shear line. There is always a sliding allowance or tolerance. Any part that will slide past another moving component must be separated by a gap. The space allows the creation of a shear line; the opportunity to exploit that mechanical requirement permits bypass.

Order of picking. Courtesy of Hans Mejlshede.

Variations in alignment of active components caused by imperfections in machining and metal surfaces, drill bit and

broach wear, imprecise rounding, and other production stages make it possible to bind pins and other parts during picking. Tolerance errors occur at several critical points. These include:

- **Plug and Shell Gap: Free rotation of the plug requires tolerance between the plug and shell. A minimum of .0025″ is considered acceptable. This means that there will be at least .0025″ at any point between the plug and shell (a total of .005″ error), depending upon the position of the plug. If there is less tolerance, binding can occur; more will result in sloppy operation.**

A tolerance of .0025″ would be maintained assuming the plug rested in the center of the shell. In reality, the plug sets on the bottom, leaving .005″ at the top where the pins make contact with each other. The average tolerance between plug and shell is about 1/3 the depth difference between one cut. Thus, if the increment is .015″, then the tolerance will be about .006″, or slightly more than 1/3 depth. This number will range between .005″ and .010″. This also explains why poorly cut keys will often open a lock having low tolerances. The cumulative effect of the key-cutter and manufacturing processes of the lock will contribute to greater latitude with regard to shear line.

- **Broaching of keyway: Broaching is the process by which a keyway is created within a solid plug of brass. There are always slight variations in the formation of wards due to wear of the broach. Depending upon the manufacturer, broaching can be extremely accurate or quite sloppy. It provides an index as to the manufacturing quality controls and the cost and security of a lock.**

Broaching causes a small amount of metal to be lost at the bottom of the keyway in order to maintain the original plug diameter. Obviously, there is also a tolerance factor between the interaction of the key and the wards, so that smooth mechanical operation will result. If low tolerance is maintained in the broaching process, then the key will not index properly within the keyway, causing up to a 0.005″ error. This must be compensated for by the manufacturer at the plug-shell interface point (shear line).

- **Chamber tolerances: There are four critical factors involving tolerances relating to chambers:**

- **Plug diameter differential: The actual circumference of the plug varies longitudinally, creating differences in the shear line between plug and shell, and allowing pins to be easily trapped. This is called the effective diameter of the plug: it does not equal the true diameter. If the effective diameter is "true" across the entire length of the plug, then the gap between shell and plug will be constant, thereby creating a precise shear line.**

- **A flat surface at the top of the plug: It may be there by design or created by an amateur locksmith and can add 0.005"-0.015" tolerance error. Chamfering does the same thing. Thus, the difference between a flat and rounded mating of plug and shell can be critical with respect to pick resistance.**

- **Off center or misaligned chambers: This is the critical alignment error that determines which pins will set first. When the plug is rotated, the farthest out-of-center chamber will be first bound. Chambers are created by a process involving either individual drilling operations, or gang drilling. Gang drilling will produce results that are more varied. This is because of the use of different drill bits for each chamber. How often the drills are replaced is also relevant. Generally, each chamber is drilled individually for higher accuracy. Chamber diameter is generally maintained to ±.03 mm. In the case of Ikon, the pin diameter is 3.0 mm, and the chamber diameter is 3.2mm; thus, the pin-chamber tolerance is 0.2 mm.**

- **Concentricity or pin centers within each chamber: Internal lateral movement or play will provide another opportunity for pins to set at shear line. The error is caused by gang or sequential**

drilling. The drill bit changes by a microscopic amount during each penetration. High-security lock manufacturers such as Ikon maintain a vertical and horizontal center tolerance of .02 mm (.001”).

29_1.4.3 Tolerance and the Binding Effect: Setting a Single Pin within a Pin Tumbler Lock

Tolerance can be said to be the basic defect that enables all locks to be picked. It makes it possible to open a lock by lifting the pins, discs, wafers, or levers individually, thereby trapping (setting) them at shear line. Whereas a key lifts all tumblers simultaneously, the pick accomplishes the same task one at a time. In its simplest form, the procedure for opening a lock (one pin at a time) can be described as three sequential steps:

- **Apply a shear force in the form of torque;**
- **Find the pin that is binding the most;**
- **Force it up to the shear line.**

As the top of each lower pin reaches the gap between plug and shell, the plug will rotate slightly; the top pin will then be trapped above the shear line. This procedure is called **setting a pin**. Opening the lock simply requires that all pins be set. The most difficult aspect of picking a lock can be the determination of the first pin that binds, or the pin that is binding the most. It is essential to understand the relationship between applied torque and the force required to lift each pin. This is necessary in order to appreciate and utilize the mechanical sensations generated during the picking process.

29_1.4.4 Forces Exerted Upon Pins

There are four primary forces that are exerted on driver pins during picking and which must be overcome through pressure applied by the pick:

- **Friction from the sides of the pin;**
- **Spring-bias force from above the pin;**
- **Contact force from the lower pin;**
- **Elastic deformation of pins.**

29_1.4.4.1 Binding Friction

The binding friction is proportional to how hard the top pin is being scissored between the plug and shell; it is a function of the applied torque. It is axiomatic that the more torque presented, the harder it will be to move a pin. To make a pin move, pressure must be applied that is greater than the sum of the spring and friction forces. When the base of the top pin reaches the shear line, the physics suddenly change. The friction binding force drops to zero and the plug rotates very slightly until stopped by another pin binding. Now the only resistance to the vertical motion of the pin is the spring force.

After the top of the lower tumbler enters the gap between the plug and shell, a new contact force is created from the bottom pin striking the shell. This force can be quite significant and will cause a peak in the pressure required to move the pin. If the bottom pin is pushed further into the shell, it creates a binding friction just as the top pin originally encountered. Thus, the amount of pressure needed to move the pins before and after crossing the shear line is about equal. Greater torque increases the required pressure. At the shear line, the pressure increases dramatically due to the lower pin striking the shell.

29_1.4.4.2 Spring Bias

Spring bias increases slightly as pins are pushed into the shell, but the difference in force is negligible and essentially of no consequence. A pin will not move without the application of enough pressure to overcome the spring bias.

29_1.4.4.3 Elastic Deformation

The mechanics of lock-picking occur in distances that are measured in thousandths of an inch, where metals behave like springs and very little force is necessary to deflect or deform metal components. When that force is removed, the metal will spring back to its original shape and position. Deformation can be used to advantage to force several pins to bind at once. For example, the application of heavy torque may aid in setting more than one pin at a time by deforming the surfaces with which the pins bind. This is especially useful where tolerances have been maintained with respect to chamber bores and their center axis. Added torque can skew the centerline of all chambers, causing tumblers to set.

Torque actually places a twist in the plug that causes the front to be deflected further than the rear. With light torque, the back of the plug stays in its initial position. When increased, the front pin chambers bend or deform enough to allow the back of the plug to rotate, causing the rear pins to bind. With the extra torque, a single stroke of the pick can set several pins simultaneously.

Exerting excessive torque can also cause problems. When the torque is great, the front pins (and plug holes) can be deformed severely enough to prevent them from setting correctly. For example, the first pin can **false-set low.** Too much torque can deform the bottom of the top pin and prevent the bottom tumbler from reaching the shear line. This circumstance can be recognized by the lack of give in the first pin. Correctly set pins feel springy if they are pressed down slightly. A falsely set pin lacks this springiness. The solution is to press down hard on the first pin. Torque can be reduced slightly, with the attendant risk that other pins will then unset. It is also possible to deform the top of a bottom pin when scissored between the plug and shell above shear line. When this occurs, the pin is said to be **false-set high.**

29_1.5 Definitions

Certain terms define physical characteristics and mechanical operations relating to lock-picking.

Balanced Driver

A balanced driver requires that the dimensions of the pin-stack (driver and lower pin) be computed and adjusted so that the overall length remains constant. This is required in order that keys with high bittings will operate smoothly, and bypass by comb picks will be prevented.

Binding of Pins

Pins are said to bind during the lock-picking process. Binding is caused by an opposite rotational force being applied to the pins to trap them in the gap between plug and shell (shear line). Binding theoretically should occur in the order of pins farthest out of center alignment between the chambers of the plug and shell. This is referred to as the "order of picking."

In theory, only one pin will bind at one time, requiring

individual manipulation. In succession, the next farthest pin out of alignment will bind. As each pin is picked, it is trapped at shear line.

Breaking Point

The breaking point occurs where lower and driver pins are split, allowing creation of the shear line.

Comb Pick

A tool that resembles a comb, having the same number of teeth as there are chambers within a pin tumbler lock. The device will allow all lower pins to be raised above shear line, thereby creating a new shear line by which the lock can be opened.

Lock Pick

A pick is a device that is usually made of spring steel with a thickness of .032” or less, and is used to enter a keyway and manipulate the active components of a locking mechanism. Picks have many different designs in order to accomplish specified tasks during bypass.

Order of Picking

The order of picking refers to the sequence in which the tumblers, wafers, discs, or levers are set. It is dependent upon tolerance errors in chamber bores and their overall alignment, plug diameter, and other mechanical features. Theoretically, pins will set in direct relation to their deviation from centerline of the plug. The pin most out of alignment from the centerline of the bores will set first. However, this is dependent upon elastic deformation and the amount of torque applied during picking. Pins may actually set in any order, but will do so based upon tolerance errors.

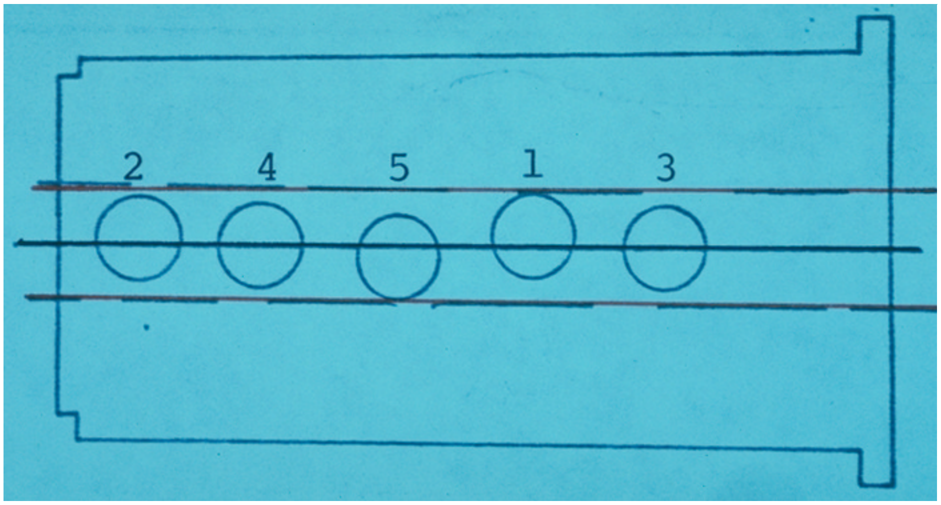


Figure LSS+2925, diagram showing order of picking, and the misalignment of the five chambers. Courtesy of Illinois State Police, Bill Sherlock.

Plug

The terms “plug” and “core” have the same meaning. A plug is the active component within the lock that contains detainers and is rotated to actuate a cam, bolt, or other mechanism.

Shear Line

The shear line is created by the gap between the plug and shell. It is the precise point where tumblers, wafers, or discs are “set” allowing rotation of the plug.

Sidebar Lock

A lock incorporating a sidebar mechanism, generally consisting of a secondary locking pin that must be retracted into the plug prior to rotation. This mechanism appears in both disc and pin tumbler locks. The sidebar was originally developed by Briggs and Stratton for automobiles and was introduced in the United States in 1935.

Setting a Pin

A pin, lever, or disc is “set” when it is trapped at the shear line by being physically stopped from protruding into either the shell or plug.

Tang

The tang of the torque wrench is that part which extends at right angles from the body of the wrench and is inserted into the plug.

Tolerance

Tolerance refers to the gaps, measured in thousandths of an inch, between moving and fixed components within the lock.
Lock-picking relies upon tolerance variations and cumulative errors.

Torque

The rotational force that is applied to the plug or tumblers during the picking process is known as torque. Its purpose is to exploit the binding affect of moving components. A torque wrench is employed for this process.

Torque Wrench; Turning Wrench

A device used in conjunction with a pick that provides the turning motion to rotate the plug and bind and set the pins, wafers, discs, or levers during the picking process.

Wedging

Opening a lock with a comb pick generally requires the use of a wedge to obtain sufficient pressure to drive all tumblers above shear line. The wedge is placed underneath the pick to provide leverage, allowing the springs to be crushed when the tumblers are elevated. Sometimes, enough pressure is applied to drive top pins out of the lock. High-security locks such as Medeco use setscrews to hold drivers in place. Otherwise, brass retainers can be forced out of position.

999 Rapping

This technique allows cylinders to be opened rapidly by inserting a specially cut blank that applies equal pressure against each lower tumbler. It simultaneously causes shock waves to the driver pins, thereby bouncing the driver pins above shear line momentarily.

SECTION 2:

Preliminary Considerations Prior to Picking a Lock: An Overview of the Successful Bypass

29_2.0 Introduction

To successfully open high-security and certified locks, planning, reconnaissance, experimentation, and a great deal of practice is often required and recommended. Especially in covert operations, time is generally of the essence. This means that the entry team must know the target lock: its specifications, differs, unique designs, idiosyncrasies, and special security features. Preparation is the key to success. Unless the entry team has opened the target lock on prior occasions or has had extensive experience with the same mechanical design, the chances of a rapid and successful opening will be greatly diminished, even with the most sophisticated tools.

The notion that high-security locks are bypassed by simply walking up to them, inserting a pick and tension wrench, working for a few seconds, and the lock is open only happens in the movies. Rarely is it the case in real operations. High-security locks are designed to be difficult and time consuming to open. That is the essence of UL 437 and other such standards. There are many issues to consider prior to actually beginning the process of picking a target lock. They relate to general considerations pertinent to all locks, specific problems that may arise or be caused by a particular mechanism, and detailed planning of covert openings.

The author, prior to an entry, always mentally reviews the following checklist. Most of the considerations are routine and automatically factored into the overall analysis of the lock in terms of its capability to be bypassed. It is important, especially for the novice, that the points raised in this section be fully understood and considered. Failure to resolve each issue can make lock-picking immensely more difficult or impossible.

29_2.1 General Considerations

- **Identification of the target lock:**

    - **Type of mechanism;**
    - **Number of pins, wafers, levers, or discs;**
    - **Likely direction of rotation of the plug.**
- **Are special tools required to pick the lock, or have special tools been developed for such purpose;**
- **Does the mechanism incorporate more than one type of locking system;**
- **Does the lock appear to be new or old; in good condition, or worn;**
- **Is the lock located inside or outside;**
- **What is on the other side of the door, and does that pose a danger;**
- **Why is the lock being opened;**
- **What is the familiarity with the lock and prior experience;**
- **What is the preferred method of picking;**
- **Can the cylinder be picked, or is it one that has been certified UL 437 or similar rating that will make the process very difficult, time consuming, or impossible;**
- **Is the lock operable;**
- **Can each pin, wafer, disc, or lever be manipulated with a pick to determine their number, whether each can be moved, and if each is spring biased;**
- **Should the lock be lubricated prior to picking. If the lock is going to impressioned, the answer is no. Otherwise, it may be wise to use graphite, LPS, solvent, aerosol cleaner, spray oil, ether, electronic contact cleaner, silicon sprays, automotive cleaners such as Gunk or carburetor solvents, or other non-lubricating spray cleaners to wash the keyway and pins. Dirt or grit makes picking difficult. WD-40 probably should not be used to clean a lock because of its ability to absorb water. When it mixes with graphite, it can cause difficulties.**

29_2.2 Planning the Bypass

- **What is the ultimate goal:**
    - **Surreptitious entry, one time only;**

   - **Generation of a key;**
   - **Multiple entries;**
   - **Remove, decode, and replace the lock;**

- **Examine the keyway to determine:**

   - **Room to work;**
   - **Clearance for movement of a pick;**
   - **Identification of the best pick to use;**
   - **Identification of the preferred tension wrench;**
   - **Where to place tension wrench;**

- **What method(s) of picking will be attempted;**
- **Which pick and tension wrench will be used as primary tools;**
- **How much tension is generally required for this type of mechanism;**
- **Is there another way to open the target lock;**
- **Are keys or key codes available;**
- **Can the lock be impressioned, and would that be easier and more advantageous than picking;**
- **Will keys be needed for the lock after entry;**
- **How much time is available to open the lock;**
- **What is the projected time that will be required to open the lock;**
- **Is there a way to bypass the locking mechanism without picking the lock;**
- **Is it possible to drill and replace the lock;**
- **Can the lock be decoded, either visually or through the use of a special tool such as the Falle-Safe Pin Decoder;**
- **If the lock is to be opened surreptitiously, be certain to return the plug to the locked position and verify that fact.**

29_2.2.1 Potential Difficulties that may be Encountered

Potential problems can be encountered depending upon many variables, often unknown until an actual attempt at picking is

begun. Problems may be both of a physical nature (to the lock and operative) and psychological. Depending upon the circumstances and constraints involved in the operation, the technician may be under high stress to perform. Such factors as time, danger, visibility, complexity of the lock, prior experience in opening the target lock or similar mechanism, risks of interruption, and consequences of being caught all must be considered.

- **Does the lock carry a high-security or certified rating;**
- **Does the lock utilize unique high-security features such as rotating tumblers (Medeco); rotating disc tumblers (Abloy, Abus); magnetic tumblers (EVVA, Chubb, Miwa); pick resistant lever tumblers such as used in safe-deposit, telephone, and vaults; sidebar (Assa, Schlage, Ikon, Evva, Medeco, Briggs and Stratton); multiple rows of pins used in dimple locks (Keso, DOM, KABA); high-security telescoping pins (Mul-T-Lock, Keso, Kaba);**
- **Is the manufacture known to utilize security tumblers.**

29_2.2.2 Choosing Lock-Picking Tools

Especially for the beginner, how to choose the correct lock-picking tools can be a difficult and confusing question, partly because commercial kits generally contain up to 100 separate items. The selection of which pick and tension wrench to use is based, at least in part, on the following criteria:

- **Type of lock mechanism;**
- **How the lock is mounted;**
- **Picking method to be used;**
- **Size and complexity of keyway;**
- **Pin, disc, wafer, or lever configuration;**
- **Required amount of torque;**
- **Bolt-actuating mechanism;**
- **Personal preference.**

Personal preference is perhaps the most relevant of all factors. The author utilizes only two or three different picks and a

couple of tension wrenches for most locks. The favorite is a long, combination hook-rake pick without a handle. A double-ended pick is very convenient for switching during the bypass process. Often, more than one pick is used to open a specific lock.

Some experts prefer picks with handles; others do not. Many claim that there is a loss of sensitivity. That may be true, but the author uses both rubber-coated picks and ones that are not. If picking many locks, a handle is preferred. Without a covering, fatigue can be a problem. Handles or rubber covering also allows the pick to be held like a pencil, very light-handed. Remember that the object is to feel the pins; anything that facilitates this is acceptable. Pick tips should rarely be broken. If they are handled properly, they will not break. This is especially true of the newer etched stainless steel varieties.

29_2.3 Eight Steps to Successful Bypass

In the author's experience, there are eight critical stages to successfully bypass a lock. These occur after acquiring the general proficiency in manipulation, and the understanding and ability to apply the techniques of lock-picking to a given mechanism. These stages are:

- **Understanding and mastering the fundamental theory of all bypass techniques. These involve the manipulation of active components that directly control the rotation or movement of a plug, cam, or other actuating device. Lock-picking theory encompasses:**
    - **Tolerance errors;**
    - **Knowledge of the design and use of bypass tools;**
    - **Determining which tools will best accomplish a successful opening, and knowing how to use such tools properly;**
- **Understanding the mechanical characteristics and theory of operation of the target lock;**
- **Analyzing the condition and design of the lock, plug, keyway, and active components;**
- **Assessing the factors that will make the lock easy**

or difficult to open;

- **Consideration of special entry conditions, limitations, hazards, or constraints;**
- **Familiarity with special bypass techniques that have been developed for a target mechanism;**
- **Determining which tools will best accomplish a successful opening and knowing how to use such tools properly;**
- **Applying one or more techniques that are most likely to open the lock, taking into account all of the information known about the target lock, bypass techniques available, and the skill and expertise of the operative.**

SECTION 3: Picking Locks

The Process of Picking

Feel-picking individual pins, courtesy of Harry Sher.

Picking simulates the action of a key. The following generic description of the process is applicable to most disc, wafer, and pin tumbler locks. Information for specific locks is presented later in the chapter. The process described below applies equally to manipulation of individual pins and rake picking, although the focus is on conventional procedures (also known as feel-picking). The technique is different for raking, but the theory is the same. The **procedure** is different when mechanical impact devices are used.

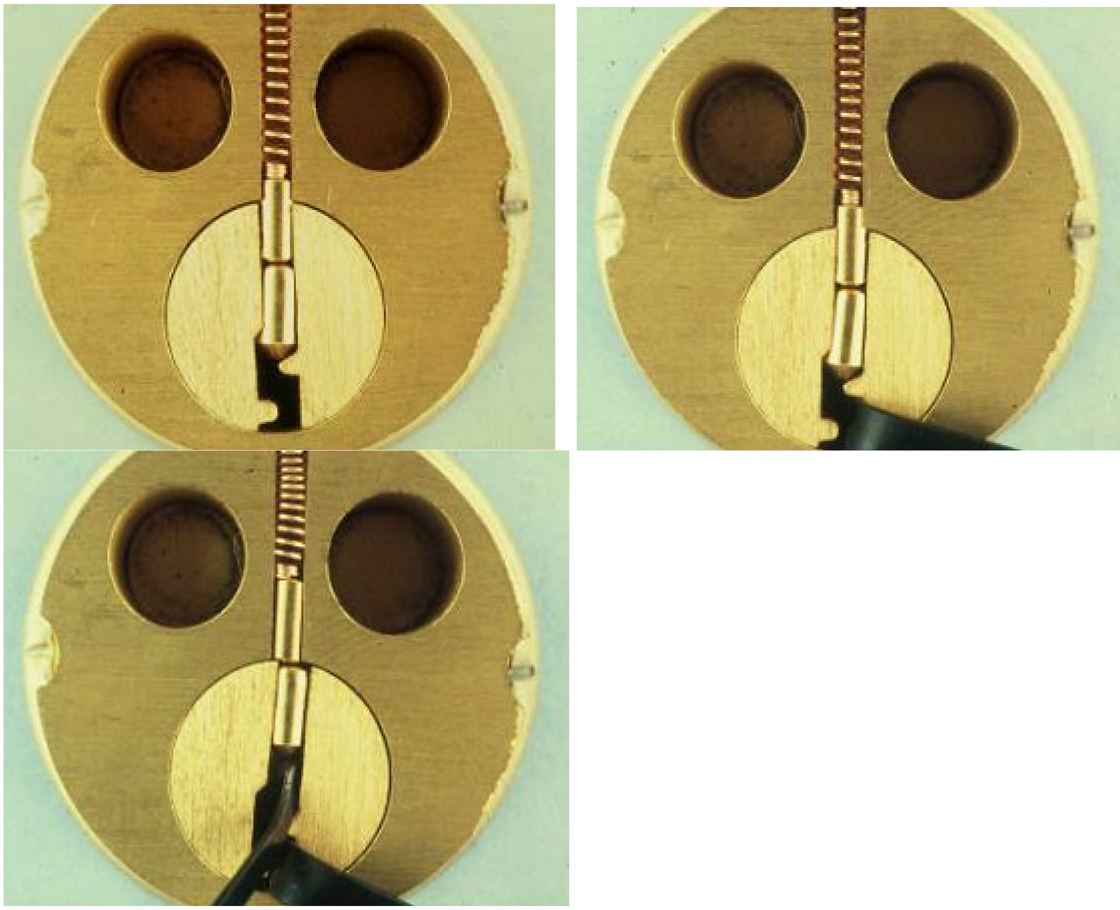

Figure LSS+2929 The process of lock picking requires the application of tension to the plug. A pick is then inserted to raise each tumbler, in order to bind it at shear line. Courtesy of Medeco.

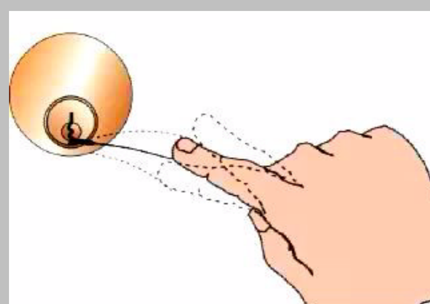
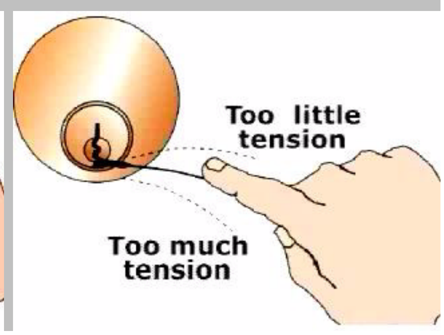
The actual sequence of physical steps involved in picking and opening any lock, and more particularly a pin tumbler lock, require three distinct operations: **the application of torque, the manipulation of each tumbler, and the actuation of the locking mechanism.** If the lock fails to open, then the operative must **assess obstacles** that prevented a successful bypass, select different tools or techniques, and make another attempt.



29_3.1 Theory: Apply Torque



- **Provide varying amounts of tension, based upon:**
  - **The type of lock;**
  - **Experience of the operative;**
  - **Feel and sensory information from the lock;**

- Trial and error during the picking process;
- Once all tumblers are trapped at shear line, rotate the plug.

29_3.1.1 In Practice: Using the Tension Wrench to Apply Torque

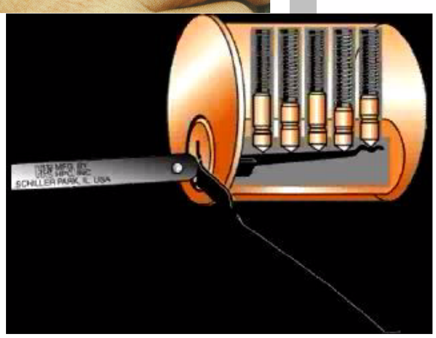


Figure LSS+2901 Methods of application of torque with the tension wrench. Courtesy of HPC Interactive Learning Series.

- **The application of torque allows the tolerance errors of a lock to be exploited in order to set pins at shear line. Often, too little or too much tension is applied, making picking difficult or impossible. During the picking process it may be necessary, as pins set, to increase or reduce tension to specific pins already picked. This is called correction tension. Properly applied, the procedure allows tension to be lessened or increased without affecting those pins that have already set. The technique is especially useful when security tumblers are encountered;**
- **The placement of the tension wrench within the keyway is a matter largely of personal preference, although the location of the wards is certainly a factor. The best place for the torque wrench, from the standpoint of control, is at the top of the plug. Because the torque is at the center axis, there is more room to manipulate the pick. Canting of the plug, causing binding, does not occur. Be certain that the wrench is actually applying torque to the plug;**
- **The properly designed wrench can be inserted at the top of the keyway. Ideally, the wrench should present not only a rotational force but also forward pressure against the plug to maintain its position. The tang will be shorter than the distance to the first pin;**
- **If the wrench is inserted at the bottom of the keyway, be certain that the tang does not dig into the soft brass. If this occurs, burrs can be**

created that may cause the plug to stick;

- **Inspect the keyway to select the proper tool. The tang should be snug when torque is applied. If the wrench is too narrow, it will slip. If too wide, it can require too much room;**
- **When inserting the tension wrench, do not interfere with the movement of the tumblers. Enough room is required to move a pick both horizontally and vertically. The tension tool can be placed at the top or bottom of the keyway, depending upon the design of the wards, vertical clearance, and required picking tools. Be certain that the tool does not contact any of the pins, nor restrict access to the keyway;**
- **When holding the wrench, use the index finger and not the thumb, to apply tension. The index finger is more sensitive; use of the thumb can result in the application of too much pressure;**
- **Begin with a light tension and increase as required. Initially, featherweight tension, approximating the weight of a penny, often works best;**
- **Apply torque to the plug so as not to wedge the bottom of the keyway. It is a common error to apply tension at an angle, thereby binding the bottom of the keyway. Different tension may be required to pick each tumbler;**

- **Tension is not a constant but a variable, dependent upon many factors. A heavy tension is required, especially in some high-tolerance locks. This can only be determined by feeling the spring bias upon each tumbler, then determining the order of picking. Once that order has been decided however, the actual tension required to pick the lock may be slight;**
- **The object in applying torque is to bind only one pin at a time. Too much torque binds more than one pin and can make the lock impossible to open;**

- **Torque should be applied based upon the type of lock and the feel of the tumblers. The application of tension is in large measure a personal preference. Some locks pick better with a featherlight torque; others require very heavy turning pressure. Begin**

with a slight tension;

- **The correct application of torque will result in the plug turning slightly as each tumbler is picked. Generally this is progressive, although when security tumblers are employed such turning will only be for a few degrees;**
- **Learn how to change picking tools while maintaining tension on tumblers that have already been set. This requires that constant tension be applied while switching tools;**
- **Learn how to switch tension wrenches while maintaining a constant tension. This is a bit more complicated and requires that a second tension wrench or small screwdriver be employed to maintain the position of the plug while a new wrench is inserted;**
- **When rake picking, often the tension must be varied slightly without releasing pins that have been set.**

29_3.2 Theory: Manipulate each Tumbler

- **Simulate the action of a key by individually raising each tumbler to shear line. Try to determine the "order of picking";**
- **Whereas conventional picking raises each tumbler in a specific order based upon tolerance errors and misalignment of the chamber bores, raking is the random simulation of the depth of each pin. Try raking the lock. Try picking and raking;**
- **Feel each tumbler at shear line;**
- **Split each tumbler at shear line, and retain the driver above the gap between plug and shell.**

29_3.2.1 In Practice: Manipulating with a Pick

- **The lock will tell you how it needs to be picked and the order of picking;**
- **Analyze the keyway. The pick must be able to meet each pin. There must be space to move the pick and to insert a torque wrench without touching the pins. If the keyway wards are slanted, then insertion of a**

pick at an angle will almost always result in a tumbler being raised;

- **A thorough understanding of the principles of the lock will insure successful bypass;**
- **In order to successfully pick any lock, manipulation of short pins next to long pins and long pins next to short pins must be possible with the selected pick tool;**
- **How far pins must be raised is determined by the length of the bottom pin;**
- **Do not use the pick as a lever. Generally, minute hand movements are all that is required to manipulate tumblers;**
- **Determine if the lock is mounted upside down;**
- **Decide the best place to insert the tension wrench;**
- **Determine which way the plug turns. Generally, mortise dead bolt cylinders mounted on left hand doors will pick counterclockwise (clockwise with right- hand doors). Usually, the bolt must go in the opposite direction of the doorjamb;**
- **Insert the pick into the keyway to verify that there are no obstructions;**
- **Test each spring for bias. Difficulties in picking can result from weak, broken, or missing springs. If there is a problem, try introducing a cleaning or lubricating agent. Heavy springs are generally easier to pick;**
- **Run the pick to the back of the keyway lift and lower the last tumbler;**
- **Count the total number of tumblers in the plug. The number of pins must always be determined in order to provide a reference during picking and to understand the potential difficulty of the task;**
- **Determine the condition of the pin-stack by running a half-diamond pick through the plug to test each pin. Make sure that each pin moves freely and is not sluggish. Oil or grease may have been used that can cause such a condition. Graphite will also cause problems in a humid environment or damp climate;**
- **Make certain that there are no foreign objects in the keyway or jammed pins, master pins, or a loose**

cam. A lodged pin may be cleared by trying one of the following:

- **Spray lubricant: run a blank or rake pick through the lock, then remove and clean;**
- **Compressed air: Do not use your mouth unless you like the taste of solvent;**
- **Bellows (used for enemas);**
- **Try picking: pins may be jammed at shear line;**

- **Select an insertion point for the tension wrench, and verify that there is room for the pick to move without restriction;**

- **Determine the order of picking. Conventional picking requires manipulation of one tumbler at a time. There is no set order, although it is preferred to pick from the back to the front. As each pin is set, there is an absence of spring bias upon that tumbler;**

The term "order of picking" refers to the alignment and tolerance of the bores or chambers with respect to centerline. The bore that is the farthest from center will theoretically be picked first. The next farthest bore would be picked second. Such order would continue, setting pins closer in alignment to the theoretical centerline of all of the bores.

Some locks will pick easier in one direction than another, especially if the pin chambers are not in perfect alignment. The same condition will occur when using a key. Depending upon the bolt works, this may or may not be an obstacle.

- **Select the appropriate tension wrench, based upon keyway design, clearance, type of bolt-actuation system, and personal preference, and apply tension;**
- **An absence of spring bias upon a pin does not mean it is set. Too much tension may have been applied, lodging the pin in the shell. Generally, as each pin is picked there will be an absence of spring bias on that pin. However, this does not mean that the tumbler is at shear line;**
- **If it is an interchangeable core lock and the**

control core is inadvertently picked, the assembly can be removed and the bolt actuated. Otherwise, the plug may be picked again to the conventional shear line;

- **Try raking the lock as an alternative to picking;**
- **Try a combination of picking and raking; the author often utilizes both procedures in one session;**
- **Try picking in opposite direction;**
- **Verify that the applied torque is sufficient to overcome the resistance of the bolt works;**
- **If a security tumbler is encountered, alter the amount of applied torque to set the pin. Release tension slightly, to attempt to set that pin;**
- **After a sufficient number of contacts with each pin during one picking session, release the tension and try again;**
- **If physical or mental fatigue or frustration causes a problem in acquiring sensory information, rest for a few minutes; it is amazing what a short interval can accomplish. Often, one can try to pick a lock for several minutes without success. After just a short break, the lock can be immediately opened;**
- **If the plug is picked in the wrong direction, use a plug-spinner to rotate in the opposite direction while maintaining a picked status. It is suggested that a screwdriver or tension wrench be inserted while manipulating the plug-spinner. If done correctly, the plug can be reverse-rotated without dropping any drivers into lower chambers.**

Figure LSS+2902 The use of the HPC Flip-it tool. The plug-spinner is a spring-loaded device that can spin the plug in the opposite direction without allowing driver pins to drop into lower chambers. This is especially useful if the plug s picked in the wrong position. To operate, the spinner main spring is wound; the tang is inserted into the keyway, and the spring is released. Photographs courtesy of HPC Interactive Learning Series.

Use of a plug spinner, courtesy of Harry Sher.

29_3.3 Theory: Actuate the Bolt, Cam, or other Locking Mechanism

- **Rotate the plug to the unlocked position.**

29_3.3.1 Practice: Retracting the Bolt

- **The bolt may require more torque than anticipated, causing the inexperienced technician to believe that the lock cannot be picked or that the plug has been picked in the wrong direction. This is especially true in the case of padlocks because of shackle pressure;**
- **It is sometimes necessary to switch tension wrenches, or use a screwdriver to turn the plug in such cases;**
- **Try to learn which way the plug is required to turn to retract the bolt;**
- **Look for a very slight rotation, indicating that the lock is in fact picked.**

29_3.4 Theory: Assess Obstacles to Successful Bypass

If the lock does not open on the first attempt, evaluate:

- **Was the lock actually picked, but the plug could not be turned due to the resistance of the bolt mechanism. Could this resistance have been misinterpreted as picking in the wrong direction;**
- **The plug may appear only to turn in one direction; this may be due to worn tumblers;**
- **Spring-bias error caused by broken, compressed, wrong spring, or too heavy a spring;**
- **Not enough room to move a pick, resulting in lifting more than one tumbler at a time;**
- **Wrong style of pick;**
- **Wrong picking technique;**
- **Secondary locking pin, restraining plug from turning;**
- **External mechanical problem which stops plug from turning;**
- **High tolerance between plug and shell;**
- **Too many tumblers;**
- **Long tumbler next to short tumbler;**
- **Made an error in counting the number of tumblers in the lock;**
- **Which way is the lock easiest to pick;**
- **Could any of the tumblers be felt when they set;**
- **Are security tumblers used? If so, in which positions;**
- **Did all but one tumbler appear to set? If so, a security tumbler was not picked;**
- **Could the order of picking be determined;**
- **Adapt torque and picking technique as required;**
- **Change picking technique from conventional to raking;**
- **Pick the lock an adequate number of times, utilizing techniques adapted to the specific situation;**

Difficulties caused by operator error:

- **Could each tumbler be felt during picking? If not:**
  - **Too much tension;**

- **Too little tension;**
- **Lock was picked in wrong direction;**

- **Pick and rotate to 180° and inadvertently drop one or more drivers into the bottom of the keyway;**
- **Pick in wrong order and release one or more tumblers by forcing lower pins into upper chamber.**

29_3.4.1 Practice: Correcting Errors in Picking

- **There are few errors that cannot be corrected during bypass attempts;**
- **If an error is made, simply attempt to determine both the problem and remedy. Often, errors will be complex, so it may be necessary to change several techniques;**
- **If a set pin is floating, there will be no tension;**
- **Some pins will set quite easily;**
- **If a pin is lifted against spring bias and it does not set, a release of tension will cause the tumbler to be forced downward;**
- **If a pin is set, gravity will cause the pin to fall but there will be no spring bias exerted against it;**
- **Sometimes, no pins will set. This can be caused by:**
  - **High tolerance;**
  - **Picking in the wrong direction;**
  - **Security tumblers;**
- **The tops of all bottom pins may be rounded to match the surface of the plug in order to create a closer fit, such as in the Mul-T-Lock;**
- **There may be a short pin below a long pin in the plug;**
- **There may be a bottom pin trapped above shear line;**
- **If a dimple pin tumbler lock is picked such as a Kaba, extreme caution must be exercised not to pick and rotate more than 20°. To do so may result in one or more tumblers falling into the keyway.**

29_3.5 Personal Comments and Observations About Picking

29_3.5.1 General Issues

The theory presented in this chapter provides the fundamentals to successful bypass. However, many issues can only be resolved through experience and practice. The following comments are of a general nature relating to difficulties experienced during picking.

- **The cost of the lock generally relates to its ease in picking. Cheap locks do not generally contain high tolerance components;**

- **Patience is required to pick some locks; it is a fact of the trade;**

- **Vary the tension, tools, and picking techniques. Locks generally may be opened using a variety of tools and procedures;**

- **Multiple attempts may be required. It may be necessary to pick a lock one or more times in order to effect an opening. The time required to pick any given lock can vary from five seconds to thirty minutes or more. Luck definitely plays a factor in the ability to open a lock;**

- **The time required to bypass a lock can be affected by additional issues, including:**

  - **Pressure that the operative is experiencing regarding the "window of opportunity";**
  - **Hazards that may be encountered;**
  - **Security or complexity of the lock;**
  - **Experience of the operative;**
  - **Importance of the assignment;**
  - **Fatigue;**
  - **Other factors.**

These matters should not be ignored when planning a covert operation.

29_3.5.2 Sensory Perceptions During Picking

Two basic questions are always asked by new students to bypass: **What sensations and information is felt during picking, and what is the lock supposed to feel like during the process.** The ability to feel and imagine what is happening inside of a lock is the primary critical skill of the accomplished lock manipulator. Sensory data is complex, and dependent upon many factors. An integration of the skill of the operative with the physical characteristics of the lock is required.

Essentially, what we feel is a very slight increase in the rotation angle as the correct sequence of tumblers is trapped at shear line. This “turn error” or added play is generally less than .002”. Sometimes an almost imperceptible click or snap is also heard or felt as each pin sets.

29_3.5.3 Specific Difficulties That may be Encountered when Picking Pin Tumbler Locks

Many difficulties can arise when picking a pin tumbler mechanism. Critical problems include:

- **Bad springs;**
- **Cold weather;**
- **High tolerances;**
- **Rotating tumblers (sidebar);**
- **Jammed plug, caused by dirt, residue, broken spring, stuck master pin;**
- **Mechanical jam;**
- **Damaged plug from warping caused by attack;**
- **Broken pick lodged in keyway;**
- **How the lock is mounted, resulting in access difficulties, limitations on freedom of movement for the insertion of pick and tension tool, and restrictions on rotation of plug;**
- **Security tumblers;• One or more tumblers at false shear line;**
- **One or more tumblers raised above the shear line;**
- **Jammed master pin;**
- **Mechanical jam that prevents plug from rotating although plug is actually picked;**

- **Physical fatigue and loss of sensitivity.**

29_3.5.4 Locks That are Master Keyed

As detailed in **Chapter 11**, most locks within a business, hotel, apartment, or large complex are master keyed. Depending upon the keying system and the characteristics of the lock, multiple keying levels can make picking a great deal easier. Master pins or spacers are utilized to create added shear lines and thus provide many more opportunities to set each pin. Generally, only two or three wafers will be used unless the system is extremely complex.

Often, a tumbler position having a spacer can be identified by feeling two clicks as the pin is lifted. However, if the wafer has a smaller diameter than the driver and lower pin, then there will be a springy region as the spacer passes through the shear line, because the pin will not bind. In many cases, the master pin is larger than the driver and lower pin. This situation is recognized by an increase in friction as the pin passes through shear line, and a more positive response when the pin is set.

Master pins can also cause serious difficulties in a plug where the chamber holes have been beveled, especially if heavy torque is applied. In this situation, the spacer can twist and jam at the shear line. In certain cylinders, it is also possible for the wafer to actually fall into the keyway if the plug is rotated 180°. To prevent this occurrence, place the flat side of the pick in the bottom of the keyway **before** turning the plug too far. If a master pin or driver does enter the keyway, thereby preventing the plug from turning, the flat side of the pick can be used to push the offending pin back into the shell.

It may be necessary to manipulate the torque wrench during this procedure to relieve any shear force that is binding the spacer or driver. If that fails, try raking the drivers with the pointed side of the pick. If a spacer falls into the keyway completely, the only option is to remove it. A hook-shaped piece of spring steel works fine for this, though a bent paper clip will work just as well unless the spacer becomes wedged.

SECTION 4: Ways of Bypass

Specific Methods of Bypass

29_4.0 Introduction

There are several universally recognized and accepted methods of bypassing a lock through the manipulation of active components. The techniques that are covered in this section include:

- **Conventional picking of individual tumblers;**
- **Rake picking;**
- **Rocker picking;**
- **Picking through the use of impact tools, such as snap guns and vibrating devices;**
- **Comb bypass.**

These standard techniques will not work with certain high-security and certified locks, including sidebar, rotating tumbler, special lever-tumbler mechanisms, and certain vending machine locks. Data regarding the bypass of these and other specialty locks is covered later in this section, and in **LSS+/^{x} CD/ROM.**

29_4.1 Conventional Picking

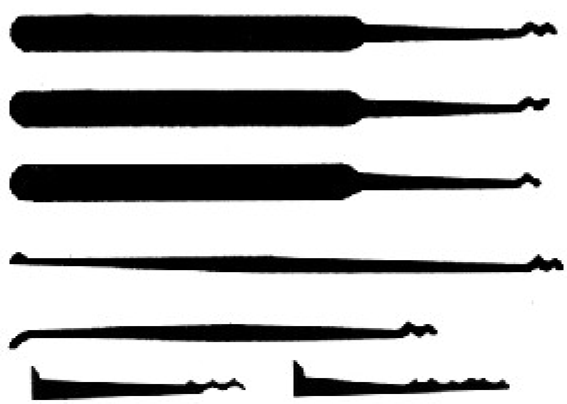
This discussion will focus on picking the pin tumbler lock, but in general is equally applicable to the disc, wafer, and lever locks. Specific techniques for bypassing these mechanisms are presented later in this chapter. The reader is directed to the preceding section for a detailed examination of the theory and practical aspects of bypass. Picking is actually a combination of individual manipulation and raking of some or all of the tumblers. Often, one or more pins are individually picked; then all of them are raked until the lock opens.

Almost all locks that have some form of shear line and tolerance errors can be picked. However, patience and skill are required to pick not only high-security locks, but some of the less expensive ones as well. Lock-picking relies upon a **negative locking theory**; the vertical binding of pins to block rotation always occurs, until the tumbler is lifted to the correct height. In contrast, impressioning relies upon a **positive locking theory**. It is desirable that the vertical binding of tumblers always occurs except when raised to the correct height.

The cost and security rating of a lock is only a general index to its pick resistance. Sometimes, even the most expert craftsman

is unable to open a lock regardless of cost or complexity. Often the use of different tools, a change in tension, variance of technique, or simply a short rest can mean the difference between a successful bypass and failure. Picking a lock in the conventional fashion is a rather straightforward procedure. That does not mean it is simple, but it can generally be done "by the numbers." As noted elsewhere, picking is based upon cumulative tolerance errors.

To pick a lock, the correct order of out-of-tolerance pins must be determined. That is, those pins that are farthest out of alignment on an imaginary centerline longitudinally across the plug will be bound first. It is a matter of physics. With torque applied to the plug, the pin that deviates the most from center alignment will be the first to be contacted when scissored between the plug and shell. The primary function of torque is to bind pins at that point where they are wedged at shear line. The "trick" in picking locks is to correctly determine the order in which the pins do in fact bind, then to cause each one to "set" at shear line and remain there. When all pins are so set or split (with the drivers residing above shear line and the bottom pins below the break), the lock will open because there is nothing to prevent rotation of the plug.



In its simplest theoretical form, lock-picking requires that **the correct order of picking be established; the proper torque be applied; each tumbler be lifted to shear line; and those pins which have been picked are retained in that position.** A detailed analysis of each of these procedures is presented in other sections so there is no need to repeat the material here.

Obviously, there are many obstacles between the beginning of this journey when the pick and tension tools are inserted into the keyway and the end of the trip when the lock is opened. Such matters as tolerance, keyway design, security tumblers, pin-stack configuration, master keying, locking mechanisms, and other issues can vastly complicate the procedure. Regardless of the type of lock, the theory is always the same. A. C. Hobbs, quoted in the introduction of this chapter, was precisely correct almost 150 years ago in his assessment of locks that could be picked.

29_4.2 Rake Picking

The technique known as raking or scrubbing is a shortcut for the traditional and more methodical means of picking a lock. Raking, when done properly, will open many locks quickly unless there is

a large difference between tumbler lengths. When raking a lock, no specific tumbler is targeted for manipulation; the rake is gently or vigorously moved across the pins, depending upon many factors.

In the author's view, much less talent and training is required to rake a lock, but the chances of success, especially with the more difficult locks, are greatly diminished. Having said that, however, raking may also make it easier to determine which pin sets first. Proficiency in raking does not require the same level of sensitivity, feel, and touch that is developed by a real practitioner.

Raking will always open **some** locks. Picking will generally allow bypass of **all** locks. Often, locks are picked **and** raked to accomplish a bypass. Raking can be analogized to driving a car. An inexperienced driver has no problem driving on a straight road. However, any turns, bends, or obstacles may cause difficulties, especially at high speed. So it is with raking.

A lock with similar bitting depths for all tumblers or a stair-step pattern with no security tumblers and poor tolerances will be easy to open. When, however, any of those parameters change, the inexperienced operative or one with little training in the real art of lock-picking will have trouble. Rake picking in many cases may allow rapid determination of which pin sets first, especially where all pins seem to bind and exhibit the same friction or resistance to movement.

Raking should place just enough pressure upon all of the pins to overcome the spring bias and binding forces exerted upon them, but not so much as to exceed the collision force of the lower pin traversing the shear line. Any pressure within this "window" will

suffice. In practice, any pick can be used for raking, although an actual rake pick may be preferred. The tip is run across the tumblers from back to front several times. This may raise some or all of the pins to shear line. If that does not occur, the pick may be moved slowly across each tumbler or each may be raised individually, often with varying tension. It must be remembered that raking is random action, with less precision than conventional picking. It really is the rapid manipulation of each tumbler.

As the pick passes over each pin, it will move that pin to the shell but not **through** shear line; the shell will block the movement of each tumbler unless too much pressure is applied. So, the trick is to apply **just enough pressure** and to allow flexibility in movement of the pick, so that it will ride over a pin when that pin is blocked from vertical movement at shear line. If any tumbler is forced into the shell, then one must start over. During rake picking, if the proper torque is applied and the proper pressure placed on each pin, the plug will rotate slightly as each tumbler sets. Concurrently, the driver will be trapped above shear line and the lower pin will fall to the bottom of the keyway. It is recommended that light then heavy tension be used, at least by the beginner.

In theory, one stroke of the pick over the pins will cause the lock to open, and sometimes that is indeed the case. In practice, at most one or two pins will normally set during a single stroke, so several passes are required. Thus, the pick is moved over the pins several times while the amount of torque is adjusted according to feel. Depending upon the lock's mechanical characteristics and those of the pin-stack, pins will tend to set in a particular order. The theory of why pins set is covered elsewhere in this chapter. Generally, a lock can be raked as a result of the misalignment between the center axis of the plug and the axis upon which the holes were drilled.

If the axis of the chamber holes is skewed from the centerline, then the pins will set from back to front when the plug is turned one way. Likewise, they will set from front to back if the plug is turned the opposite direction. Most locks will have this skewing error. Although raking can allow rapid opening, it still requires practice to become proficient. Many characteristics will inhibit the ability to open a lock in this fashion. In such cases, individual pins can still be raked.

29_4.2.1 The Procedure to Rake Open a Lock

This procedure is a generic description that is applicable to most disc, wafer, and pin tumbler locks. Information for specific locks is presented later in the chapter.

- **Insert the pick and torque wrench into the keyway. Without applying any torque, withdraw the pick to assess the spring bias on the pins to insure that there are no obstructions in the keyway, and to count the number of pins;**

- **Reinsert the pick, then apply a slight tension. As the pick is removed, apply upward pressure to the pins just slightly greater than the minimum force necessary to overcome the spring bias;**

- **Gradually increase the torque with each stroke of the pick until pins begin to set;**

- **Now keeping the tension fixed, rake back and forth over those pins that have not set. Be very careful to allow the pick to ride over set pins. This is the essence of raking: only apply enough tension to depress pins that feel springy or differently than pins that have already lodged at shear line. If no additional pins set after several passes, pick each pin individually or release the torque and start over, repeating the process;**

- **Once the majority of the pins have been set, increase the torque and rake with a slightly increased force. This will generally cause those remaining tumblers to set.**

29_4.2.2 General Rules and Principles for Rake Picking

There are a number of general principles and rules to successfully bypass a lock by raking:

- **Rake picking does not target any specific tumbler but rather applies force to each in a random fashion;**

- **The function of the rake pick is to randomly simulate the bitting of a key while applying sufficient torque to set each pin at shear line;**

- **The force applied to tumblers may be varied as the rake is passed across their surface. The range of force will depend upon many factors and include both gentle and vigorous motion;**

- **The pick must be free to come into contact with all pins;**

- **Light tension is generally preferred when first raking a lock to set any possible pins and to feel the status of all tumblers;**

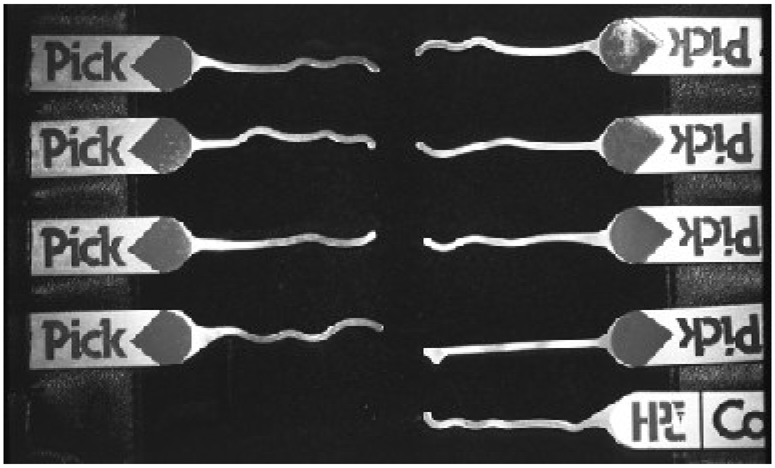
- **After the first rake, one of three conditions will exist:**
  - **Pins are in an original position, not bound, at rest;**
  - **Pins are bound, but not set;**
  - **Pins are set;**

- **Remember: pins will only pick one at a time;**

- **Pins should be raked two or three times. If the lock does not open, then the tension should be released, listening to hear how many tumblers were probably set (indicated by clicking or snapping upon release). If pins did not set, then generally the cause is either too little or too much tension;**

- **Raking is generally accomplished on the outward stroke (removal of pick) rather than on the inward stroke;**

- **Often, tension must be varied during the picking process from slight to hard without losing control of the plug. This can be a tricky procedure, because there is a very slight range of torque that**



will retain set pins at shear line. For the beginner, the best learning exercise is to mount locks on a board and rake with only two or three tumblers inserted.

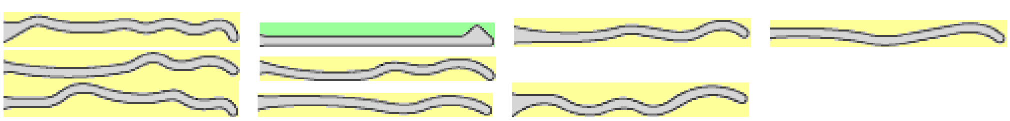


Figure LSS+2903 The pick must be free to access each pin individually without disturbing the position of adjacent pins. In the diagram, a rake pick has been inserted so as to reach the last tumbler. The photographs demonstrate how the pick is moved in and out of the lock. Courtesy of HPC Interactive Learning Series.

29_4.3 Rocking Open a Lock with Computer Generated Rake Patterns

A slightly modified approach to raking employs specially designed picks in a process called **rocking**. The procedure is different than raking, in that each pick in a series or set has a carefully designed signature of varying depth simulations. Rocker picks are not, strictly speaking, rake picks although there are some design similarities. They are often complex in shape and generally double-sided.

The procedure for this type of bypass requires that a pick be inserted fully into the keyway, then lifted and rocked in a vertically angled motion while applying torque. The theory is that at some point, random motion of the pick and the selected bitting pattern of the tool will lift each tumbler to shear line. Both sides of the pick should be utilized; light tension is recommended. HPC and other vendors produce rocker picks. The HPC Israeli designed series (HPC COMP-1) contains nine picks within the set and simulate various tumbler combinations, determined from computer modeling. These picks can be quite effective for opening certain locks. Various signatures are shown below.

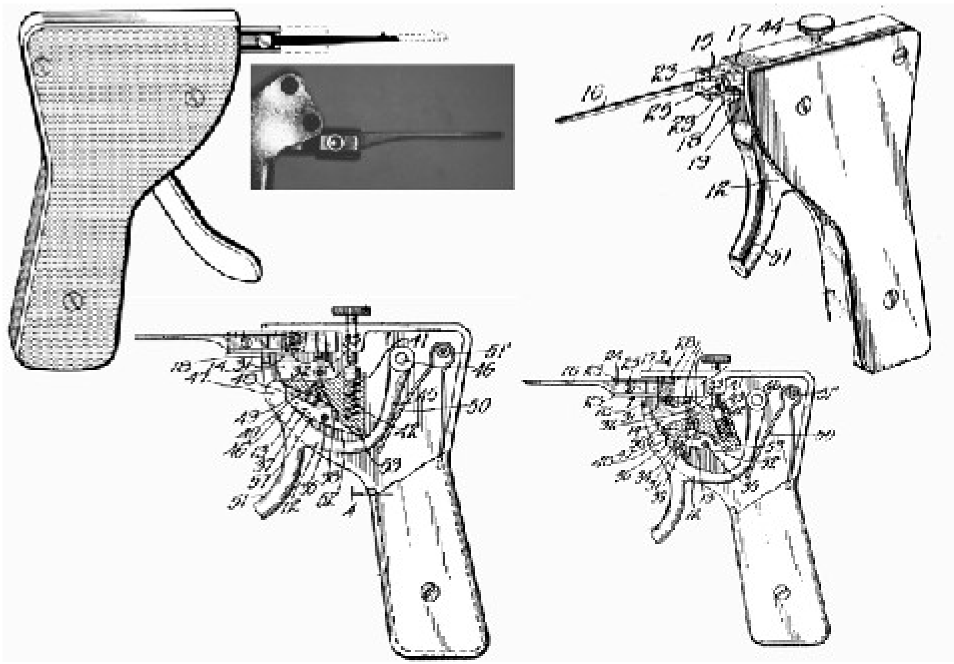
29_4.4 Bypass Using Impact Tools

Use of a pick gun requires skill. It also leaves forensic indications. Courtesy of Hans Mejlshede.

A discussion regarding the impact pick gun, by Harry Sher.

How does impact picking work? Courtesy of Harry Sher.

There is a class of lock-picking tools that rely upon the generation of a mechanical shock or impact applied to the base of all tumblers simultaneously in order to bounce drivers into the shell for a brief window of time. These tools can be loosely categorized as impact guns or tools and are primarily designed for pin tumbler locks. Included in this definition are

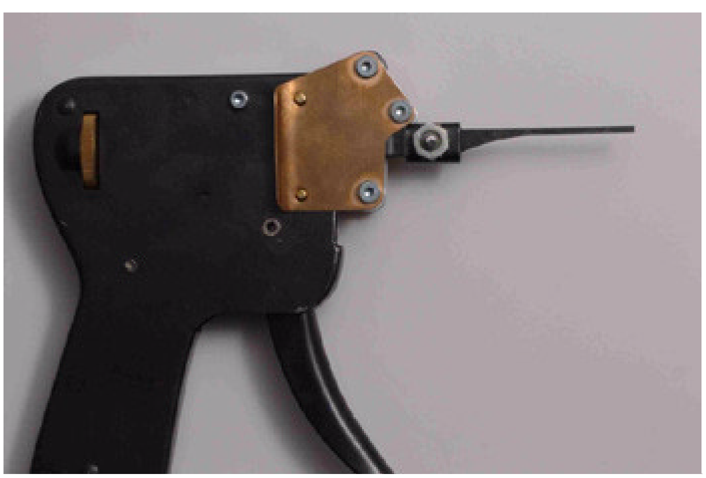


mechanical devices such as manufactured by HPC that transmit energy through a steel tip. The energy is generated by the operator pulling a spring-loaded trigger that moves the tip vertically. Depending upon the tool, the tip-travel and spring tension can be adjusted.

Vibration picks can be classed in the same general family. They utilize an electric motor to generate movement and different oscillations at the tip of a spring steel wire or blade. These tools can be quite effective in opening locks, especially those having security tumblers. However, they do require some practice and will not allow everyone to use them effectively. The author prefers conventional picking or raking and considers impact tools as gizmos and shortcuts to mastering the art of bypass.

Many law enforcement agents utilize impact tools because they have not acquired the traditional lock-picking skills that are customarily developed by a professional locksmith. Although these tools will open many locks, they are in the view of the author "gimmicks." They still require talent and an understanding of their working principles. They offer the promise of instant success without learning the complex theoretical and mechanical underpinnings so necessary to operate in today's security environment. Any competent criminal will usually install high-security locks in their homes, offices, safes, storage enclosures, and anywhere else that will contain the evidence or the fruits of their crimes.

Sophisticated criminals have a far greater ability to afford the best in security hardware. Impact-type tools may open some of these locks, but they should only be viewed as one tool in the arsenal of the covert entry team. These devices should never be thought of as "the" entry tool, nor should be relied upon in such instances. Pick guns, in many forms, have been the subject of U.S. patents. As early as 1927, percussion and violent rotational force was employed as a means to open pin tumbler locks (**1667223(259)** and **1639919(260)**). See also Epstein and his 1923 patent for a impact producing implement (**1450435(261)**), and (**1403753(262)**) by the same inventor in 1922.



29_4.4.1 Snap Gun Construction

Exploded views 1, 2. There are many different tips available for the HPC pick gun.

 **The use of pick guns and forensic analysis of locks. Courtesy of Hans Mejlshede.**

Mechanical snap guns generally are constructed with a pistol grip, trigger, and removable blade that is either straight or angled. The tool is operated by placing the blade under the pins and squeezing the trigger. This causes a spring within the pistol to retract and release, violently moving the blade in an upward direction.

This pick gun is unique, in that the blade can be reversed for use on European profile cylinders. It was developed by Kurt Zuhlke.

Other similar tools operate on the same principle but have slightly different designs. A piece of wire fashioned as a spring can be as effective as the electric vibrating gun, detailed below. It appears that the first snap guns were patented by Wakstein and Hanflig in 1934, then by Segal in 1943 and Miskill in 1951, (**1944006(263)**, **2309677(264)**, **2565254(265)**). See also Wakstein (**1977362(266)**).

29_4.4.2 Theory of Operation

All impact tools operate upon the same principle and which is discussed elsewhere in this text. Essentially, energy is applied to lower pins that in turn is transmitted to driver pins. If done correctly, in terms of force, angle of contact, and consistency between all pins, then all drivers will for a brief period, float or reside **above** the shear line. If a rotating torque is applied during this brief interval, then the plug can be turned.

The actual physics of the tool is based upon Newton's Third law of motion. The snap pick has been used by locksmiths since at least 1934, when the first patent appears to have been granted for such a device (**1944006(267)**, **2565254(268)**, **2309677(269)**). Snap guns cannot be used as a conventional picking tool; they are designed to act upon **all** tumblers at one time, rather than individual pins. Several factors determine whether the lock will respond to this type of manipulation:

- **The shape and design of the keyway will control how the tip makes contact with the tumblers and its vertical freedom of movement. The pick must be able to move without obstruction. Paracentric keyways**

can pose a serious problem;

- **The thickness, condition, and length of the tip of the impact tool must be correct. The tip cannot be distorted or bent and must be long enough to make contact with each tumbler. The tip material must be thin enough to move about freely in the keyway just below the pins. There can be no sharp edges or burs on the tip or along its surface;**

- **The vertical orientation of the tip must be correct so that the center of each pin is struck, rather than the sides or chamber walls. The position of the pick and its angle of attack is critical;**

- **The pick strikes the pins, causing them to bounce. It does not vibrate or oscillate as with an electric vitiation tool;**

- **The condition of the springs in each chamber will determine how each pin moves and what force is required;**

- **The length of the tumblers, their metal content, and weight will determine how much force is needed to move them above shear line;**

- **The precise time when torque is applied will determine if the plug can rotate or if one or more tumblers are caught in the lower chambers;**

- **The presence of foreign materials such as dirt, oil, or debris can affect or retard the ability of pins to freely move within each chamber.**

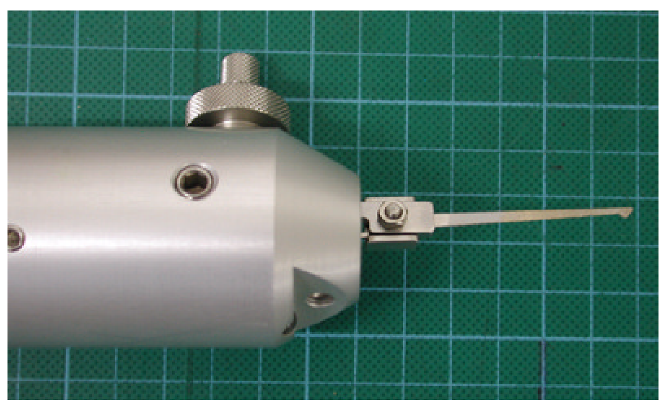
See the description in **Chapter 26** for added information.

29_4.4.3 General Rules and Principles for the Use of Impact Pick Tools

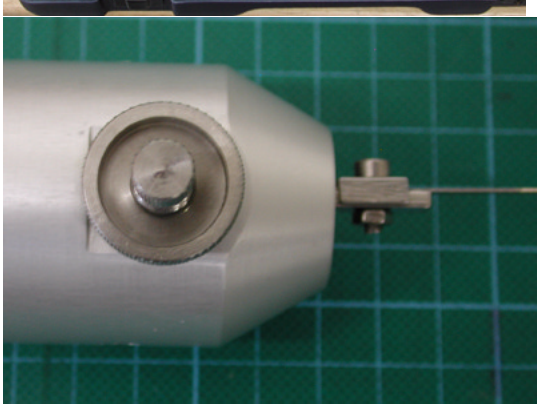
There are a number of general principles, guidelines, and rules for the successful and proper use of impact picking tools.

Failure to follow these guidelines will result in increased difficulty in opening locks or the inability to bypass certain mechanisms. This discussion primarily applies to snap tools, although the principles are similar for electric vibrators.

- **Impact tools present a totally different method for bypass. The tools cannot be used to manipulate each tumbler individually. Do not attempt to pick each pin;**
- **When squeezing the trigger, do not move the gun up, down, or to the side;**
- **The blade must strike all pins at the same time. An offset blade, which requires holding the gun at 90°, are quite difficult to control. The top of the blade must be exactly parallel to the shear line, with no sharp edges or burs;**
- **If a thinner blade is required due to the design of the keyway, then material should be removed from the tip;**
- **The angle of attack must be 90° ±4°. The blade cannot be successfully used in a slanted keyway. There can be no angled upward pressure on any pin; the strike must be from below the center-point of the tumbler;**
- **The tip strikes the pins, transmitting a reaction to abutting tumblers. The pins do not actually vibrate or oscillate. The tip cannot be distorted or bent;**
- **The intensity and range of movement of the tip must be adjusted depending upon the bias placed on the tumblers by their springs;**
- **The pick should not be wiggled or jiggled in the lock. It does not work that way;**
- **The sides of the keyway nor back of the plug should ever be touched by the pick tip;**
- **The correct amount of tension must be applied precisely at the moment that all pins are above shear line. Do not apply too much tension or the pins will bind. Begin with a slight tension, then increase it as required. A standard tension wrench or the blade of the tool can be used to create rotational force. The application of tension is critical to the success of the process. Too much**



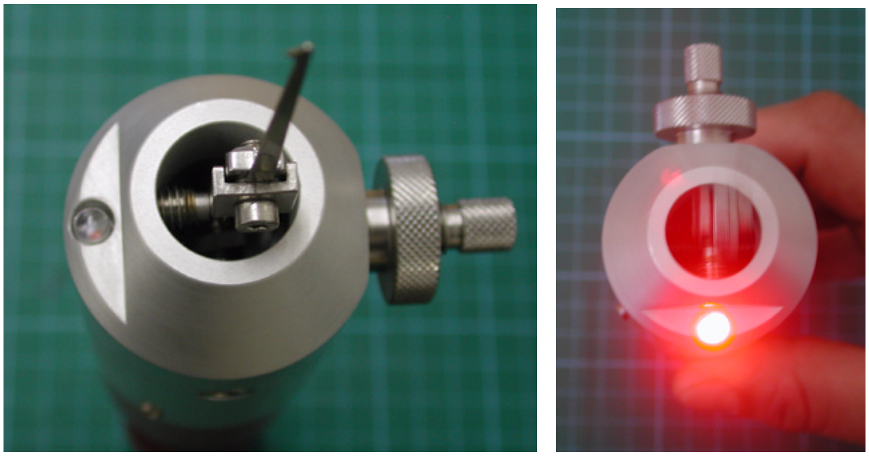
torque will result in a binding of both bottom and top pins and will prevent the top pins from being bounced above shear line. Too little tension will result in both bottom and top pins being moved by the force from the vibrating tip. The optimum torque will bind the bottom pins, but not the top pins, allowing the shock from the pick to be transmitted through the bottom pins, but not moving them.



- **Do not apply tension prior to a release of energy from the gun;**
- **The active motion of the pick is in the upward direction; no tumblers are picked during the downward stroke or below the pick.**

29_4.4.4 Electric Vibrating Tools

Many companies produce vibrating pick guns. The design allows the tip to move at various frequencies or intensity. MSC produces a well engineered tool that allows a variety of different tips to be inserted. An LED provides illumination to the surface of the keyway.



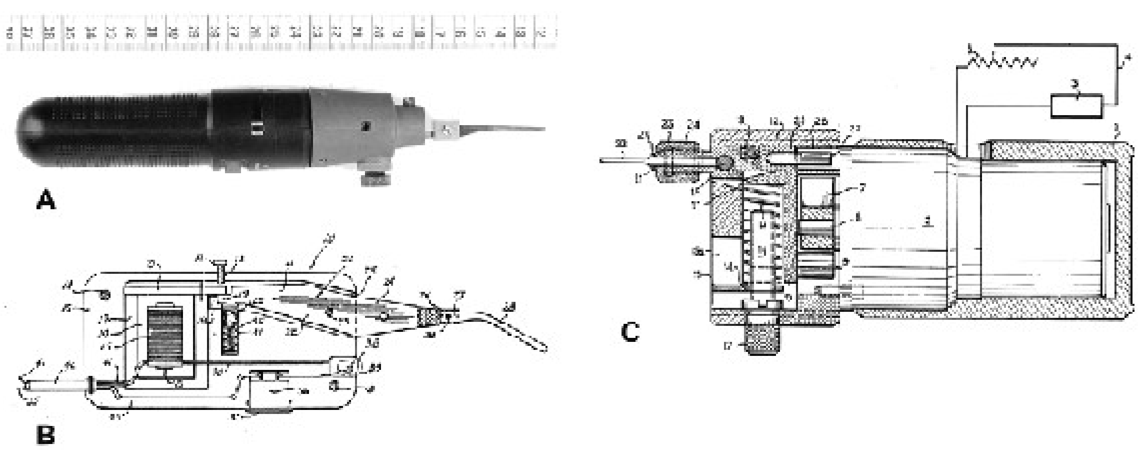


Figure LSS+2932 The MSC Electropick allows controlled manipulation of pin tumblers.

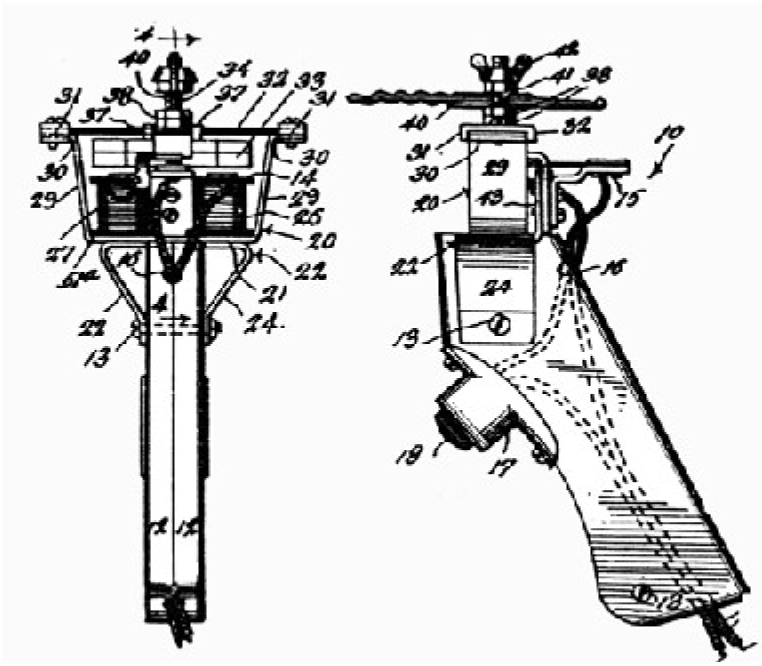
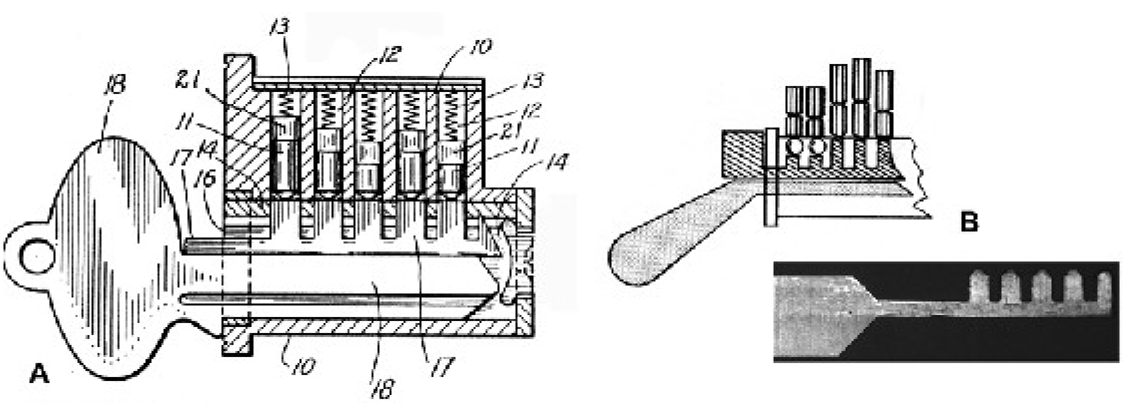
LSS203: Demonstration of the MSC electropick on a profile cylinder



The HPC tool creates oscillations of varying intensity, depending upon blade setting. The tool's operation is based on the same theory as the snap pick, with slight variance.

Exploded views 1.



To bypass a lock, the blade is inserted into the keyway to contact the base of the tumblers. The fundamental difference in operation to the snap tool is that tension can be applied while the lock is vibrated, so that the tool resembles an automated rake pick. In the alternative, pins can be vibrated and then torque applied as with the impact tool. Torque can also be applied with a tension wrench or the blade of the tool itself. This tool can be extremely effective in opening some locks, with little or no experience with bypass. Two electrically powered snap pick guns have been patented in the United States: one driven by a solenoid (in 1979), and an earlier version controlled by an electromagnetic coil (in 1966) (**3264908(270)** and **4156375(271)**).

Exploded view.

29_4.5 The Comb Pick

The comb pick has probably been in existence for over a hundred years. Its success relies upon a manufacturer's failure to utilize balanced drivers in pin tumbler locks, thereby creating the ability to force all lower pins above the plug. When this occurs, the teeth of the comb will in effect create a new shear line.

In the properly pinned lock, each pin-stack has the same length. That is, a short bottom pin will have a correspondingly longer driver. If the bottom pin is for a deep cut, then the driver

will be that much shorter.

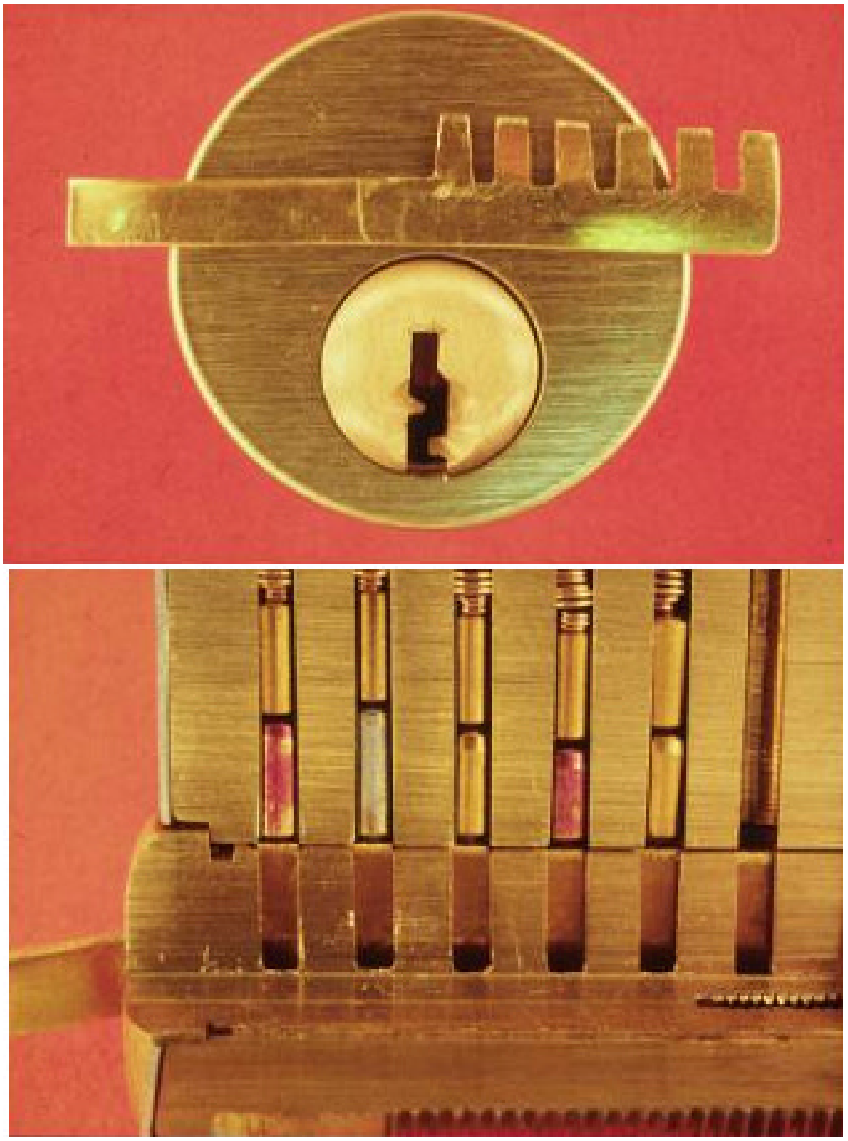


Figure LSS+2930 photographs showing how the comb pick creates a new shear line. Courtesy of Medeco.

The overall length of the pin-stack is computed by adding the length of a compressed spring and all pins within a chamber. The pin-stack must be longer than the vertical dimension of the upper chamber. If not, then all pins in the stack can reside in the top chamber, and there will be nothing to keep the plug from rotating. A U.S. patent was granted for a comb pick in 1936 (**2064818(272)**). Corbin locks manufactured from 1902 to the mid-1960s were particularly vulnerable to comb picking because they utilized a .116" ball bearing in each pin chamber to reduce

wear in high traffic cylinders. The comb pick would utilize the bearings to create a unique shear line and thus presented a serious security issue.

29_4.6 Shimming Open a Lock

As described elsewhere in this text, shimming using a fine wire can open a pin tumbler lock. This practice is utilized for three distinct procedures:

- **Lock disassembly where no key is available;**
- **Decoding of the lock using the Falle-Safe Pin Lock Decoding system;**
- **A method of forced-entry that requires drilling a tiny hole in the front of the lock.**

The theory underlying all shimming procedures is straightforward. A very thin wire with a thickness of between .0015" and .002" is inserted between lower tumblers and drivers, at shear line. The shim splits the pins, mirroring the physical characteristics of the correct key. Depending upon the technique, the shim can be inserted from the back of the cylinder for disassembly, from the front of the cylinder for covert entry, and from the base of the pins to decode their length.

29_4.6.1 Falle-Safe Decoding System

The Falle-Safe Pin Lock Decoder is described in Chapter 31. It is a sophisticated and highly precise tool, originally developed for use by government intelligence agencies. It allows the insertion of an extremely fine shim wire between the pin tumblers and their chamber walls to measure the exact length of each lower pin.

29_4.6.2 Drilling and Shimming

This procedure requires that a very small hole be drilled through the front of the cylinder, corresponding with the precise location of the shear line. An extremely fine wire is then inserted, while a pick is used to raise each tumbler (from front to back) to shear line. The wire is forced between upper and lower pins until it reaches the last pin. At that point, a shear line has been created by the wire: all drivers are above the wire, and all lower pins are below it. The plug can be turned and the bolt actuated. The pin lengths can be measured while the

lock is in the picked position to allow generation of a key. The hole can then be filled, erasing any trace of the procedure.

29_4.6.3 Lock Disassembly

Often, a cylinder must be disassembled for which the keys have been lost. Although this practice has been detailed elsewhere in this book, it will be summarized here. It is in fact the exact same procedure as employed when **drilling and shimming** described above with slight modification. The theory underlying this technique is that a fine shim wire can be forced between top and bottom tumblers to create a shear line. The wire is inserted into the gap between plug and shell from the **rear** of the lock after the cam and retaining screws have been removed. The operation requires two actions: insertion of the wire with a constant pressure applied to it, and the raising of each tumbler in succession, from the rear of the lock forward using a blank key.

Shims may be purchased or they can be produced by cutting mainspring wires from watches and clocks. Often, a curved tip is easier to insert between pins. The author prefers a shim having a width of at least .0625." If the end becomes damaged, it is simply cut with scissors. Security tumblers, except for serrated ones, can be shimmed in the same fashion. However, remember that some pins may be found in upper chambers. To shim open the lock, the following steps must be accomplished:

- **Insert the wire at shear line from the rear of the lock;**
- **Advance the shim until it contacts the first pin-stack and apply pressure. Do not apply too much pressure, however, or this can prevent the bottom pin from falling, or the tip of the shim can be deformed;**
- **Insert a blank key completely into the plug;**
- **Remove the blank slowly until the wire catches at the split between top and bottom pin. Feel the pin as it scratches the side of the shim. The minute gap between top and bottom pin can be felt;**
- **Move the blank back and forth, if necessary, to manipulate the pin that is to be split by the shim. Do not move the blank forward when manipulating a single pin. The blank may, however, be withdrawn**

slightly and then pushed back into a position to move the pin up and down. If an attempt is made to insert the blank to raise a pin that has already been split, the shim will be deformed or dimpled and may be difficult to remove;

- **It is sometimes difficult to lodge the shim between pins. It may be necessary to raise and lower a pin several times with just the right pressure in order to lodge the shim at shear line;**
- **As each pin is split, the shim will move forward across the plug: the blank will not be able to move as far toward the cam;**
- **When the last pin has been split, turn the plug at least 20° and remove the shim;**
- **Withdraw the plug with a following tool.**

29_4.6.4 Picking with a Blank Key

A blank key can be utilized to open some locks, much the same as if a shim were inserted to the rear of the plug. The theory is that a slight torque is applied as a blank is slowly withdrawn. As it moves across each tumbler, the lower pin will drop to the bottom of its chamber if the right amount of tension is applied. A major European lock manufacturer was quite embarrassed to learn that one of their profile cylinders could be opened in like manner with one hundred percent repeatability by using a blank key. Upon being notified of the problem after the locks were released to different customers, an investigation revealed that one manufacturer in the group was pinning the plug, while another inserted springs and top pins into the shell. The cylinder and plug were mated at one of the factories and repinned with the correct combination for a specific customer. The pinning by two different automated facilities was done for efficiency. Unfortunately, the diameter of the top and bottom pins were slightly different, although the diameter of the chambers was correct, and sufficient to allow proper vertical movement. The author tested one of these locks and found it to be extremely easy to open within a few seconds.

29_4.7 Multiple Tumbler Sets and Cross Picks

LSS203: Demonstration of the MSC cross pick on a lock with four rows of

tumblers

Locks may contain multiple bitting surfaces to provide added protection against picking. A number of picks have been developed to manipulate all of the rows of tumblers at one time, much like a rake pick. MSC in Hamburg, Germany makes a pick to open three and four rows of pin tumblers. As shown in the video demonstration, the pick is raked across the pins simultaneously while tension is applied.

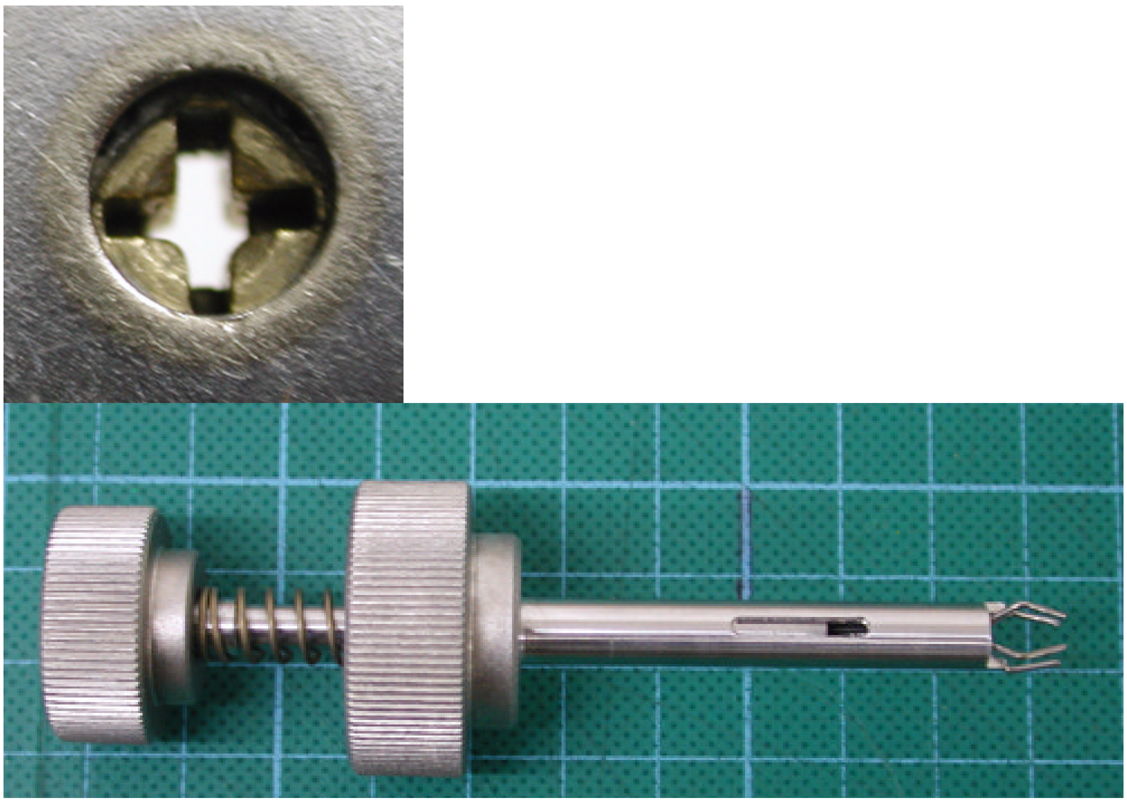

Figure LSS+2931 The MSC cross pick has four protruding wires that make contact with each row of tumblers, as shown in the lock. Each set of pins is manipulated at the same time.

SECTION 5: Skills Acquired

Developing Lock-Picking Skills

29_5.1 The Basic Skills

It should be obvious to the reader that picking a lock is a

complex process encompassing many variables. Although with practice most obstacles are overcome more or less automatically, one must develop specific skills by addressing each unique mechanical characteristic. Lock-picking skills require a great deal of time to perfect. Knowing the theory of bypass is a small step in acquiring competence in the art. A. C. Hobbs was one of the greatest lock pickers. He summarized the characteristics required of one who wishes to be effective at bypass:

- **Ingenuity in the development of tools;**
- **Able to assess the invisible anatomy of a lock mechanism;**
- **Patience and persistence;**
- **Fundamental knowledge of the internal workings of the lock;**
- **Self-confidence.**

Hobbs felt that one must also have an inborn skill, delicacy of touch, and an ability to memorize numbers and calculate permutations. Finally, he stated that the expert must be able to accumulate knowledge about people's minds and the way that they think. The author recommends certain exercises to hone skills, especially for the beginner. It is much like learning to fly an airplane; one practices stalls, dives, climbs, adjusting to wind and other variables in order to become proficient. Lock-picking is no different.

The exercises outlined in this section should be completed in short sessions; they can be fatiguing, with diminishing results. After a few minutes, fingers can become very sore and a resultant loss of concentration will occur. If the ambient temperature is either hot or cold, even more difficulty can be encountered. It is also recommended that for the beginner, a lock having only two tumblers be mastered first in the practice exercises; then slowly, more tumblers are added until a six or seven-pin lock can be opened. Locks should be mounted on a practice board or door so that variance in picking techniques and tension can be mastered. Picking cannot be learned by holding the lock by hand during actual tumbler manipulation because such does not simulate real conditions.

To learn about the lock and its mechanical configuration, it is recommended that the plug with lower pins be held in the hand. Run a hook-pick through the keyway, thereby demonstrating how each pin is raised to shear line and the minimal effort required

to do so. This technique will provide a feel of the pins and the movement of the pick inside of the lock. Practice by moving each of the pins to shear line. A cylinder with one pin (such as a Schlage 923) should then be used. Start with one long pin in the #3 position. Light tension is applied. Learn the feel of one pin and spring.

Remember that much of picking is a state of mind, believing that the lock can be bypassed. A five-pin lock with one tumbler set becomes a four-pin lock. When a lock is approached, a great deal of analytical thinking may be required to successfully bypass the mechanism. Certain things may be known from prior experience, industry reports, or knowledge of fellow craftsman.

As previously noted, each lock has its own special characteristics that will affect the ease with which it is opened. The recognition and exploitation of "personality traits" of a lock separates experts from amateurs. Locks will talk about themselves: they will provide feedback to diagnose traits. It is then a matter of relying upon experience to decide on the correct approach for a successful opening. This process may occur in seconds or may require some planning. In high-security bypass scenarios, it is always best to practice on sample cylinders before attempting an actual opening. This is especially true if sophisticated decoding methods are employed.

The novice will generally underestimate the analytical effort that is a necessary part of lock-picking. Incorrectly, they often think that the pick opens the lock, and that the torque wrench is a passive tool that simply places the required tension on the plug. In truth, many factors and forces come into play during the process.

29_5.1.1 Basic Skills: Lock-Picking and Hand Coordination

Mastering the correct method to move the pick over wafers, discs, levers, or pins is surprisingly difficult. This is because of the requirement to maintain a fixed position or path for movement, independent of the amount of force to be exerted. Lock-picking requires the application of a relatively fixed force that is independent of the position of the pick. However, that force may instantly vary, depending upon the feedback (resistance) received from each pin. That feedback is based upon feel and sound. A great deal of practice is required to acquire this skill.

29_5.1.2 Basic Skills: Lock-Picking and Analytical Thinking

Because the internal components cannot be seen during lock-picking, their position must be visually reconstructed from the information gathered from sound, touch, smell, and vision. That mental image is the key to successful bypass. Lock-picking consists of the exertion of pressure to move active components (discs, wafers, levers, tumblers), and the coincidental application of torque upon the rotating plug, in order to bind the pins and trap each of them at shear line. A number of training exercises can enhance the ability to successfully bypass a lock. These are detailed below. At all times while picking a lock, one must:

- **Know what is happening inside of the lock;**
- **Know when a pin is binding;**
- **Know when a pin-stack is not bound;**
- **Know when a pin-stack is set.**

29_5.1.3 Bouncing the Pick

This exercise enhances the ability to move the pick over tumblers with a fixed pressure while sensing the resistance of each pin. Learning how to hold the pick so that the exerted pressure is controlled by the fingers or wrist rather than elbow or shoulder is most important. Focusing on the tip of the pick and where it is making contact is of equal significance.

Generally, three fingers are required to hold, balance, and control movement of the pick. Which fingers are used is a matter of personal choice. One popular method is to utilize two fingers to provide a pivot point, while another provides vertical leveling and pressure. The pick may also be held like a pencil. With this method, the wrist generates the pressure; the shoulder and elbow provide the force to move the pick in and out of the lock. The wrist should not be used to move the pick **and** apply pressure.

An excellent way to learn the feel of a pick tracing the contour of the pins is to move the rake over the tumblers of a picked lock, with the plug being slightly rotated. The pins cannot be extended into the shell, so the pick must adjust to the contour of their height to shear line. Rapidly moving the pick in and out

of the keyway will cause a rattling sound to be heard and felt. It is this same feeling that will indicate that a pin has been set. Failure to hear or feel this rattle will indicate a falsely set tumbler.

29_5.1.4 Setting Picking Pressure

One of the problems for new students is learning how much pressure to apply during picking. Although such pressure will vary, there is a range of force that must be learned. Initially, the novice will apply pressure only on the outward stroke when the pick is being removed. With practice, pressure can also be applied on the inward stroke.

Minimum force can be considered as that which is required to overcome the spring bias on the first pin, without any torque being applied. This can be felt by applying pressure against the pin with the flat side of the pick. Remember that the spring force increases as the pin is depressed; the number of pins with which the pick comes into contact also becomes greater. Initially, no torque should be applied. Exert enough pressure to press each pin into the shell. Each pin should spring back as the pick moves past. There is an associated snapping or clicking sound and springiness. Count the number of pins as the pick is withdrawn.

Maximum pressure is achieved when all pins are depressed and torque is applied. This is a variable, because the amount of tension is directly proportional to required lifting pressure. This exercise will define a “pressure window”, within which the pick must be manipulated.

29_5.1.5 Torque: How Much, When to Apply It, and to Which Pins

The purpose of the pick tool’s first contact with each pin is to receive information about the lock and its quirks. An analysis of that information allows the torque to be adjusted, causing the pins to set at shear line. It is the torque wrench that opens the lock, based upon the proper manipulation of each tumbler. Beginners may fear applying too much tension and doing damage to the lock. It is impossible to apply a force that will shear pins. Thus, there is no harm in applying either too little or too heavy a tension, other than in creating frustration at not being able to open the lock.

Varying the torque as the pick moves in and out of the keyway is one method to get around several picking problems. For example, if the middle pins are set but the ends pins are not, one can **increase** the tension as the pick moves over the middle pins. This will reduce the chances of disturbing those correctly set tumblers. If a certain pin doesn't appear to lift high enough as the pick passes over it, a reduction in torque may remedy the problem.

Torque control during picking is a real skill; it requires a great deal of sensitivity, practice, and hand coordination. There is no set answer as to how much torque to use for a particular lock or type of mechanism. Each practitioner will develop certain preferences for each kind of lock. That insight can only be gained through practice. The application of torque during picking is the opposite of the rotational force applied when using a key. In the former, tension is first applied, then pins are raised to shear line. In the latter, the key is first inserted and all pins properly aligned, then torque is applied.

29_5.1.5.1 Establishing Picking Torque

Torque must be properly integrated with pressure to be effective. This exercise will teach the range of torque needed to properly set tumblers. The minimum torque will be just sufficient to overcome the friction of rotating the plug within the shell until stopped by the pins. Note how much torque is required to move the plug, even slightly, before the pins bind. This force can be rather high for locks that have been left out in the rain and for padlocks. Maximum tension may be simulated by pushing all pins into their chambers with the flat side of the pick, then applying the rotating force necessary to bind all pins in this position after removal of the pick. Depending upon the stiffness of the tension wrench and its twist configuration in the tang, it may not be possible to hold all pins.

Too much torque and pressure create the situation described above, where the lower pins are pushed too far into the shell and the torque is sufficient to hold them there. This case would indicate over-picking; the moving of pins past shear line and freezing them there with too much torque. The window or range of picking torque can be determined by gradually increasing the tension while raking the pins. Some of the pins will become harder to move. Gradually increase the torque until some of the pins set; they will lose their springiness. While maintaining fixed torque, continue raking to set other pins.

Defining the window of minimum and maximum tension is difficult to learn. These exercises should assist in establishing those limits. In all of these procedures, an appreciation of the minimum tension required to bind one set of pins and trap them at shear line, as well as a determination of the order of picking, is the goal.

29_5.1.5.2 Step 1: Single Pin Cylinder

The author recommends the following procedure in order to learn how to apply tension and the correct degree of torque. Remember, luck does not play a part in learning about torque; skill and practice does. Initially, configure a lock with only one set of tumblers. Use a cheap cylinder with a wide keyway and poor tolerance, such as an inexpensive Kwikset. Low tolerance will make it easier to feel the pins bind. A cylinder with one pin-stack is the lowest common denominator. The first lesson to learn is the required tension that is sufficient to bind one tumbler. Enough tension must be applied to learn:

- **The feel of pins reaching shear line;**
- **How to place the tension wrench;**
- **How to move the pick inside the keyway;**
- **How to hold the pick and tension wrench in concert;**
- **The minimum amount of torque required to bind a pin;**
- **How to vary the tension. Apply less and less tension until the minimum amount of torque that will bind a pin is determined.**

29_5.1.5.3 Step 2: A Cylinder with Two Pins

Setup a cylinder with two pin-stacks about the same length. Feel how much tension is required to bind **one** set of pins. Then, identify the stack that is binding. One pin will always bind first. This is called the **order of picking**.

- **Pins will always pick in a specific sequence unique to each lock. The pins are actually setting based upon the misalignment of the plug and shell;**

- **Determine which stack is not binding. It will be noted that very little pressure is required to move this set of pins and that they will return to their**

original position when the pick is withdrawn;

- **Identify which pin-stack has been picked. Run the pick around the pins and internal chamber walls of the set pin-stack. Feel pins at shear line;**
- **Remember that the application of too much torque will bind both pin-stacks in our two-pin lock, thereby preventing picking in the proper order;**
- **The same degree of tension that bound the first pin will also trap it at shear line;**
- **Disassemble the lock and vary the pin lengths and position. Specifically, set the two-pin lock for the following different configurations denoted by a long pin = 0; short pin = 1: 00, 01, 10, 11.**

As the lock is picked for each of the above pin configurations, learn what is felt when:

- **A pin-stack that is picked; no pressure is felt;**
- **A pin-stack that is not set; feel spring bias.**

29_5.1.5.4 Step 3: A Cylinder with Three Pins

Place three pin sets in the cylinder and vary according to the following configuration: **000, 001, 010, 011, 100, 101, 110, 111.** It is very important that each permutation be picked. The length of the pins should also be varied so that on a one-to-ten scale, the short pins should be a **1, 2, 3,** or **4,** and the long pins, a **7, 8, 9,** or **0.** There is no shortcut to this learning procedure. With this exercise, four added lessons must be mastered:

- **Sequence of picking;**
- **Which pin-stack is being manipulated;**
- **Feeling of each pin-stack binding at shear line;**
- **How to place the pick in contact with only one pin at a time.**

29_5.1.5.5 Step 4: A Cylinder with Four or more Pins

Switch to a higher-tolerance cylinder such as a Schlage, Yale, or Sargent having a more complex keyway that is paracentric in design. It is suggested that the **Yale 8** or Schlage **923C** be utilized. It will be noted that it becomes harder to sense pins that are set. The 923C can be a very tough lock to pick, and thus makes an excellent training tool. At this point, the pin lengths should be varied, different tension wrenches employed, and various picking techniques should be utilized. This will allow a feel to be acquired for the relationship between torque and pin pressure.

29_5.1.5.6 Step 5: Add More Pins to Cylinder

Add more pin stacks to the cylinder. Practice with different tension wrenches. Vary the torque.

29_5.1.6 Identifying Set Pins

It is very important to identify which pins are set. This can be felt by a slight give or rotation of the plug that actually increases as the number of pins are set. When first making contact with the pin, it can be pushed down a short distance with a slight pressure. It becomes hard to move after traversing to shear line and being stopped by the shell.

Rotational torque and vertical pressure are directly proportional: the more torque, the more pressure is required to lift and set a pin. If too much tension is applied, the pins will be scissored between plug and shell and trapped in the upper chambers.

Falsely set pins can be remedied by pushing them down farther or by slightly releasing torque allowing the pin to pop back to the original position. Pins will set differently depending upon direction of rotation of the plug.

A determination must be made as to which pins are setting and their location (front or back). **This is perhaps the most important skill in lock-picking**. Many novices will falsely assume that the snapping of pins, which can be heard upon release of tension, indicates the number of tumblers that were set. This sound may or may not indicate this information and cannot be relied upon as an accurate indicator.

29_5.1.7 Turning the Plug

Two problematical questions can be encountered during lock-picking regarding plug rotation: which way does it turn and how far.

29_5.1.7.1 Which Way to Turn?

It can be very frustrating to spend a long time picking a lock, only to discover that the plug was turned in the wrong direction. There are generally no rules except common sense in this regard. A plug turned in the wrong direction will often rotate freely until it hits a stop, or until it rotates 180° and the drivers enter the bottom of the keyway. It may also be necessary to turn the plug more than 180° if that is required to fully retract the bolt. The bottom of the pick tool can be placed at the base of the keyway to keep all tumblers even with the outer diameter of the plug.

The extra resistance that is encountered when the plug engages the bolt works can also mislead one. This may be misinterpreted as a stop, falsely indicating that the lock has been picked in the wrong direction. In fact, some bolt mechanisms when engaged will present an obstacle to turning with a torque wrench because the leverage is not as great as with a key. The bolt defines direction of turn for the plug mechanism. There are some general guidelines, but in the case of cylinders, the hand of the door must also be taken into account.

Characteristically, inexpensive padlocks (such as manufactured by Master) will open if the plug is turned in either direction. In contrast, Yale padlocks will only open if the plug is turned clockwise. Likewise, locks in doorknobs, desk, and filing cabinets tend to open clockwise. When rotated in the correct direction, the plug will be stopped by the pins; so, the barrier will feel mushy with the application of heavy torque. When turned in the wrong direction, the plug will be stopped by a metal tab that will exhibit a solid feeling.

If the lock is picked in the wrong direction, a plug spinner may be use to rotate the plug in the correct direction. This device is spring-loaded and will actually place a very strong spin in the desired direction. Its purpose is to turn the plug so quickly that driver pins do not have an opportunity to drop into lower chambers. In practice, the pick and torque wrench is removed from the keyway and a small screwdriver is inserted to retain the position of the plug. Then the spinner is placed in

the keyway and spun in the desired direction while holding the screwdriver steady. The screwdriver is removed and the spinner is then released, rotating the plug in the correct direction. The torque wrench is reinserted.

29_5.1.7.2 How Far to Turn

The companion question to which way to turn the plug is how far to turn it? Desk and filing cabinet locks generally open with less than a quarter turn. Locks that are separate from the doorknob tend to require a half turn to open. Dead bolt lock mechanisms can require almost a full revolution to open. Turning a lock in excess of 180° can cause difficulty because the drivers may enter the bottom of the keyway. In certain cases, it will be impossible, due to mechanical limitations or stops, to turn the plug past a certain point.

29_5.1.8 Broken Picks

Beginners often break picks and wonder why. The causes are many and often occur when learning to bypass locks. Picks are rarely broken by experts, although it does happen. Typically, picks fail due to the following reasons:

- **Improper handling during bypass. The pick should be used as a pencil, not as a lever or wedge;**
- **Pins are bound, and excessive force must be applied with the pick in an attempt to raise them because too much tension has been used;**
- **Inexperience in trying to raise a picked pin against the shell;**
- **Pins may be bound very tightly on their own due to broken springs, dirt, contaminants, or oil in the lock.**

29_5.1.9 Gravity

Picking action will be affected by gravity, which in turn is directly influenced by the orientation of the springs. A lock with springs at the top will react differently than one with the springs at the bottom. With upward spring bias (springs at bottom of lock), gravity holds the lower pins out of the way once set. This will allow for much simpler manipulation of pins that have not been picked to shear line and the testing of pins that

have not set. Spring bias from above will allow gravity to pull the lower pins down after the top pin catches at shear line. Once set, the bottom tumbler is easy to lift.

29_5.1.10 Pins Not Setting

A failure of one or more pins to set during raking, even with an increase in applied torque, is generally caused by a tumbler that has a false-set, thereby prohibiting the other pins from setting. Consider a lock whose pins prefer to set from back to front. If the farthest pin false-sets high or low, the plug will be prevented from rotating enough to allow the other pins to bind.

It is often difficult to recognize a false-set pin, because the springiness of the front pins makes it hard to sense the small give of a correctly set back pin. The main indication is that the other pins will not set, unless extreme torque is applied. If this situation is encountered, try releasing the torque and starting over, concentrating on the rear-most pins. Often, slight tension and moderate pressure or heavy torque and heavy pressure will be effective.

29_5.1.11 Loose Plug

The plug is held in the shell by being physically wider at its front and by having a cam on the back that is bigger than the hole reamed into the shell. If the cam is not properly installed, the plug can move in and out of the lock slightly. On the outward stroke of the pick, when a pulling force is exerted, the plug will actually shift slightly. When this occurs, the driver pins tend to set on the rear of the plug holes rather than on their sides. If reverse pressure is applied, the drivers will unset. This problem can be used to advantage by simply applying pressure on the outward or inward stroke of the pick. Alternatively, a torque wrench or finger can be used to prevent the plug from moving forward.

29_5.1.12 Pin Diameter

When the pair of pins in a particular chamber have different diameters, that pin-stack will react oddly to pick pressure. As the pins are lifted, picking pressure can be resisted by the binding friction and spring force. Once the driver is above the shear line, the plug slightly rotates until some other pin binds. If the lower pin is small enough and the plug did not rotate very far, the pin can enter the shell without wedging at its edge.

Some other pin is binding, so the only resistance to motion is the spring force. The pin will not set.

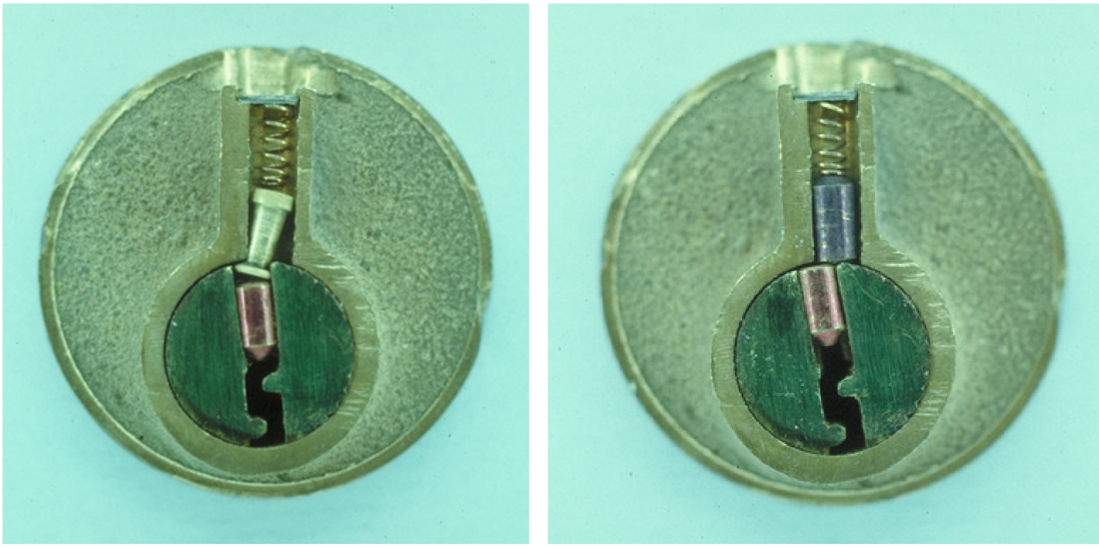
The pin feels normal at first, but then the plug binds and the tumbler becomes springy. The narrow lower pin can be pushed all the way into the shell without loosing its springiness. When the picking pressure is released, the lower pin will return to its initial position, while the large driver catches on the edge of the plug hole. The critical difficulty caused by a large top pin is that the lower tumbler tends to lodge in the shell when some other pin sets. Imagine that a neighboring pin sets and the plug rotates enough to bind the narrow lower pin. If the pick was pressing down on both the smaller, lower tumbler and the pin that set at the same time, then the narrow lower pin would be in the shell and would get stuck there when the plug rotates.

29_5.1.13 Beveled Holes and Rounded Pins

Some lock manufacturers may bevel the edges of the plug holes or round off the ends of the lower pins. This can reduce wear and help or hinder picking. There is generally a larger give, or tolerance in the travel of lower pins at shear line. The distance between the point at which the top pin catches on the edge of the plug hole, and the height at which the lower pin contacts the shell is greater when the plug holes are beveled or the pins are rounded. While lower tumblers are moving between those two positions, the only resistance to motion will be the force of the spring. There won't be any binding friction.

A plug with beveled holes requires more tumbler movement during bypass than a lock without such treatment, because the driver pins set on the bevel instead of on the top of the plug. The plug will not turn if one of the drivers is caught on a bevel. The lower pin must be contacted again with the pick to push the top pin up and off the bevel. If a lock is encountered with beveled plug holes and all the pins appear to be set yet the lock will not open, sometimes it is helpful to reduce tension and continue picking each pin. Lessening the torque will make it easier to push the drivers off the bevels. If pins unset when this happens, try increasing the torque and picking pressure. Increasing picking force, however, may jam some lower pins into the shell.

29_5.2 Security Tumblers



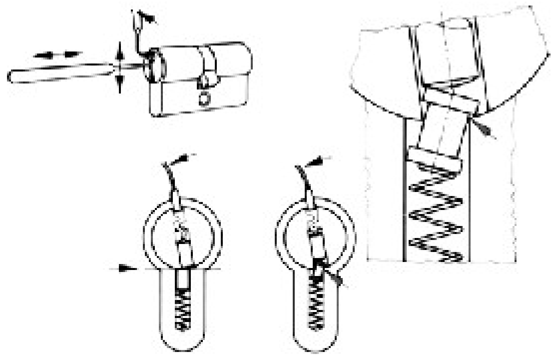


Figure LSS+2926. A lock (left) with a mushroom tumbler caught between plug and shell. The lock (right) has a slightly rotated plug, which occurs during the picking process as pins align at shear line. Courtesy of Illinois State Police, Bill Sherlock.

There are two primary means of increasing the security of a pin tumbler lock: design a complex paracentric keyway and employ security tumblers. Lock manufacturers routinely incorporate special drivers or lower tumblers in one or more chambers to frustrate picking and impressioning. The most popular shapes are mushroom, spool, conical, and serrated designs. Generally, spool-shaped pins refer to top drivers; mushroom shapes are found in bottom chambers. Each tumbler has a unique shape to facilitate false setting at shear line.

Especially in high-security locks, one to three chambers will have lower or upper security pins. These tumblers are even placed in certain padlocks, such as Abus and American Lock Company. Security tumblers will never be placed in all chambers, because the keyway would be off-center and difficulty would be encountered when inserting and removing the key. Neither is a tumbler placed in the first position, closest to the front of the lock.

Serrations can be added to pins in both top and bottom chambers, as well as the chambers themselves. Serrated master pins are rare and will not be utilized if the thickness of the wafer is less than .125”.

“S” pins are extremely effective, because they can create false shear lines both above and below the actual shear line. If the bores are tapped, serrated tumblers are very effective. However, they are extremely easy to impression. This shape was invented by Yale over 100 years ago; the first patent was granted on June 27, 1865 and was reissued in 1878.

The primary purpose of each of these modifications is to cause the pins to false-set low or high. They will allow the plug to rotate slightly, generally from 6º-15º, and prevent further setting of pins. These drivers can inhibit certain picking techniques, but generally will only make picking more difficult.

If, during the picking process, the plug stops turning after a few degrees and none of the pins can be pushed up any further, then it is likely that security tumblers are in place. The lower tip or other portion of the driver, or top of the lower pin has wedged at the shear line. Applying a light torque and upward pressure to each pin can identify the chambers containing security tumblers. Those positions with special tumblers will often exhibit a tendency to bring the plug back to the fully locked position. In the case of mushroom tumblers, raising the lower pin pushes its flat top against the tilted bottom of the mushroom driver. This results in the driver straightening, which in turn causes the plug to **counter-rotate.**

In order to pick locks with modified drivers, incorrectly set pins must be recognized. A mushroom tumbler, for example, will not have the springy give of a correctly set driver when the pin is set on its lip. Picking a lock with security tumblers

generally requires the use of a lighter torque, often with almost a feather touch and heavier pick pressure. The correction of tension during picking may also help.

The adjustment or correction of torque while manipulating each security pin must be quite precise if other tumblers are to be retained at shear line. The correct tension tool must be utilized for this exercise to allow maximum control of the plug. Raising the lower pins too far into the shell is preferred to not exerting enough pick pressure. In fact, another way to pick these locks is to lift the pins as far as possible, and then apply very heavy torque to hold them there, while releasing each one. This is called reverse picking.

29_5.2.1 Bypassing Security Tumblers

There are three methods of bypassing security tumblers: **conventional picking, impact picking, and reverse picking**. The following general rules apply to all techniques for neutralizing security pins.

- **Determine if security tumblers have been installed and if they are in the upper or lower chambers;**
- **Standard pins will pick first, because they have a larger diameter. The order of picking can thus be determined;**
- **Test to determine which is a special tumbler. The ones that cause rotation of the plug when lifted are security pins;**
- **Determine if serrated pins are used and, if so, whether the chamber walls have also been serrated;**
- **When the cylinder rotates slightly during picking, it is certain that the remaining pins are most likely security tumblers;**
- **Once standard pins have all been picked, maintain tension and bypass the security tumblers while still keeping the other drivers above shear line;**
- **Use more pressure and tension to raise security pins. They will cause the plug to rotate counterclockwise. If this procedure is not done correctly, all standard pins will release;**
- **Pins may be vibrated and moved back and forth to raise them. If one of the standard pins releases, try to pick it back without losing the other pins**

that have set;

- **Security tumblers will not pick in any particular sequence;**
- **Raking security tumblers is often effective using a very light turning force or a pick gun;**
- **When picking serrated pins, remember that bottom, driver, and chamber walls may all have the characteristic. Also, remember that all chambers may be pinned with serrated pins. They may be observed by visually examining the keyway. Serrated pins cannot be released with tension, thus they can be quite difficult to pick, especially when the chambers are likewise scored. An impact gun may be the best option for bypass.**

29_5.2.1.1 Conventional Picking of Mushroom Security Tumblers

To pick security pins, select those chambers that are so pinned, then use light tension to raise each tumbler. If the tension is correct, the mushroom pin can be forced above shear line without losing the other pins. The controlling factors are: wear in the mushroom pin, chamfer around the pin chamber in the plug, width of shear line at the chambers, and rounding of the lower edge of upper chamber.

29_5.2.1.2 Impact Picking of Security Tumblers

An impact gun can be quite effective when picking special pins. This is because the problems associated with the bypass of all security tumblers (with the possible exception of serrated) are eliminated. It will be recalled that the impact technique bounces all pins above shear line momentarily. The primary design of security tumblers is to cause trapping falsely at shear line. This procedure is ideal, because it circumvents the principal design function of the pin. It is recommended that a tweezers wrench or special round tension wrench be used for this procedure, such as manufactured by HPC. Use very light tension.

29_5.2.1.3 Reverse Picking of Security Tumblers

Reverse picking is a technique used to manipulate security

tumblers. The practice requires that all tumblers be raised above shear line with relatively heavy tension. Then, each tumbler is released, to drop below shear line. Use a raking action to manipulate the lower pins while slowly lessening the tension. This will diminish binding friction. The vibration of the pick and spring force causes the bottom pins to slide down to the shear line. A variation on this procedure involves the use of a rake pick combined with medium tension to raise above shear line, then release all tumblers.

A half-diamond pick can also be used with security tumblers to accomplish reverse picking. All pins are lifted simultaneously above shear line with the bottom side of the pick. Tension is then applied. The diamond tip is then used to let each tumbler drop. This is a very difficult procedure to successfully accomplish.

SECTION 6: Tools used in Bypass

Bypass Tools

29_6.0 Introduction

A variety of simple to sophisticated picking tools can be purchased from vendors in the United States and Europe. An example of a commercial kit, produced by the Falle-Safe Securities Company, is described below.

Lock-picking tools can be subdivided into two primary categories: picks and tension wrenches. The first classification includes conventional picks, sophisticated computer-designed picks, rakes, and specially designed pick tools for each kind of locking mechanism.

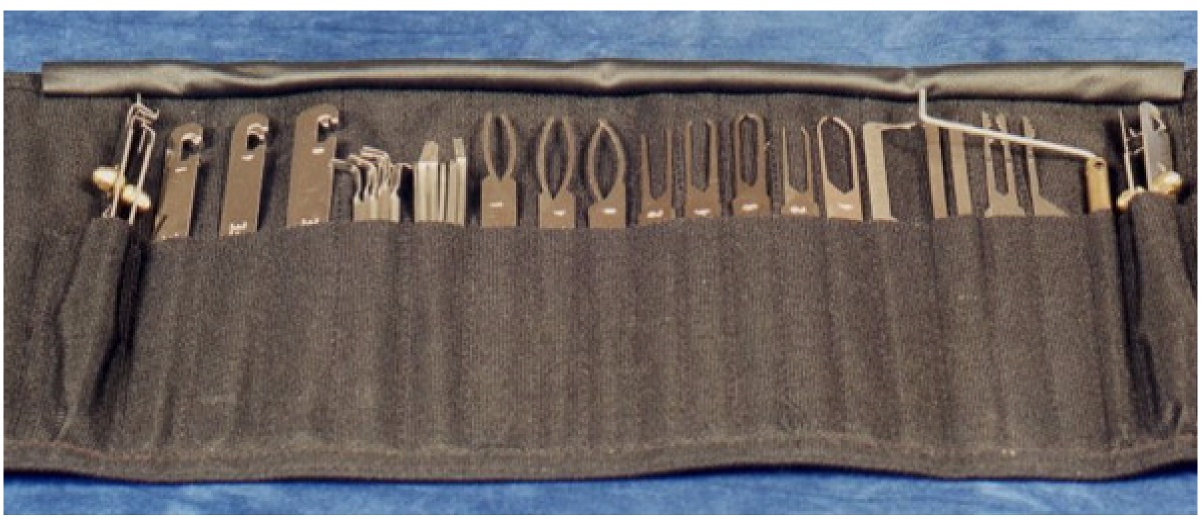
Tension or torque wrenches are produced in a variety of sizes, shapes, and configurations: some very simple and others quite ingenious. Our discussion will examine specific types of tools, their requirements, design, application, and construction. The primary focus of this Section is on wafer and pin tumbler locks. Tools for lever locks, and specifically high-security mechanisms utilized on safes and vaults, are also detailed.

29_6.1 Basic Pick Set

Many companies market pick sets. Perhaps the most sophisticated

of these, for the working professional, is the Falle-Safe collection. This commercial item is sold to locksmiths as well as government agencies. There are 93 tools, picks, and torque wrenches included in the standard set. An excellent variety of stainless steel tension tools, including single and double-ended, variable wrenches, and tools with single and complex bends are provided.

Within the kit there are 22 separate picking tools, 3 stainless steel rakes, and a set of 5 lever lock picks. There are 6 double-ended deep-curved picks, 6 double-ended graduated-curved picks, 6 double-ended progressive curved picks, and 4 double-ended curved picks. Each of the picks is fabricated from carbon tool steel. This steel has been nickel-plated to prevent corrosion. There are no double bowl-ended, bowl-ended, diamond-ended, or double diamond-ended picks in these kits, as the manufacturer does not believe they have any utility.



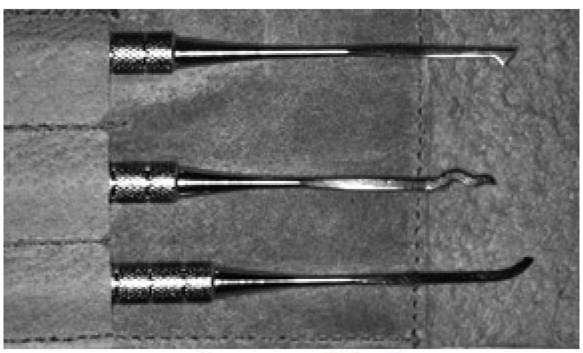


Figure LSS+2921 The John Falle pick set detail. Courtesy of John Falle.

This kit is an example of an all-inclusive lock pick set that will open virtually any mechanism. There are optional extras available for those countries where lever locks are prevalent. Falle-Safe does provide certain restricted items in the kits it offers to government intelligence agencies, such as decoders for high-security locks.

HPC and many other vendors also produce a variety of kits, shown below. Specialty picks produced by HPC, and recommended by the author include the NDPX set of three "dental" picks made of tool steel. These types of tools can be extremely useful and should be an adjunct to the professional arsenal. See patents (**4186577(273)**, **4006613(274)**), (**6082159(275)**).

29_6.1.1 Essential Characteristics of a Pick

The basic pick must have certain characteristics in order to function properly. These include:

- **Ability to imitate the actions of a key in**

order to raise individual tumblers to shear line;
- **Ability to make contact with each tumbler.**

29_6.1.1.1 Pick Shapes and Pick Tools

Picks are produced in many shapes and sizes, although certain designs must be used for certain locks or detainer configurations. For most pin tumblers, the author ordinarily uses only three different picks. The remaining two-dozen varieties contained in the standard pick kit are rarely employed. Picking is both a science and an art; personal preference and comfort play a large part in the selection of tools for a given lock.

There are four critical design criteria for any pick:

- **Shape of the end of the pick which comes into contact with the active components of the locks;**
- **Simple or complex angles associated with the contact surface;**
- **Gripping surface that allows the user to manipulate and move the tip and controls how the tip contacts tumblers or other moving parts;**
- **Tang, which is the connecting portion between tip and handle.**

Essentially, the handle and tang of most picks are the same. The handle must be comfortable and allow a firm and controlled grip; the tang must be thin enough to avoid moving the wrong pins. The design of the tang must be such that it is not too thin to create a spring, causing loss of feel of tip-pin interaction. Feedback is all-important in lock-picking; anything that diminishes that feeling is detrimental.

There are three considerations in the design of the tip of a pick: ease of insertion, ease of withdrawal, and transmission of feeling when the pick meets the tumblers.

29_6.1.1.2 Materials Used for Producing Picks

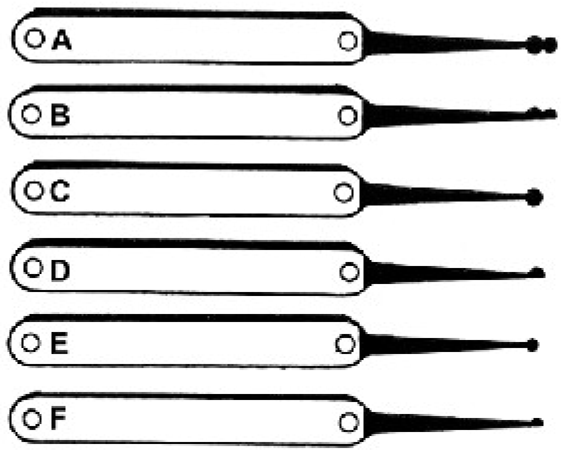
Many experts choose to cut their own picks. The author prefers to use handmade picks and tension tools in certain situations, especially where commercial picks are too large. Picks can be produced from many materials, although spring steel in .020” to

.032” thickness is desirable. Several custom pick manufacturers utilize etched stainless steel for precision forming. These picks, such as produced by HPC and Falle-Safe, are extremely strong yet thin. They offer very good freedom of movement. In an emergency, picks and tension tools can be fabricated from many commonly available materials, including steak knives, spring steel street cleaner bristles, bicycle spokes, unwound springs, and brick strapping material.

Tension tools can be made using metal of .040”-.050” thickness from steak knives, spatulas, pancake turners, or large bread knives. Picks can be produced using a 5” bench grinder with cutoff wheel, such as the B&D 790I, with a 1/2” arbor and 3600-RPM motor, or by hand filing. A needle nose vice grip and a burnishing wheel are also necessary.

With practice, precision picks can be made quickly. First, create the forward angle, using the front of the grinding wheel. Holding the material at a 45° angle, remove enough metal to create the proper slope. Do not overheat the metal or it will lose its temper and break during use. Next, create the back angle using the corner of the grinding wheel. The tip of the pick should be held stable to avoid breaking and to allow precision rounding. The cut should be made to about two-thirds of the thickness of the material.

Once the tip is shaped, the tang is formed, also using the corner of the wheel. The dimensions of the tang are largely dictated by the type of lock to be picked and personal preference, although a sufficient length will allow the tip to pass over the back pin of a seven-pin lock.

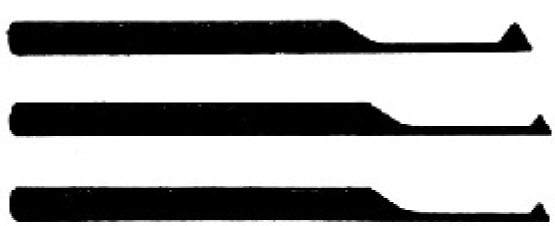


A hand file or burnishing wheel should be used to smooth all edges. If there are any jagged surfaces, difficulty in holding the pick will be experienced, as well as possible noise from tumbler interaction and loss of sensitivity of feel.

29_6.2 Specific Pick Shapes

Conventional picks as well as rake picks come in many shapes and sizes, although there are really only four distinctive shapes: **hook**, **rake**, **ball**, and **half-diamond.** The more common designs will be summarized here. In certain cases, picks may need to be modified for smaller keyways, especially in padlocks and some file cabinet locks.

29_6.2.1 Ball Pick



The ball pick is used for double-wafer cylinder locks, such as Chicago. The **double-ball** is primarily used as a rake pick.

29_6.2.2 Half-Diamond

Diamond picks are used for tumblers that are closely spaced, especially in the disc or wafer lock. The design allows for sliding of the pick to feel and move the tumblers. It also can bounce the pins like a pick gun. Diamond picks are especially useful for reverse picking, required with security tumblers.

The **half-diamond** tip, having **shallow** angles, is relatively easy to insert and remove. It allows significant pressure to be applied during forward or reverse movement. The same design with **steep** angles provides more information about the pins, although it may be harder to move within the lock.

A shallow half-diamond can more rapidly pick a lock, where the tumblers are about the same length. However, two deep pins separated by a shallow pin can pose a problem for this design.

The steep-angled diamond pick may also be used with difficult keyways such as the **Yale 8**, where vertical clearance is obstructed.

29_6.2.3 Half-Round Tips

The half-round tip works well in a disc tumbler lock, in dimple locks, and in locks where tumblers are closely spaced.

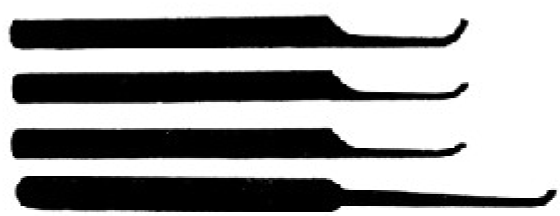
29_6.2.4 Full-Diamond and Full-Round Tips

The full-diamond and full-round tips are useful for double-bitted locks that have pins at the top and bottom of the keyway.

29_6.2.5 Rake Tips

Rake picks are designed to manipulate tumblers that all have minimal differences in their length or have ascending or descending lengths, much like a stair-step. Rake picks are quite popular throughout the world. The rake tip primarily works on **groups** of pins but may also be used to raise tumblers individually. The design of most rakes precludes forward pressure; contact occurs as the pick is withdrawn. With skill, a rake allows one to feel each pin and apply varying pressure as the tip interacts with the pins. There are many rake tip patterns; some very simple and some extremely sophisticated. Many have been designed with computer simulations.

Rakes incorporate many patterns. The primary shapes include diamond, ball, double-ball, half-ball, and half double-ball. Some rake tips are flat or dented on the top to make it easier to align the pick on the pin. Some are curved, with one, two, or three ridges. Some have equally high bumps; others vary both the center-to-center distance and height.



Complex rake tips are designed to simulate the signature of the key bitting and to achieve multiple and varied tumbler positions as the pick is moved in and out of the lock. Rapid insertion and removal of these picks, coupled with a vertical rocking or tilting motion, will cause the shear line to be crossed many times. With practice and a proper sense of when pins are binding or setting, a lock can be opened quickly.

Some rake picks have the capacity to set two or three pins simultaneously, depending upon design and the torque applied. The picks have the added advantage that they can be reversed

during the picking process, thus offering double the variations in bitting signature. As was noted in **Chapter 26**, raking a lock leaves definite indications of bypass in the form of scratches on the bottom of tumblers, and metal fragments or dust.

29_6.2.6 Curved or Hook Picks

The curved pick is available in many angles and radii for different applications, depending upon keyways and warding patterns. Generally, hook picks are designed to get behind or between two tumblers that have very different lengths. They are especially useful in lever locks.

Deep curved picks are for use on wafer locks and locks with very straight keyways. The basic idea is that the pick is levered from the bottom of the lock, allowing placement of each pin into its correct position in one smooth action. This saves time and simplifies the picking process.

Graduated and progressive curved picks are identical in every respect to deep curved picks, except they have a much stronger shaft. These are used in locks with more complex warding such as Yale, where levering up the base of the keyway would be impossible. They can also be used in circumstances where there is a very long pin next to a very short one. In this situation, a pick is required with a very large curve in its tip, in order to move the pin into the correct position without over-lifting the adjacent tumbler. Experience proves this an extremely awkward situation.

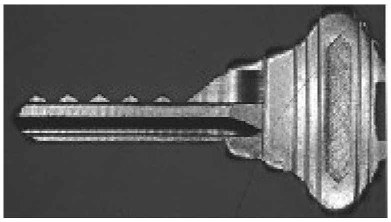
Thin curved picks are rarely used and are designed for locks with very complex keyways. Such is the case with the Evva, where the warding crosses the keyway at several different positions along its length. These tools are extremely thin, requiring very light tension to prevent them from bending.

29_6.3 Vibration and Other Mechanical Picking Devices

There are several methods of picking a lock, using a mechanical or electromechanical device that simulates the action of individually raising the tumblers, levers, or discs. All picking techniques that create vibration or shock waves are based upon essentially the same theory: creating a momentary gap between the lower tumblers and drivers. The underlying principle should be familiar to anyone who has played pool or taken high school physics. When the cue ball strikes another ball squarely, the cue ball stops and the other ball deflects with the same speed and direction as the cue ball.

These special tools provide a sharp, focused shock to all of the pins simultaneously. That energy is transferred to the driver pins which, for a few milliseconds, are driven above shear line. If torque is applied at precisely the right moment, then there is a window of time at which all bottom pins are in the plug, and all driver pins are in the shell. At that moment, there is nothing to impede the plug from rotation, and the lock can be opened.

29_6.4 999, Bump, Percussion or Code 12 Rapping Keys



LSS202: The use of the "bump key" or "999" key, by Hans Mejlshede.

Use of a bump key, by Harry Sher

This is a procedure that is used to open conventional pin tumbler and dimple locks. It is also referred to as bumping, and appears to have its origins in Denmark. The term is derived from the description of a key that has all cuts to the deepest level (9 cut). The key has also been referred to in Europe as a Code 12 or bump key. In England, the process is referred to as percussion opening.

The theory behind the use of the 999 key, Courtesy of Hans Mejlshede.

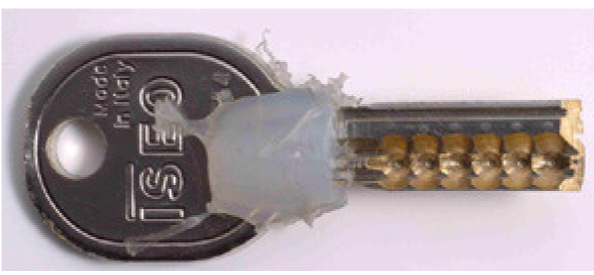
The procedure requires that a specially cut blank be inserted and “rapped” in order that shock waves be created so that tumblers can be bounced above shear line. The technique is essentially identical in theory with the use of a pick gun.

Rapping is based upon Newton's Third law of motion: for each action there is an equal and opposite reaction. Thus, the application of energy that causes the pins to momentarily bounce can be used to open a lock.

In practice, a rubber or wooden mallet, plastic screwdriver handle, hardwood handle, or rubber workbench top can be used to initiate shock to the pins. A special key, with all cuts to the deepest point (hence the name 999), must be inserted so that the **ramps** (not valleys or flats) are pressed against each of the lower pins. After the key has been inserted to the proper position, several sharp raps are applied to the top of the key. If a tabletop is used, then downward contact is utilized. At the same time, forward pressure and a slight rotation is exerted on the key. When the proper force is applied to the key, combined with the correct shock, each tumbler will be caused to bounce above shear line; the plug will then be free to move.

The proper technique for the use of the 999 or bump key, Courtesy of Hans Mejlshede.

An alternate method, once the retaining screws have been removed, requires that controlled pressure be applied to the rear of the plug, while the lock is lightly rapped against a tabletop. The proper creation of shock will bounce the tumblers above shear line, allowing the plug to be moved forward in order to trap the drivers.



The requirements to rap a lock are as follows:

- **The lock must be clean;**
- **The pins must move easily in their chambers;**
- **The plug-retaining screws must be removed prior to**

rapping;

- **The lock should be held between the thumb and index finger;**
- **Slight pressure should be applied to the key;**
- **The lock should be struck from above;**
- **Once all pins are set, care must be taken not to slide the plug forward so that pins relock at the next tumbler position;**
- **Turn the plug slightly after all pins are set, prior to opening.**

A similar technique has been applied to dimple locks. The key requires that all pin positions be bored to the maximum depth, and a stop be applied at the shoulder. Here, a bump key for the Iseo six pin lock has been constructed with a stop made from a glue gun. The inventor was Oliver **Diederichson** in Hamburg, who also developed the Sputnik picking tool. The key is fully inserted into the lock, then withdrawn one pin position. Rapping is accomplished in the same fashion as with a conventional cylinder.

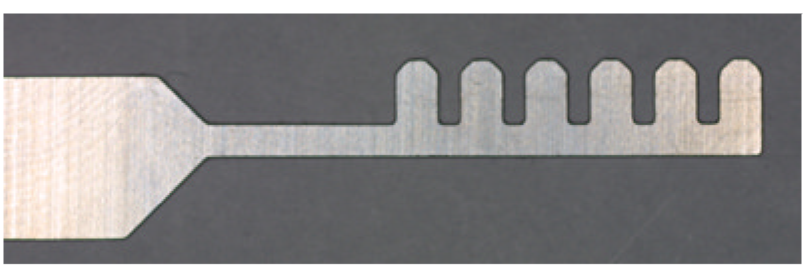
29_6.5 Comb Picks

Figure LSS+2927 The John Falle comb pick set. These picks have been designed for different cylinder chamber sizes and spacing.

Buday described this technique in 1936 (**2064818(276)**). Comb picks appear as their name implies: they are formed with teeth, spaced with the same center-to-center dimensions as the tumblers in each chamber. There is one tooth for each pin. A comb pick creates a new shear line by forcing all tumblers into the shell.

The function of the comb is to raise all tumblers above shear line and to crush or compress the springs, making room for the pin-stack. Generally, a comb pick is used with a wedge underneath it in order to aid in lifting the tumblers. In many instances, the brass retaining strip above the top chambers is actually broken loose, allowing unlimited room for the pin stacks to rest.

Comb picks are difficult to utilize in paracentric keyways, because the wedge cannot be raised. So also, certain high-security locks use setscrews to seal the top chambers and often cannot be combed.



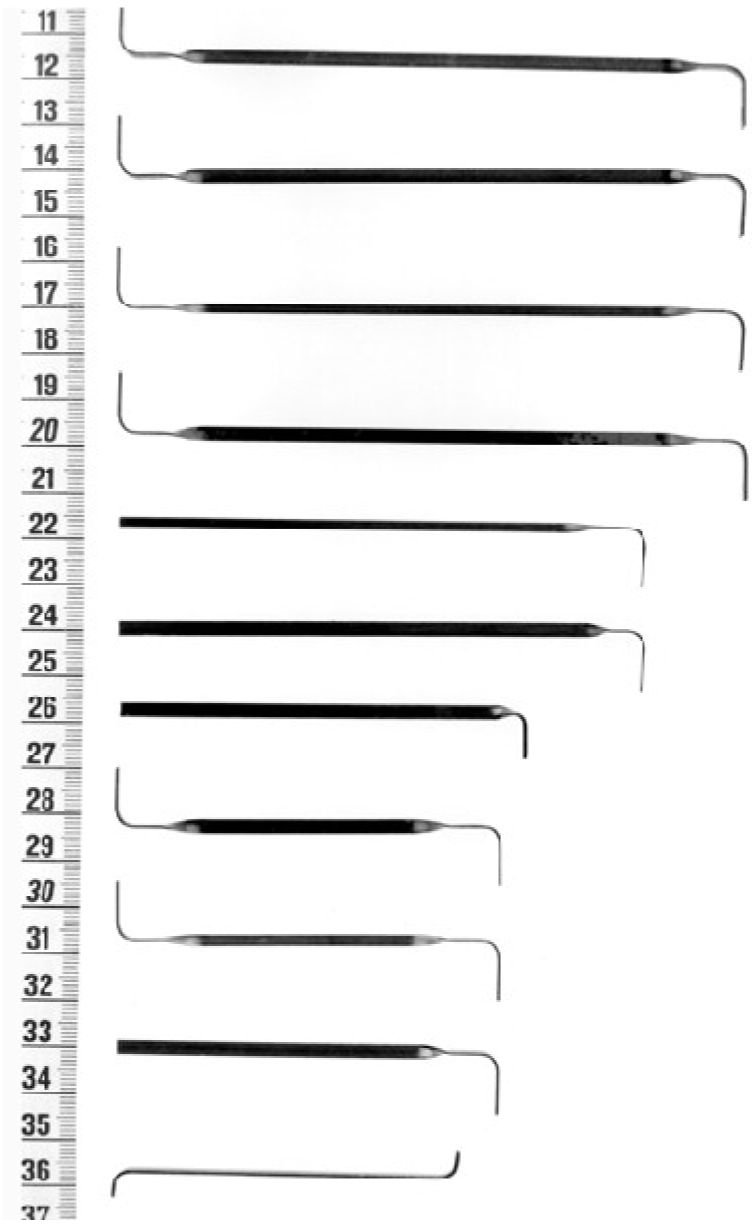


Figure LSS+2904 A John Falle comb pick.

29_6.6 Tension Wrench

There are two required tools to bypass most locks: the pick and the tension wrench. Each is equally important. The tension tool, or more precisely named, the torque wrench, provides the means to apply the rotational force necessary to bind the pins and turn the plug after all wafers, pins, discs, or levers have been raised to shear line. The tool is indispensable to all forms of lock-picking and comes in a variety of shapes, sizes, and tensions.

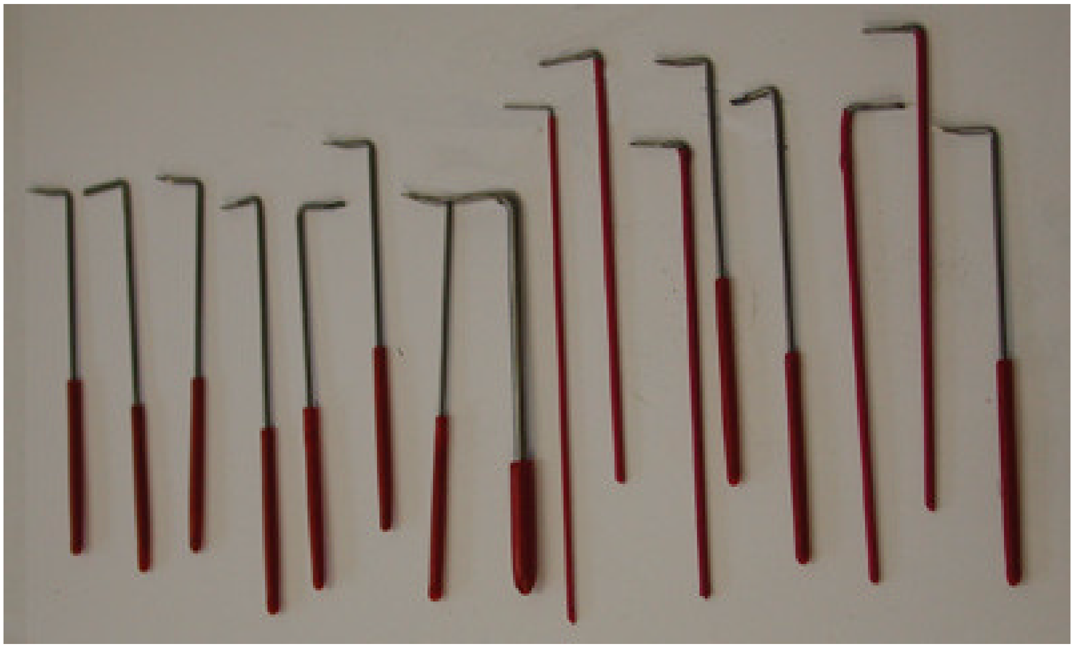

Figure LSS+2905 Special torque wrenches produced by MSC in Germany are plastic coated and are available in many lengths and tang sizes and thicknesses.

LSS201: MSC Assortment of tension wrenches, courtesy of Mahmod Abu

Shanab

Just as there are many variations in pick designs, every skilled lock picker has a preference for a tension wrench. Torque wrenches can be grouped into six general classifications: **light, medium, and heavy tension; narrow, medium, and wide tangs**. Torque wrenches are available in many shapes, lengths, sizes, widths, and thicknesses, for both the tang and main body. Some wrenches will have different angle bends in the handle. It is suggested that wrenches be provided with the following tang widths: .025″, .030″, .042″, .075″, .093″, and .125.″ There are few universal wrenches, perhaps with the exception of the Falle-Safe tool, because of the differences in locks and keyways. Wrenches must be capable of working with any lock, in any position, and allow the application of torque without obstruction. One unique design was invented by Cooke (**4606204(277)**) that involved an automated method of placing tension on a plug.

29_6.6.1 Criteria of the Basic Tension Wrench

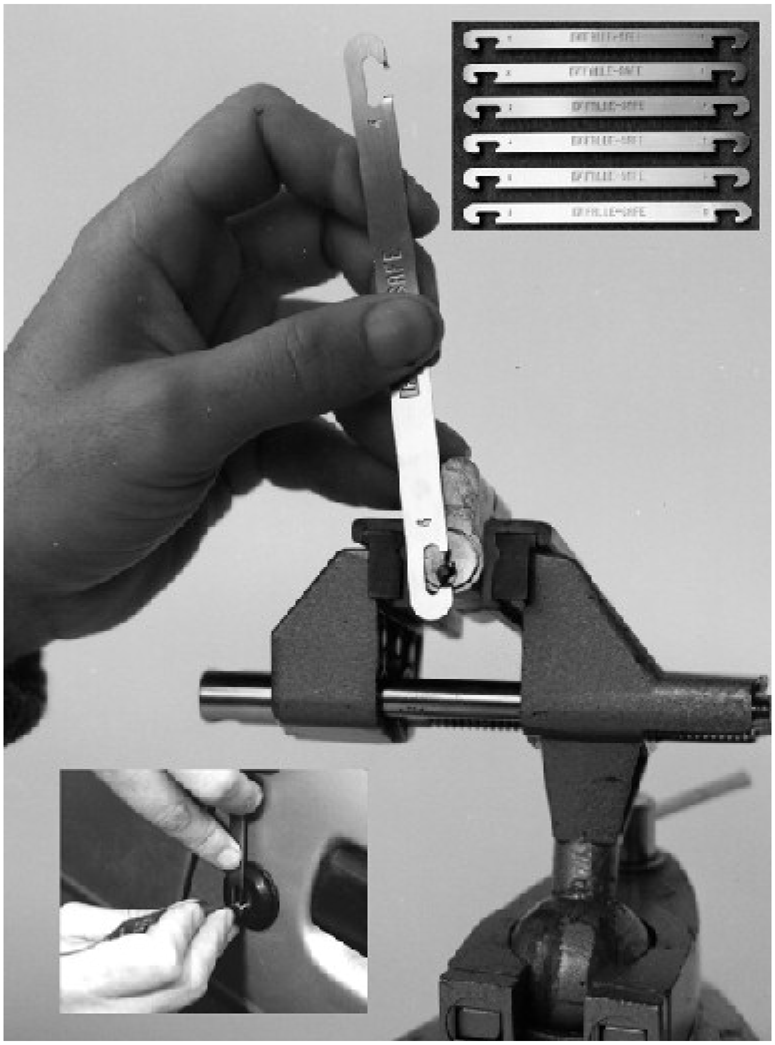
The essential requirements of a tension wrench include:

- ***Ability to hold all pins in place;***
- ***Ability to apply torque while manipulating a pick;***
- ***Ability to hold pins after they are set.***

Additional design criteria include the material thickness, length, and width of the tang and handle. The orientation of the wrench with respect to the head and handle will change based upon a number of factors. Often, a 45°-90° twist is incorporated into the head-handle junction, for ease in manipulation. Torque wrenches may also be constructed as sliding plates, secured in the keyway with locking pins. The author prefers the Falle-Safe turning wrench that employs this design because of the precision control it affords during the picking process.

Regardless of materials and design, all torque wrenches have a head and handle. The head is generally ½″ to 3/4″ long; handles can be up to four inches in length. There is generally a bend at the point of head-handle junction. This bend must be designed to allow the wrench to overcome any protrusions, allowing the plug to be securely gripped.

Long handles provide precise control of tension and rotation,



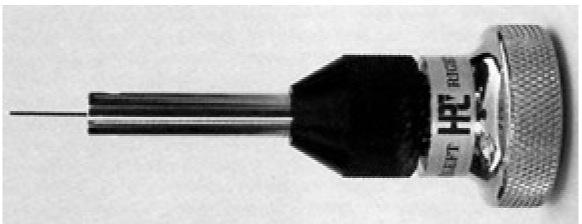
although if too long they can meet doorjambs. The purpose of the handle is to act like a spring, setting the amount of torque that is applied. The width and thickness of the wrench head determines how well it will fit into the keyway. A number of tension wrenches are normally offered in a professional pick set because of the differences in keyways.

Tension wrenches are generally made of spring steel stock, and are from .020”-.040” thick, and 1/8”-3/16” wide. Wrenches can be made from many materials other than spring steel in an emergency, including eight-penny nails, bicycle spokes, and screwdrivers. For high-tolerance locks, an Allen wrench can be modified by filing (not grinding) to create half a tang. This tool can then be inserted into the top or bottom of most keyways for more precise control.

29_6.6.2 Bent Tension Tools

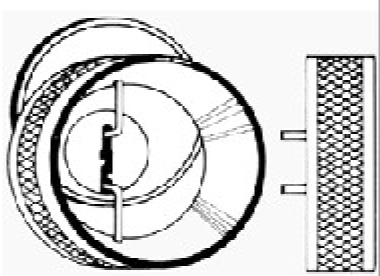
Normal tension wrenches having a single tang can obstruct entry and manipulation of picks in keyways with complex ward patterns. Specially designed bent tools, produced by Falle- Safe, bind as they are inserted into the keyway and turned. These tools are produced in four different widths: 2.25 mm, 2.5 mm, 2.75 mm and 3.0 mm. Generally, one of these tools will fit at the very bottom of the keyway, and minimize its obstruction. They should only be used on locks that do not have mushroom tumblers.

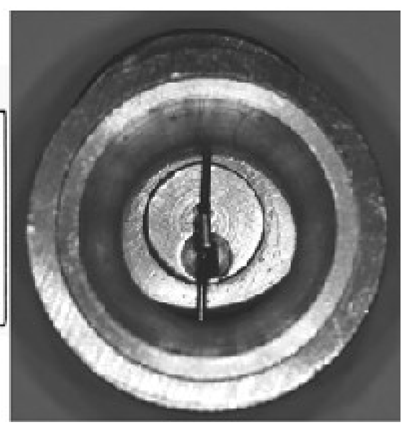
The unique Falle-Safe fixed tension tools have two prongs that enter into the bottom and the top of the keyway, causing a minimum obstruction. The widths of the two prongs vary. Each end of the tool is double-sided for reversal, allowing torque to be applied in an upward or downward direction.



The benefit of these tension tools is most apparent on locks that contain mushroom tumblers. When picking a mushroom pin, the core has to be rotated in the opposite direction from opening in order to push the heads of the mushrooms above the shear line. This is very difficult to accomplish with standard tension wrenches; control of the core is lost the moment reverse torque is applied. The fixed tension tool, however, becomes an integral part of the core: both move in concert, providing precise control.

29_6.6.3 Plug Spinner





A plug spinner can be very helpful if a cylinder is picked in the wrong direction. Often, due to wear of the plug or tumblers (because it is a right or left-handed lock) or the location of the lock, it may be easier to pick in one direction. The plug

spinner provides a means to apply high rotational torque to the plug when picked and move the lower pins across shear line without having any drivers drop into lower chambers.

29_6.6.4 Special Torque Wrench Designs

Specially designed torque wrenches, such as the **round** torque wrench manufactured by HPC and MSC (Germany), can make picking easier and allow more rotational control of the plug. This device looks like a spring-loaded donut, with protruding pins at the 6 and 12 O'clock positions. The pins insert into the keyway and provide complete access for picks. The pin at the 12 o'clock position is adjustable to fit any keyway.

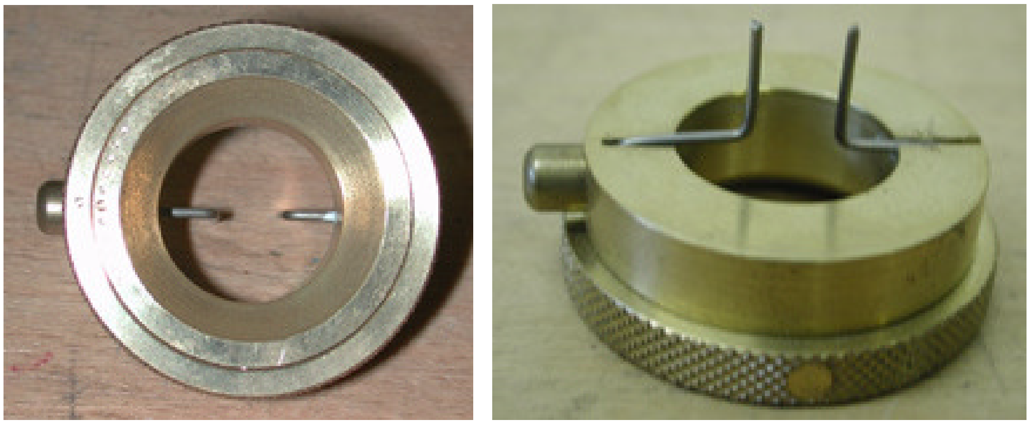


Figure LSS+2906 MSC in Hamburg, Germany produces a similar round torque wrench to that of HPC. It may offer somewhat better control and feel of core rotation and has calibration markings.

Tweezers, also offered by HPC, provide for control of the plug, much as the round torque wrench described above. The arms of the tool enter the keyway at the top and bottom of the plug. Tweezers have a tendency to release during picking; the author does not recommend their use.

The **Falle-Safe** tension wrench is the best designed device that the author has utilized to pick pin tumbler locks. It is adjustable and allows for precise control over the plug.

SECTION 7: Opening Locks

Picking Specific Locking Mechanisms

29_7.1 Picking Warded Locks

Originally developed by the Romans, these locks can have very intricate and complex designs, with many angles and zigzags, likened to a puzzle or maze. Nonetheless, a warded lock still is based upon blockage in some form of the keyway. Thus, all are subject to bypass by a key with any material removed that could encounter a ward. The portion of the key that remains will spread locking bands, or otherwise actuate a bolt.

Rim and mortise locks can still be found in old hotels and homes. Warded mechanisms are also very popular in inexpensive laminated padlocks, and they are used for cabinet and furniture locks. Warded locks are the easiest of any mechanism to pick and impression. It will be recalled that their security resides in the placement of obstacles (wards) in the keyhole that blocks entry or turning of the key or access to the release for the bolt or shackle. Wards may be of the rotating type that require barrel and bit keys to pass them. This is the traditional hotel key. Wards in padlocks take a different form and are blocks of metal located around the keyway. They prevent any key that does not have matching cuts from turning.

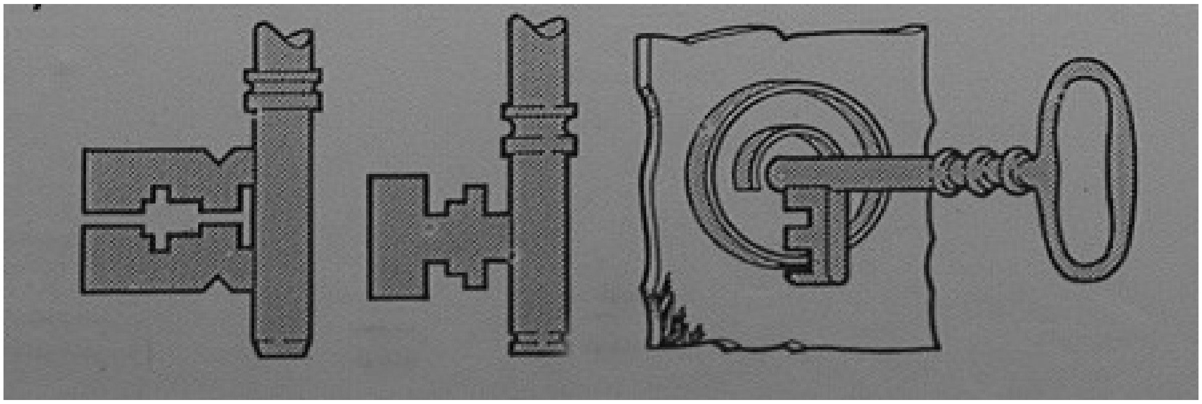

Figure LSS+2907 Examples of traditional warded keys. The mechanism (right) shows the interaction of the circular wards and the fundamental design of all warded keys. Note the removal of material on the key to pass the wards. This also is the principle that underlies all skeleton keys.

29_7.1.1 Skeleton Keys and Picks

Skeleton or passkeys can be fashioned for any type of warded mechanism. A set of five skeleton keys is available from HPC that will open most of the warded padlocks. This set has different tip configurations that are designed to spread single, double, or triple locking bands. A homemade “T” shaped pick can also be made to accomplish the same result.

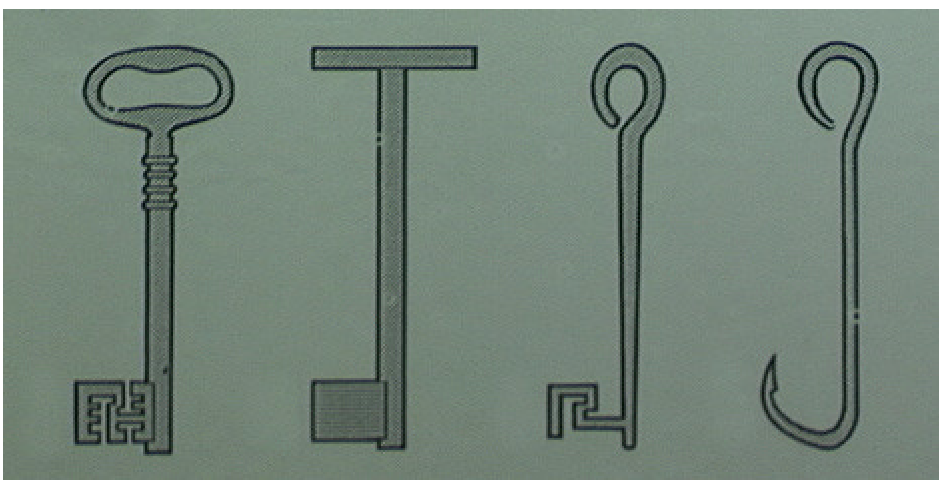

Figure LSS+2908. The above illustrations (from left to right) show a standard warded key, a blank for a warded lock, a key that has been produced by impressioning, and a burglar's skewer for manipulating the bolt.

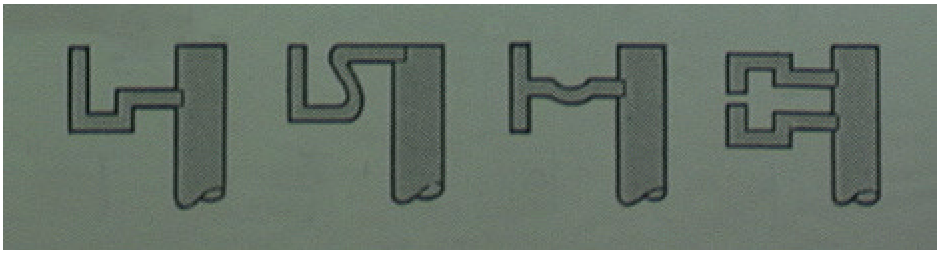

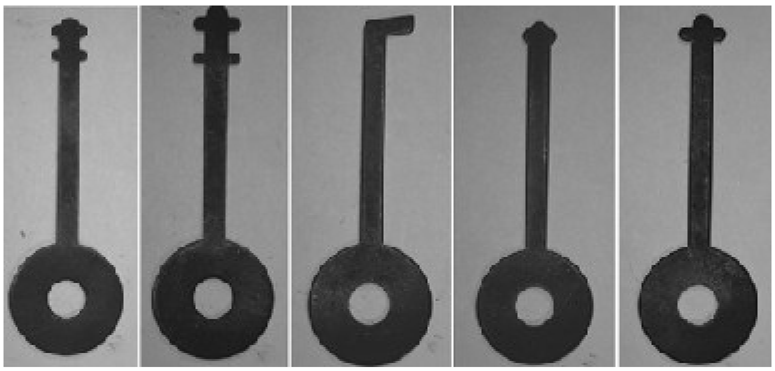

Figure LSS+2909 Examples of different skeleton keys for warded locks.

29_7.1.2 Picking Warded Mortise Locks

It is a simple matter to bypass wards and thereby reach the lever that actuates the bolt. A buttonhook pick can be made of .03"-.050" heavy piano wire and can be used to raise the lever, so as to pass the bolt without restriction. Perhaps the most difficult task when opening one of these old locks is to know the internal mechanical configuration and where to place the pick.

29_7.1.3 Picking Warded Padlocks

The warded Master padlock is probably the most popular inexpensive device of its kind in the world. It is typical of all padlocks and will be used for illustrative purposes in this text. It has four primary components: the **pass plate** allows turning of the key; the **ward plate** prevents turning of the key; the **rotating ward plate** is at the bottom of the keyhole and defines the keyway; and the **top plate** forms the center and stops the key. See **Chapter 13** for a complete description. Keys for the Master padlock have symmetrical rectangular cuts that correspond exactly with the placement of the wards. They allow the key to turn after it has been fully inserted. The protruding portions of the key will separate blades of the locking bands that are utilized to retain the shackle.

It can be seen that releasing the shackle simply requires the simultaneous expansion of the locking bands. The insertion of a skeleton key, an "L" key, or a hooked pick can be used to accomplish this task. If there are two or three locking springs, then two picks can be utilized, or a passkey with two "T" configurations can be employed. Slight pressure applied to the shackle, by either pulling or pushing, coupled with a twisting of the bands to about a quarter turn, will open the lock. Spreading of the locking springs may require some manipulation, but the bands are easy to locate.

29_7.1.4 Impressioning Warded Locks

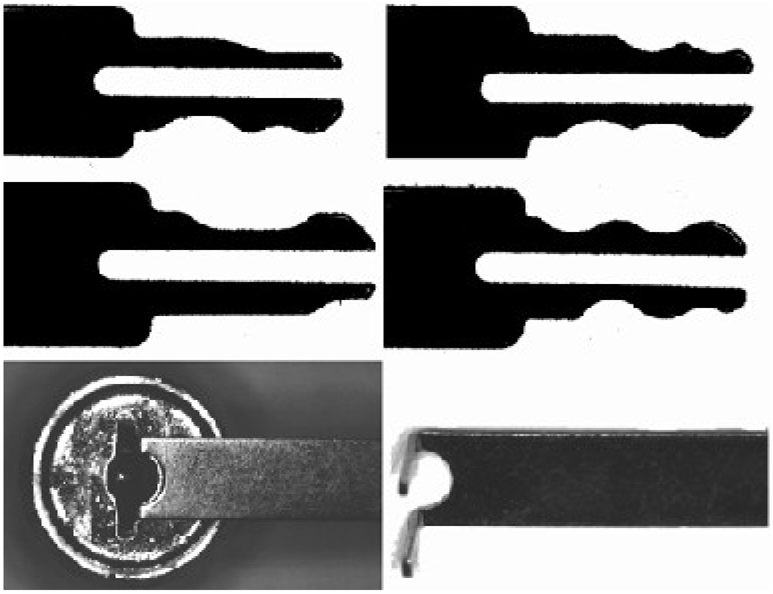
Warded locks can be impressioned easily. See **Chapter 30** for a description of the procedure.

29_7.2 Picking Wafer Locks

29_7.2.1 Introduction

Wafer locks are extremely popular and can be found in almost every installation requiring low to medium security. They are used on filing cabinets, desks, mailboxes, padlocks, doors, lockers, cars, garage doors, and many other applications. This mechanism found universal acceptance in the vending industry as the result of Chicago Lock introducing the first wafer design in the United States. There are also sidebar wafer locks that were first introduced by Briggs and Stratton in 1935 for use in automobiles. The same design is prevalent today in General Motors products.

Wafer locks can be identified visually by looking into the keyway: the discs will always appear flat, rather than rounded. The plug comprises about eighty percent of the overall diameter of the lock. Wafer locks, by their design, are easy to pick either conventionally or by raking. It will be recalled from **Chapter 15** that their mechanical locking principle relies upon a single wafer moving vertically in the plug, either above or below shear line. A plug, containing all springs and discs, rotates within a shell. The key simply centers each wafer so that neither the top nor the bottom protrudes from the plug's surface. Tolerance errors in the disc and plug allow these locks to be picked. The size of each disc will vary slightly because they are stamped. Parts are generally cast and so the walls of the shell may not be uniform.



Depending upon design, locks may have wafers that extend only into the top **or** bottom portion of the shell, or, in the case of double-bitted locks, will protrude in **both** directions when locked. The key having the correct bitting will always force all wafers to the **center** position. Any bitting position on the key that are either too low or too high will allow or cause a wafer to protrude from the surface of the plug, thereby preventing rotation. All wafers are always of the same overall length. Depths are determined by the correlation of the internal slot length and position to the vertical position of that slot within the wafer. Thus, filing the tops of discs cannot change combinations.

The plug is generally retained by an arc ring, an extra disc that protrudes into the shell, or by screw and cam. Regardless of design, the lock is picked by moving all wafers or discs into alignment with the top and bottom of the plug. There are generally four, five, or six depth cuts, although this is by no means a hard and fast rule. They differ from the pin tumbler lock in that the wafer or disc is a great deal easier to trap between the plug and shell. Thus, there are two points of engagement for the wafer (top and bottom of the plug), rather than just one, in the case of the pin tumbler. This fact allows raking with a much higher degree of success. The order of picking is not particularly critical, nor is tension. In fact, the author generally utilizes a stiff tension wrench to pick these locks.

Wafers are much thinner than pins, so more care must be exercised if picking individual discs, in contrast to raking. There is less distance inter-disc, so movement of the pick must be more controlled. Additionally, the plug may be heavily spring loaded for the actuation of certain bolt mechanisms, so more tension than normal may be required to actually turn the plug. There is a very different feel when picking wafer locks as compared to pin tumbler.

29_7.2.2 Picking Tools

Almost any pick tool can be used to open wafer locks, although certain tools work particularly well or have been specially designed for the task. Generally, a hook, ball, half double-ball pick or rake is preferred by most experts. There are, however, rocker picks, keys, and double-sided picks such as the HPC DSP-1 and COMP-1. Depending upon the design of the pick, a tension wrench may or may not be required.

In deciding upon which pick to use, the size of the keyway and design of the tumbler pack must be considered. As with the pin tumbler, free access to wafers or discs must be obtained with both the pick and torque wrench inserted. Often, two picks and a tension wrench may be used; thus, clearance is critical.

29_7.2.3 General Picking Procedure

Picking wafer locks is similar to pin tumbler in terms of overall procedure. The following discussion applies to all wafer and disc locks that do not employ sidebar designs. Specific information pertaining to single and double-bitted mechanisms is presented later. Training exercises, with respect to acquiring picking skills, follow the same guidelines as pin tumbler locks. The following general considerations apply when picking wafer locks:

- ***Wafer locks are easier to pick than pin tumbler, however, and the same principles and procedures apply;***
- ***Picking wafer locks may feel quite different than pin tumblers in some cases;***
- ***Wafers are thinner than pins, therefore, more care must be exercised when manipulating individual wafers;***
- ***There is less distance between wafers as compared to pins, thus it is easier to lift more than one wafer***

at a time;

- **Wafer locks may require slight to heavy tension; it depends upon the particular mechanism;**
- **The plug may be heavily spring loaded and require a great deal of torque;**
- **Raking is generally the fastest and easiest way to open wafer locks;**
- **Many locks are opened using a combination of raking and conventional picking;**
- **The discs will pick in a sequence, just as with pin tumbler, but such sequence is not usually relevant;**
- **Most wafer locks can be successfully raked;**
- **In order to successfully bypass a wafer mechanism, all discs must be aligned at shear line;**
- **A wafer lock may have one or two shear lines: at the top, bottom, or top and bottom of the plug;**
- **The Chicago double-bitted disc pack uses a hairspring to retain all discs in a sandwich configuration. There may also be a spring-loaded locking bar at the back of the tumbler pack that must be released to turn the plug;**
- **Double-bitted locks will pick in sequence. Each wafer will have its own spring;**
- **If rocker picks are utilized, slight rotation off-center may be required;**
- **If the keyway is very worn, the lock may be opened by inserting a key and jiggling, much like the use of rocker picks;**
- **Wafer locks can be bypassed by inserting a blank key fully into the plug, then slowly withdrawing while applying slight tension;**
- **Wafer locks, regardless of design, are quite susceptible to raking. Far less skill is required for successful bypass. Wafer locks can generally be opened in seconds using either technique;**
- **Using double-sided rocker picks is easier on a worn keyway.**

29_7.2.3.1 Applying Torque

Generally, a much smaller tension wrench is utilized because of reduced keyway size. The author prefers specially designed

torque wrenches described earlier that rely upon the anchoring of two pins at the top and bottom of the keyway for the application of tension. HPC and other manufacturers make tools for double-bitted wafer locks, such as the HPC DSP-1.

Torque wrenches for double-sided locks are available in different widths. Their design makes them well suited for pushing aside shutters on vehicle locks. A small screwdriver can also be quite handy for picking double-bitted locks if nothing else is available.

29_7.2.3.2 Picking Single-Bitted Wafer Locks

It is simple to determine which way to pick discs in a single-bitted lock. They will always move towards what can be considered as the top of the keyway. The first tumbler closest to the front of the plug will be partially visible, and indicate the direction to apply pressure.

Once rotational force is applied, the pick is inserted. Each wafer can be manipulated individually, or all wafers can be raked. Less precision is required to open one of these locks in terms of pick control and movement. Remember, wafers may need to be moved up, down, or in both directions alternatively to align them at shear line. The basic principle of picking any wafer lock, regardless of the number of bitting surfaces, is the same.

29_7.2.3.3 Picking Double-Bitted Wafer Locks

In the double-bitted lock, the procedure for manipulation of the pick and tension tool is different and slightly more complicated, depending upon the type of pick and torque wrench that is used. In locks where wafers extend to the top and bottom of the plug, conventional picks must be inserted and removed from the keyway using two different vertical orientations. This is especially difficult if a standard tension wrench is used, because it often must be switched from one side of the keyway to the other with some wafers already set. In this case, the thumb can be pushed against the plug to hold it in position while the torque wrench is moved.

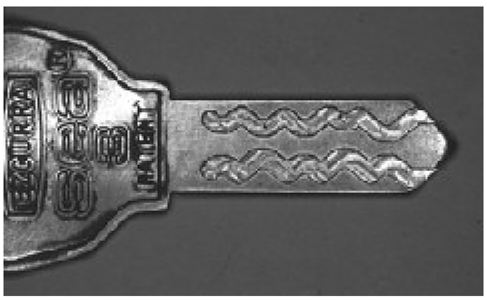
All tumblers oriented in one direction must be manipulated. Then, while maintaining tension, the pick is removed and reinserted with the tip pointing in the other direction. The process is then repeated until all wafers, both top and bottom are aligned. Generally, not all of the wafers will set on the first pass in

either orientation, so the procedure must often be repeated several times. This must be accomplished while maintaining tension; otherwise, those discs already set will return to their original position. Wafers should be picked on top, then the bottom.

If the proper tension wrench is not utilized, picking double-bitted locks can be quite frustrating. This is because there is no easy way to maintain torque while switching picks or pick surfaces. If a special double-sided pick tool is utilized, such as the HPC DSP-1, then bypass can be a great deal simpler to accomplish. With this or a similar tool, moderate up-and-down motion is applied with some tension. The pick itself may provide the needed torque or a separate wrench may be inserted (**2279592(278)**).

Once a double-bitted lock is picked, the plug should be rotated to about 45°. The keyway can then be packed with string or other material that will then allow free rotation, retaining the wafer configuration. Remember that some locks will only rotate a maximum of 90°.

29_7.2.4 Picking Abloy Disc Locks



The Abloy disc lock is a highly secure disc wafer mechanism produced in Finland. It is relatively inexpensive and can be field programmed. There are several versions of the design, based upon the number of discs, keyway shape, and gate shape and position. As described in **Chapter 17**, the primary concept was derived from a traditional combination lock and wheel pack containing rotating discs, each having one gate. The manufacturer claims 60,456,176 possible permutations. The lock contains ten concentric discs, each with one active gate and several false gates. The action of the key will turn all discs so that the gates are aligned, allowing a sidebar to retract to clear the obstruction for full rotation of the plug. Removal of the key automatically scrambles the position of each disc.

Although these locks cannot be effectively picked in a conventional manner, most can be decoded and opened using a special tool that was designed for each version. The precision decoder allows the manipulation of each disc and provides information from which the true gate can be sensed. The result of decoding also places the gate of each disc in an aligned position so that the lock can be opened. From the information derived, a key can also be produced. See **Chapter 31**, for

information regarding the Falle-Safe decoding tools.

29_7.2.5 SEA and Evva 3KS Sidewinder Locsk

The SEA and Evva 3KS sidewinder locks are a wafer mechanism. In actuality, they are a modified pin tumbler design but operates on essentially the same principle as most wafers. The lock utilizes gravity rather than springs to locate the tumblers when a key is **not** inserted.

In the case of the SEA design, the tumblers have side-protruding pins that engage with the tracks on the surface of the key upon insertion. Chambers at the top and bottom of the shell correspond with those in the plug. In order for the plug to rotate, all pins must be centered so that they do not extend into the shell (much like the wafer lock). The picking procedure is similar to traditional wafer mechanisms. The Evva 3KS is much more complicated and utilizes two sidebars that align on either side of the plug with six sliders. A special tool has been developed by John Falle, discussed in **chapter 31**.

29_7.2.6 Tibbe Lock

The Tibbe lock is utilized in Ford automobiles in Europe, and on Ford Mercur and Jaguar in the U.S. It is a wafer mechanism and similar in principle to the Abloy. A defect in the design allows a set of tryout keys or a special decoder to open a high percentage of these devices. John Falle has devised a unique decoding process that is described in **Chapter 31**, and in **LSS+/^{x} CD/ROM**.

29_7.3 Picking Lever Locks

29_7.3.1 Standard Lever Locks

Lever locks offer all levels of security. Some may have up to ten levers and can be extremely difficult to bypass.

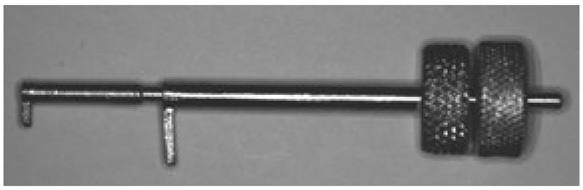
29_7.3.1.1 Tolerance Errors

Two forms of tolerance errors allow lever locks to be picked:

- **The failure of the edge of the gates of all levers to be vertically aligned with each other, not in a parallel plane;**
- **A failure of the fence to enter the gate of each lever at the same precise point.**

These errors are caused by the following manufacturing imperfections:

- **Difference in width of levers or gating;**
- **Difference in the length of the levers;**
- **Tendency of the top of the fence (portion not secured to the bolt) to flex when tension is applied;**
- **Tolerance differences from the pivot point to the edge of the tumbler.**

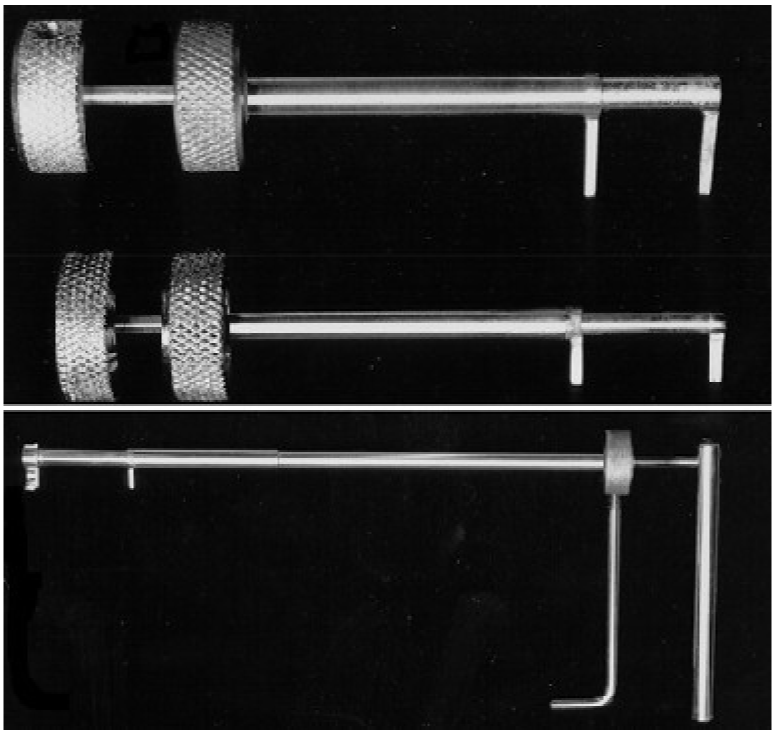


Each lever presents different imperfections to allow picking. Some will have parallel errors, some may have gate misalignment, and others may exhibit both errors.

29_7.3.1.2 Specific Picking Tools

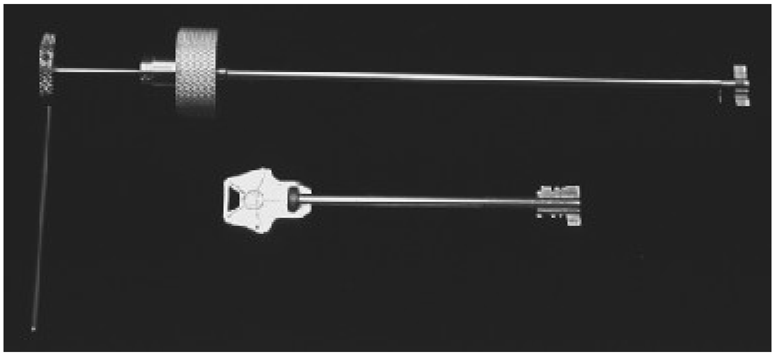
Figure LSS+2922 The John Falle two-in-one wheel pick set and two locks that it will open. Courtesy of John Falle.

In order to pick a lever lock, a special tool known as a two-in-one pick may be employed. This tool was originally developed by Hobbs and was used in conjunction with a weighted line to maintain constant tension on the bolt action. Such a technique is still in use today by safe technicians, especially where there are two separate lever mechanisms to be picked.



The wheel pick accomplishes two primary tasks: it provides a constant tension to the stump or fence while allowing the simultaneous manipulation of each individual lever. The center of the pick is hollow and fits over the post, the same as the proper key. The lower protruding section of the pick is used to enter that portion of the lever that transmits energy to the bolt, and causes it to slide when all levers are aligned.

Another shaft, with a slightly larger diameter, rotates around the smaller, lower shaft. The protrusion from this piece is used to manipulate each lever and can be moved vertically to accomplish the task. It has the thickness of one lever. When operated together, this pick can be used to open most mechanisms. When rotary tension is provided to the lower portion of the pick, the stump or fence is forced against the edge of all levers. Assuming a tolerance error, the gate on the lever that is most out of alignment will first encounter the stump. When the lever is moved to the position where the gate is aligned with the stump, the stump will move slightly, trying to enter.



Picking lever locks with a two-in-one pick in certain respects resembles impressioning. There is a difference in feeling when manipulating false and true gates against a racking stump. The levers that are bound against the racking stump will be felt to move slightly, although there is a trade-off between tension and lifting pressure. Loose levers are not bound by the stump in their “true” gate, although they will feel tight when in a false gate. If the false gate has been designed with the exact same dimensions as a true gate, then the lock may be very difficult to pick.

A modified tension wrench and hook pick may also be used to bypass lever locks. However, some lever mechanisms can only be

opened with a two-in-one wheel pick, or a modified device. A more traditional tension wrench can be made from .100” piano wire and must be shaped according to the internal dimensions of the lock and the trunnion. A standard turning wrench or a special “L” shape will work. Whichever is selected, it must be capable of reaching and throwing the bolt.

A pick can be fashioned from .035” spring steel stock and should be formed in the shape of a high hook. Although thinner picks will not have the strength to lift tumblers, the pick cannot be thicker than one lever. The tip angle should be designed to point straight at the lever. In the Falle set, special picks are made for use on locks that have warding around the keyway. In such cases, an angle at its tip is required in order to avoid the warding.

John Falle produces a set of "jiggers" for manipulating levers. This process is similar to utilizing tryout keys in wafer locks. The kit shown (right) is a set of JIGGLERS or tryout keys for locks containing two Levers such as UNION and LEGGE. Most of these locks are very easy to open because of the limitations caused by having only two detainers. Security of these locks could be enhanced by introducing different profiles but these tools can bypass any profile.

The tools will open most locks but vigorous movement may be required. Derivation of an accurate code is difficult, because they are not stable within the lock. Most of these locks will open after trying just a few different tools.

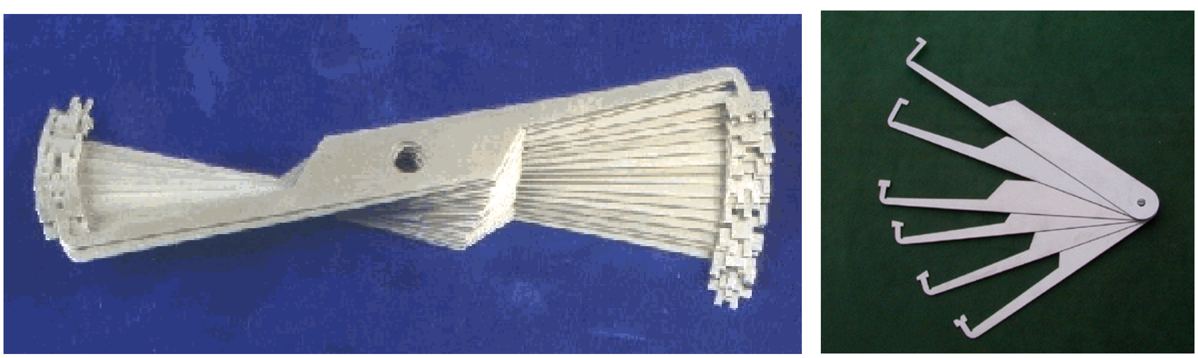


Figure LSS+2923 Two sets of "jiggers" to bypass lever locks. Courtesy of John Falle.

John Falle produces **wheel picks** as well as pick and decode systems for most **lever locks**, including high-security locks on safes and vaults.

Figure LSS+2924 A variety of tools are produced by John Falle for opening high-security lever locks. Courtesy of John Falle.

29_7.3.1.3 Theory of Picking Lever Locks

Successful bypass of a lever lock requires that all gates be lifted to align with the stump. As with the pin tumbler mechanism, the location of each gate can be sensed with the application of pressure exerted by the stump against the edge of the lever. Obstacles to deriving this information are incorporated in most mechanisms. These include false gates and barrel and curtain assemblies to block access to the keyhole during rotation. In theory, then, the steps to successful bypass are:

- **Know the type of lock and its theory of operation;**
- **Apply tension to the bolt so as to bind the levers by rotating 45°;**
- **Locate and lift each lever to align its gate with the stump;**
- **Trap each lever when aligned;**
- **Turn the wrench toward the levers to unlock.**

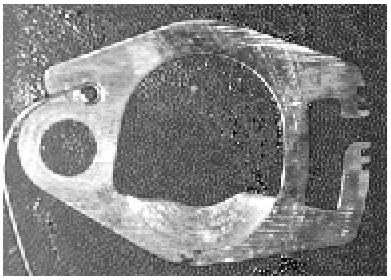
29_7.3.1.3.1 From the Perspective of the Lock Picker

An excellent description of the fundamentals of lever lock-picking appeared in a Bell Laboratories patent (**3402581**). In

1968, a pick resistant lever lock was developed for coin telephones. An excerpt from the patent application succinctly described the process:

"The basic problem of a lock-picker is to rotate each lever, without the benefit of a key, to a point at which each lever gate is in alignment with the fence portion of the bolt. This problem is readily solved by skilled lock pickers by any one of a number of methods, most of which employ some combination of the following steps.

First, pressure or tension is exerted on the moveable locking members in a direction to open the lock. This step is typically accomplished by rotating the plug and its associated cam with some suitable tool. The tension thus applied takes up the clearances between the lever pivot pin and the pivot hole in the levers and between the fence and the top radius of the levers.

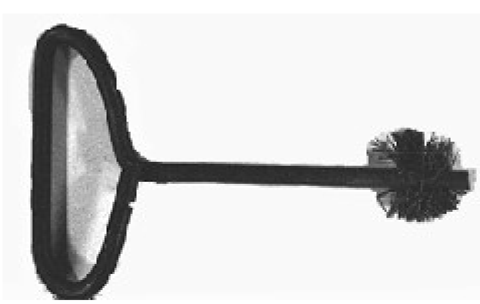


Next, each individual lever is rotated with a picking tool. As the gate is aligned, the lever is moved further toward the fence by the amount of clearance between the pivot hole and the pivot pin under the urging force of an individual lever return spring. The spring conventionally biases each lever toward its home or locked position.

Each lever gate is aligned with the fence in this manner, and each is held in that position by the combined force of the tensioned bolt and the lever return spring associated with each of the levers."

29_7.3.1.3.2 Conventional Picking Technique

To **conventionally** pick a lever lock, the appropriate tension tool is inserted into the keyway; the exact area must be located on the bolt to apply rotary force to the mechanism. After torque is exerted, the hook-pick is inserted. Each lever is lifted in turn until trapped; then the torque wrench is turned to throw the bolt. While maintaining tension, each lever in succession is raised until trapped as the stump partially enters its gate. False gates and serrations may be encountered that are used to frustrate picking. In such case, tension must be adjusted during the picking process to lift an individual lever in order that the true gate may be found.



In at least one high-security lever lock, the manufacturer placed a precise number of false gates to either side of the true gate, not realizing that such pattern could be used to advantage. In order to pick this lock, one simply counted two gates; the third would be the one that required alignment of the gate.

Often, one or more false gates are placed on the levers where the stump contacts the edge of the gate. These may take the form of matching sawtooth serrations on the stump and lever edge, actual indentations near where the real gate is found, or H configuration gating. Certain high-security lever locks, such as S&G and Western Electric, have been specifically designed and patented to frustrate picking.

If a lever is picked to a serration or false gate, then all other tumblers may be extremely difficult or impossible to raise. In the alternative, once a lever has been trapped by a false gate, all other levers may be raised easily but none will set at the point where the stump is aligned with the gate. Generally, more torque is required to pick a lever lock than a pin tumbler or wafer mechanism. There must be an individual assessment and adjustment of tension as each lever is picked. However, it will also be noted that levers that are not set will raise quite easily. Weber invented a special pick set for lever locks in 1984 (**4457191(279)**).

The degree of binding of each lever may change due to the relative position of the bolt and pivot point. Thus, it is important to maintain a constant pressure to keep those levers that have been set in such a position. If a lever is trapped at a false gate, often the tension wrench can be vibrated and the lever raised and lowered rapidly until it is released.

Lever locks can also be picked using a borescope to determine the

wear on each belly, based upon the length of travel from the pivot-point. This is dependent upon the depth of cut of the key. See **Chapter 31** for a detailed discussion of the procedure.

29_7.3.2 Picking Safe-Deposit Lever Locks

Locks utilized in safe-deposit vaults generally provide higher security than the traditional lever mechanism. They often have dual control, requiring that both renter and the bank must insert keys at the same time. These locks can be picked, but often require a special tension wrench and hooked pick with a greater tip angle. The following special considerations will apply when bypassing these locks:

- **Those levers closest to the racking stump (fence) will generally be picked first;**
- **The pick can be no thicker than one lever;**
- **When a lever is picked, the top edge will generally rest on the fence;**
- **Any significant lessening of torque will release any picked tumblers;**
- **As with conventional lever locks, the tumbler lengths may vary slightly; thus, the first lever which sets will often be the most difficult;**
- **Application of tension must be in conjunction with movement of each lever; working the fence into each gate is required;**
- **After setting more than two tumblers, picking may become quite difficult; tension may have to be slightly released in order to manipulate added levers;**
- **When all levers are precisely the same length in high-security locks, it may be necessary to set the one closest to the bolt first, because there is more pressure applied to this lever from the bolt mechanism;**
- **The use of heavy torque can wear down the edge of the tumblers slightly; this can be of assistance where serrated levers are encountered.**

The "drill and pick" procedure may also be utilized to bypass lever locks. This technique requires that a hole be drilled directly above the gates to allow a wire or probe to be inserted

into the lock. Each lever is picked and retained in position by the wire. It is much like shimming a pin tumbler lock and accomplishes the same result.

Procedure to open a lever lock with the "drill and pick" technique. Courtesy of Harry Sher.

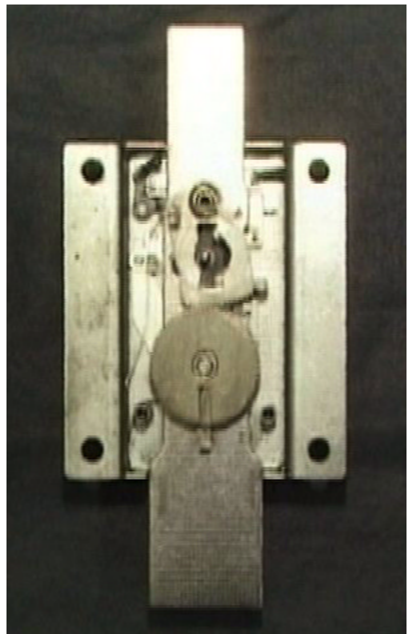
29_7.3.3 Safe Opening Tools

Specialized tools have been developed to pick and decode **high-security lever locks,** found in safes. It will be remembered that there is a preference for lever mechanisms for use on security containers outside the United States. John Falle, Martin Newton, and others have developed **unique wheel picks, pin and cam systems,** tools and techniques to covertly compromise the highest security locks.

Figure LSS+2928 Safe opening tools for many different locks are available from John Falle and others. Two popular European locks are shown: (middle) Fichet Monopole, and (right) Fichet mounted lock. The Fichet Monopole decoder kit is

available and described elsewhere in this text.

29_7.3.3.1 Opening High Security Lever Locks



Specialized techniques are required to open many of the high security lever locks that are utilized in safes. Picking procedure are shown to open the Kromer Convar, Kromer Novum, Rosengrens ABN, and the Stuv mechanisms. Detailed information is also presented regarding the Rosengrens RKL10 lock. Markings on the levers can also be utilized to analyze the lock prior to picking, and to provide forensic indication of such action.

29_7.4 Sidebar Lock

A **sidebar lock** is a mechanism that incorporates a secondary locking bar that retracts into the plug to allow rotation after all tumblers are aligned. The sidebar principle appears in both disc and pin tumbler locks, and was originally developed in the United States by Briggs and Stratton for the automobile. There is evidence that the technique was actually patented in England in 1919. Sidebar designs actually evolved from a combination of the wafer and lever locks, and can offer high-security in both wafer and pin tumbler mechanisms. They are extremely resistant to picking because direct binding of pins is impossible.

Interestingly, there are many parallels in the design of the sidebar in comparison to modern combination locks. Each has gates into which a fence must drop in order to actuate the bolt. Each has a moving tumbler for each bitting position or, in the case of a combination lock, dialed number. The only real difference is in the number of depths or permutations available to each and the movement required for alignment. In the combination lock, it is rotational for each of the wheels in the wheel pack; in the sidebar wafer lock, it is the vertical movement of each wafer, determined by the bitting of the key. Pin tumbler sidebars add rotation as a security component.

29_7.4.1 Briggs and Stratton Sidebar Wafer Locks

The original Briggs and Stratton sidebar design is still in use today in millions of automobiles. Since 1984, Ford has also utilized a similar design. The GM lock consists of six wafers, each having a concave-shaped V gate that is cut into the side of the wafers at one of five locations, depending upon the desired

bitting depth. Each of the wafers rides in a channel within the plug (which also contains the springs, wafers, and sidebar). In this regard, a sidebar plug is similar to a traditional wafer lock. However, this is where the similarity stops.

A rectangular channel is cut along one side of and perpendicular to the plug in order to contain the spring-loaded sidebar. This metal bar floats within the slot, applying a constant pressure by its convex V surface against the sides of all of the wafers. The sidebar can only retract fully into the plug when all of the wafers are individually raised, so that each of their gates mates with the protrusion of the sidebar. The proper key will lift each individual wafer to align its gate to the sidebar. Depth coding is determined by the placement of the gate along the vertical surface of the wafer in one of five positions. Field disassembly and recombinating of these locks is quite simple, and can be accomplished rapidly.

The entire plug assembly is inserted into the shell of the lock. In the case of the ignition, the shell is actually part of the steering column. The application of torque to the plug will only cause the sidebar to catch on the corresponding channel in the shell. Thus, manipulation of tumblers accomplishes nothing. See **Chapter 23** for a complete description of the lock.

29_7.4.2 Sidebar Disc Locks

Abloy, Chubb, and other manufacturers of cam and cylinder locks developed a modification of the sidebar wafer principle. Rather than wafers, these locks employed rotating discs, much the same as within a combination lock. Disc sidebar locks function on the same principle, however, as the original Briggs and Stratton; only the design of the gate structure is different.

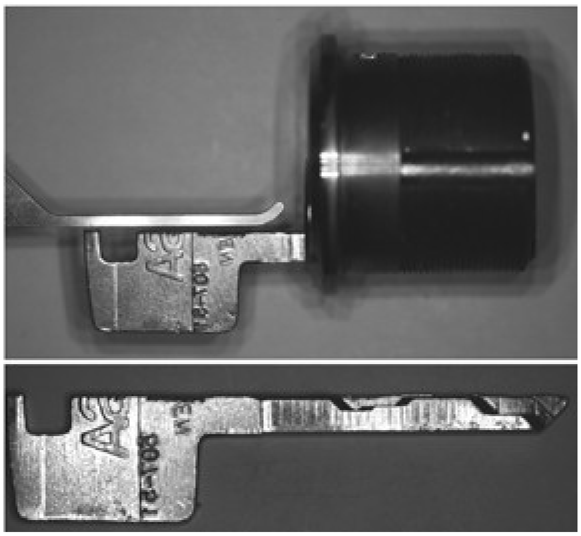
29_7.4.3 Sidebar Magnetic Disc Locks

A further design departure from the original sidebar lock is a unique mechanism developed by Evva (Austria) and Ikon (Germany) that utilizes eight very special magnets embedded in the key. They in turn drive eight magnetically rotating discs to control two sidebars. Each of the discs has a gate, much like the Abloy. All gates for each set of four discs must be aligned for the sidebars to retract. They cannot be picked or otherwise compromised in any traditional manner and are ideal for high-security complex keying applications. See **Chapter 19** for a complete description of these locks.

29_7.4.4 Sidebar Pin Tumbler Locks

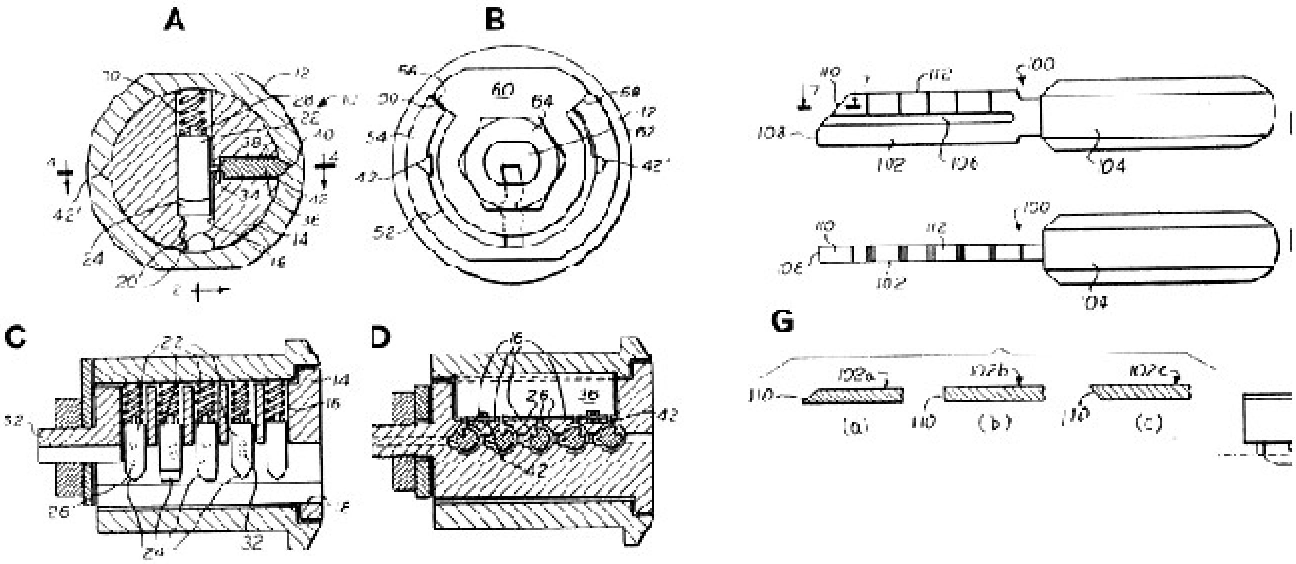
Medeco, in 1967, created the sidebar revolution in pin tumbler locks with their radical design of rotating tumblers. See **Chapter 17** for a full description of the Medeco lock. This mechanism is another permutation of the original Briggs and Stratton. Substituting pins for wafers, the inventors developed two different kinds of locks, both employing the sidebar principle for maximum security.

A cam lock was introduced that has several single spring-loaded pins, almost resembling a mixture of a traditional wafer and pin tumbler lock. However, each of the tumblers has a small hole placed along a vertical surface, to correspond with pins protruding from a sidebar. The vertical and **horizontal** location of the holes determines the depth code for the key bitting and rotation angle.



The correct key not only lifts each pin to the proper height but also rotates it in one of three orientations to align all of the holes so that the sidebar may enter and retract into the plug. The high-security pin tumbler version of the Medeco sidebar added one more security layer to the cam lock, described above. A full set of lower and upper pin tumblers was incorporated into the design. Thus, the original Medeco, and the new Biaxial are each a standard pin tumbler lock with all of the attributes of a high tolerance, certified device. In addition, a sidebar is added that can only be retracted when all of the pins are lifted and rotated to the correct position.

29_7.4.5 Picking Sidebar Wafer Locks



Although there are claims to the contrary, the Briggs and Stratton lock cannot actually be picked effectively. It can, however, be impressioned and decoded as described in **Chapters 30** and **31**. A unique GM and Ford decoder system has been developed and was patented by Joosten in 1987, that allows the rapid decoding and opening of these locks. This system is fully described in **Chapter 31**.

The lock can also be opened by drilling a small hole to the right of and centered over the sidebar at a 30° angle. A wire or straight pick is then inserted to place pressure directly upon the sidebar. Because the keyway is off-center, there is room to physically depress the sidebar against each of the wafers. Each

wafer is then picked, causing the bar to become rigid. There is no rotating tension to be applied; just pressure on the sidebar until retracted.

Medeco cam locks can be decoded based upon the use of a set of depth-rotation tryout keys. This procedure is more fully described in **Chapter 31**. It was also the subject of a Japanese patent. Medeco pin tumbler locks can be picked, impressioned, and decoded. However, special tools are required and a great deal of expertise. A patent was granted for the first Medeco pick and decoding tool in 1976. Since that time, several techniques have been developed to accomplish bypass. Four patents have been granted to Hughes in 1999, 2000, and 2001, for tools to pick the Medeco and other locks (**5956984(280)) (6041629(281)) (6138486(282)) (6173595(283)**). Falle-Safe produces a special decoding tool and procedure that is more fully described in **Chapter 31**. The technique involves the use of a fine shim wire and decoder to ascertain the required rotation and depth of each pin.

The original Medeco series were much more susceptible to picking and decoding because the channel on the side of each pin extended to the chisel point. Some of the newer pins have eliminated this characteristic by running the groove only partially down the pin. In addition, special security pins described elsewhere in this text are now employed in the Medeco Certified locks. Various pick tools have been developed over the years for Medeco products. One utilizes a “twisting wedge” point, made from a standard diamond pick. The last 1/32” is heated until blue, then twisted 15°. It is then filed to a wedge shape. To pick some series, a featherlight tension is applied. Raking is done to shear line, then regular tension is applied and the tumblers are rotated until the sidebar is aligned. Small mirrors have also been used to view the relationship between the channels and chisel points on the bottom of the pins.

There are other sidebar locks that, in the opinion of the author, are not as secure as the Medeco. Assa and Primus utilize a secondary locking sidebar, but unlike Medeco, the mechanical sidebar function has been split from the process of raising tumblers to shear line. The result offers the ability to obtain the unique sidebar code, and circumvent that portion of the lock’s security. Then, it is easier to bypass the lock in traditional fashion.

Picking Medeco locks. A discussion by Harry Sher.

29_7.4.5.1   Opening Sidebar Locks with Tryout

Keys

Tryout keys have been available for many automobile locks for almost fifty years. They can be used to open wafer and lever locks primarily, although keys may be devised for any mechanism with poor tolerances. These specially cut keys take advantage of the gap between the plug and shell, and theoretical versus actual differs. In fact, the correct key for a given lock only approximates the required depth-cut. It is rarely absolute. For example, a tumbler may theoretically be cut for a depth of .065" of bitting on the key, for a #1 cut. However, in reality, the tumbler will not block rotation of the plug with a bitting measurement of .063"-.067". Thus, a key having a cut of .063", .064", .065", .066", and .067" will work.

Now, let us say that the next cut, a #2 in our example, has a theoretical depth of .070", but will actually operate from .068"-.072." A tryout key can be made with a depth-cut of .0675", that will raise either a #1 or #2 tumbler to shear line with slight rocking. What this means is that a few keys can be made to approximate the depth cuts of all tumblers. The original Briggs and Stratton sidebar lock for automobiles, manufactured in 1935-1968 and used in all General Motors products, utilized six wafer positions with four possible depths. There were **4,096 (4^6) theoretical** differs. However, the tolerance of the lock allowed a 1.5 cut to open a 1 or 2, and a 3.5 cut to open a 3 or 4. Thus, in fact, there were only two depths for each tumbler position: a 1.5 and a 3.5 cut. The actual number of differs then became **2^6**, or **64.** Sixty-four tryout keys would open any General Motors vehicle in the United States prior to 1968, when the number of depths was changed.

In the later version of the lock, five depths were established as shown below. Three different bittings are required to open this series. There is a one-half depth tolerance, thus, a 1.5 will work for a 1 and 2 cut; a 3.5 will operate a 3 and 4 cut; and a 4.5 will operate a 4 and 5 cut.

DEPTH CODE	***ACTUAL DEPTH***	***TRYOUT DEPTH***	***TRYOUT DEPTH CODE***
1	***.248***	***.235***	***1.5***
2	***.223***		
3	***.198***	***.185***	***3.5***
4	***.173***		
5	***.148***	***.160***	***4.5***

For the same reason, combination locks used in safes can be manipulated and opened with automatic dialers. Although there are theoretically 1,000,000 combinations in a three-wheel, 100-segment lock, in fact, there may be as few as 290,000 actual combinations based upon 1.5 increment steps (1.5 increment steps, 100 divisions, 3 wheels: $\mathbf{66^3}$). The number will be reduced to 64,000 with 2.5 increment steps.

Tryout keys are generally produced on soft blanks and are milled to provide the maximum lateral movement by widening the wards and making the blank thinner. A unique variable key generation system, produced by Falle-Safe, is based upon this same theory. See **Chapter 31** on decoding. Tryout keys may also be designed for pin tumbler locks. In such cases, the ramp angles for each cut may be taken advantage of to provide added depths that may be simulated during oscillation of the key. Rocker picks are based upon the same general premise as tryout keys, but they are not usually designed for specific depth cuts. Their movement is less restricted, and thus they can simulate a wider latitude of depths.

29_7.5 Vehicle Anti-Theft System (VATS)

VATS was introduced by General Motors in 1986 on Corvettes in order to deter theft. Since this car was the most often stolen vehicle in the United States beginning in 1954, this was the first beta test of the system. Since that time, it has been incorporated in many other vehicles. The system, as described in **Chapter 23**, is based upon the integration of a simple resistor “pellet” in the head of the ignition key, together with a traditional sidebar mechanical lock. When inserted, a set of contacts reads the value of the resistor and transmits that information to a microprocessor in the vehicle. Electrically, the system is quite simple yet effective and easy to implement.

If the resistor value matches that stored in memory, the car can be started in the usual fashion when the key is turned. If the value does not match, the electrical and fuel systems are disabled and a fifteen-minute delay is triggered, during which **no key** may be used to start the vehicle. At the end of this period, the cycle begins again. The security of the system rests in the inability to derive the resistor value from the internal processor and the time delay that occurs whenever an improper value is input.

The system can be bypassed through the diagnostics port on the microprocessor with the proper test equipment. The only other way to compromise the system appears to be by obtaining the correct key, reading the value of the pellet with an ohm meter, then duplicating the key on the correct blank. To legally duplicate a key, a locksmith simply follows the same procedure.

29_7.6 Picking Axial (Tubular) Pin Tumbler Locks

The first patent for a tubular configuration was granted in 1934; the lock was manufactured by Chicago Lock Company. Axial pin tumbler locks are extremely popular in a variety of applications worldwide. They have proliferated into vending, telephone, banking, alarm, access control, and many other uses. These mechanisms can be found in mortise cylinders, cam, and padlock configurations. One reason they are so popular is that they are essentially impervious to climate and environment: temperatures, frost, dust, salt and other factors will generally not affect operation. Their popularity makes them a target for thieves, and thus, detailed information will be provided here.

Axial locks are based upon the same operating theory as traditional pin tumbler mechanisms: equivalent bottom and driver pins are placed to create a rotating shear line. The principle difference between the two designs rests in the location of the pin stacks. In conventional locks, all pins are contained within a rotating plug, wherein each chamber is oriented in a straight line, traversing the full length of the plug. Only the first pin is exposed in the keyway. In the tubular lock, pins are generally oriented in a circle around the axis of the plug rather than in a straight line, although this is not always the case. All pins are usually visible.

Axial keyways are defined by their diameter, number of active pins, diameter of the pins, spacing, number of dead (non-moving) pins, and whether the active pins are flush or protruding from the shell. The “standard” keyway uses a Taylor 137, Ilco 1137s, or HPC 1SP blank, .375” diameter. Most axial locks have standard keyway diameters. There are, however, undersized locks that have smaller keyways, making it impossible to insert the standard tubular pick.

Master keying schemes have been developed for axial locks, including the use of traditional master pins and additional master rings. Special keying systems and options are also available. Chicago and Fort, for example, offer instant rekey

systems, and which are discussed elsewhere in the text. Due to the acceptance of these locks, many special bypass tools and techniques have been developed for the locksmith trade. Several of these devices, primarily manufactured by HPC, are detailed in this section.

29_7.6.1 Definitions

There are a number of terms describing the parts of an axial lock and their bypass tools.

Bottoming Out

The springs and pins are compressed within their chambers to the maximum.

Dead Pins

These are solid pins placed between regular pins to act as wards. Generally, there is no more than one in a cylinder. Their function is to inhibit the entry of picks and keys. They can be bypassed by extending feelers in the bypass tool past the outer edge of the pick.

Feelers or Tynes

Sliding pins, shims, or other similar devices are used in pick tools to manipulate each corresponding tumbler within the lock. The tynes are generally very fine, flat spring steel shims that are placed axially around the circumference of the bypass tool. They mate with the pin tumblers and depress them, based upon the application of pressure exerted upon the tool.

Key

A key for an axial lock is, in effect, a round hollow shaft with indentations of varying depths placed around its circumference. They correspond with the depth of each pin tumbler. The key generally has a guide that fits into the slot on the shaft and facilitates rotation.

Keyway

The keyway is the round opening that allows a tubular key with a specified diameter to enter and depress the tumblers to shear line. It is formed so that the key fits over a slotted shaft.

Pin-Stack

The pin-stack consists of a spring, driver, top pin, and any master pin.

Shaft

The shaft provides the medium for transmission of rotational energy by the key and is the method by which the shear line is created and aligned. One thick round disc or rotor is generally affixed to the shaft. In combination with a mating parallel rotor, it creates a shell, plug, pin chamber and shear line. The shaft generally terminates in a cam that is used to actuate the bolt mechanism.

Shear Line

A shear line is created in the axial lock by the placement of two parallel stacked concentric rotors or discs, having holes drilled around their circumference. As in the conventional pin tumbler lock, a pin-stack is contained within each of these holes.

Shell

The shell is actually formed by one of the two concentric rotors that are affixed to the body of the lock. The other rotor, attached to the shaft, is the equivalent of the plug in a conventional pin tumbler lock.

Zero Cut

There are generally eight depths in most tubular locks: the zero cut is a no cut; the number eight is the deepest cut.

29_7.6.2 Producing Keys for Axial Pin Tumbler Locks

There are a number of manual and automatic cutters available to produce tubular keys. These can be small, handheld units or sophisticated and expensive computer controlled milling machines that are capable of reproducing virtually any key. The author recommends the HPC handheld cutters for use in the field. These devices allow generation of the “standard” keys rapidly in any environment.

29_7.6.3 Pick and Decoding Tools for Axial Locks

29_7.6.3.1 Introduction

Many picking and decoding tools have been developed to open these locks and generate keys. Actually, these tools manipulate tumblers, impression each pin, and decode pin length. Their operation will be discussed in this chapter, although they could just as logically be presented in **Chapter 30**, Impressioning, or **Chapter 31**, decoding locks.

The first decoding devices were patented by Harvey Wilson in 1953 and Robert Gruber in 1966 (**3149487(284), 2059376(285), 3251206(286), 2070342(287)**). Shortly thereafter, HPC began manufacturing and developing a wide array of tools for virtually every axial lock. A newer device was invented by Persson in 2001 (**6230529(288)**).

29_7.6.3.2 Basic Pick and Decoding Tool Design

Both pick and decoding tools for conventional axial locks generally operate upon the same theory: a modified form of impressioning. Virtually all picks employ a sliding shim or pin that is used to depress corresponding pin tumblers within the lock. Each shim is caused to drive the lower pin to shear line and stop. The position of each shim can thus be used to reproduce the correct key once the lock has been opened.

HPC has introduced many modifications since the first axial picks were introduced. Today, there is a selection of sophisticated bypass tools to open virtually any tubular lock. There are a number of different tools available, each designed for a specific lock design. They are produced in plastic and tool steel, and vary in sophistication. They all, however, perform the same function.

Some tools allow the manipulation of individual tumblers; others work on all pins at once. A particularly clever tool is called the "peanut." It is available for several different keyway diameters and is made of delrin plastic, with embedded shims. These devices are very small and convenient.

29_7.6.3.3 Tension Tools for Axial Locks

Tension tools may be constructed to allow conventional picking of

tubular locks. Generally, these take the form of square shapes, often using a specially cut Allen wrench. Square shapes, having measurements of about .62” on a side, are popular but are difficult to use. Remember, axial locks must be picked as many separate times as there are pins for just one revolution. Conventional picks may be utilized to manipulate each pin.

The main problem in conventionally picking these locks is that of leaving the plug partially rotated. The criminalist should be alert to this condition. As noted elsewhere in the text, a partially rotated shaft may also have been caused by a key being withdrawn that did not have a guide pin. It could also result from the use of a special master key or instant rekey system that allows removal of the key in any position.

Special forcible-entry tools are available, including hole saws and lock pullers. Hole saws, without the pilot bit, are quite effective; a needle nose pliers is used to turn the shaft. See **Chapter 32** for these techniques.

29_7.6.4 Security Features Incorporated within Axial Locks

In order to frustrate the use of traditional bypass tools and techniques, a number of manufacturers have developed high-security axial locks. Generally, telescoping or tube pins are utilized as the primary mechanical design alteration to increase security. In addition, springs of different tension, as well as mushroom, spool, and serrated tumblers may also be employed. Counterboring of chambers, and rotating plugs are other techniques. Some axial locks are UL listed.

29_7.6.4.1 Rotating Plugs

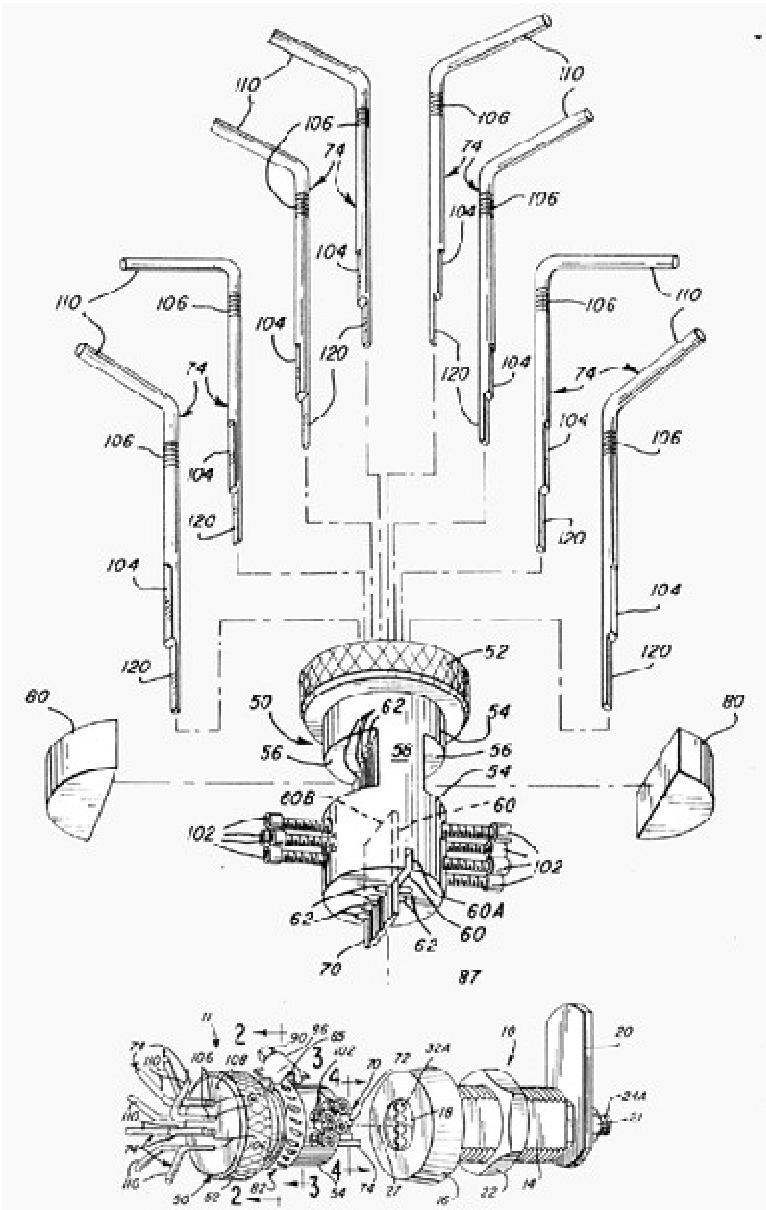
When this security feature is incorporated, the application of pressure to the face of the lock will cause the plug to rotate. These locks can be picked once a **single** pin is set. The procedure to bypass locks with rotating plugs is:

- **Insert the pick without any torque;**
- **Apply a slight turning tension as the tool is inserted;**
- **Once the initial pins are picked, release, and maintain a marginal turning pressure;**
- **Determine the sequence of picking.**

29_7.6.4.2 Counterboring of Chambers

Chambers close to the shear line are often counterbored or enlarged and widened to allow lateral movement of the pin. Once the tumbler is partially picked and the plug slightly rotated, the pins in such chambers cannot reach shear line. When they are picked, they will feel as if set at shear line, when in fact they are not.

29_7.6.4.3 Tamper-Resistant Locks



Combination pins that resemble master pins are used to create another shear line, making picking more difficult.
The second shear line is located at the "0" cut position. The lock is actually picked and can be turned slightly, but there is a steel roll-pin to prevent complete rotation.

29_7.6.4.4 Square Pins

Locks made in the Orient may contain square pins that reduce the cost of manufacture. These can be bypassed with standard picks.

29_7.6.4.5 Rectangular Keyway

Chicago Lock introduced an axial device having a rectangular keyway in about 1985, called the Tubar. These locks had a series of eight pins in two rows and featured a dual sidebar. Initially, no pick tools were available and bypass was quite difficult. The lock originally had a number of design problems and could be forcibly entered with little difficulty. See **Chapter 17** for a detailed description.

Exploded views 1, 2, 3.

29_7.6.4.6 Shrouded Entry

Locks in high-security applications can be protected with shrouds and pick guards to restrict the entry of bypass tools. These elongated metal throats cover the keyway, making manipulation of tumblers difficult. They are popular in coin-operated laundry machines; they can be bypassed using the HPC ALCP-10 automobile lock face cap puller. Pick guards may cause problems when a total lockout occurs. They are used on alarm switches and vending

machines and are very popular, assuming there is ample space for mounting. The HPC TLG-10 is an example of a shroud.

29_7.6.5 Basic Picking Theory for Axial Locks

Bypassing axial pin tumbler locks differ in several respects from conventional lock-picking. In many ways, opening is easier than when using traditional techniques and tools. Because all pins are accessible and may be observed, they can be individually picked with greater precision and less difficulty. There is more room to physically manipulate tools without affecting adjacent tumblers.

Although picking pins individually can be accomplished, it rarely is, because of the difficulty in applying torque to the shaft. Picking these locks with the class of bypass tools that utilize moveable feelers actually relies upon a modified form of impressioning and picking. Each pin, simultaneously, is biased with a corresponding spring loaded feeler or tyne. These shims are used to depress the pins in concert.

The underlying principle relies upon the fact that the resistance of the tyne will approximate the bias placed upon each pin by its spring. When the feeler is pressed against a pin, it will continue to move the pin until stopped by shear line. As the pin moves in the lock, so moves the feeler. Thus, whatever the distance the pin moves to reach shear line, so will the feelers move from the tip of the pick tool. In this way, the lock can be decoded after being opened.

In order to move the feelers, the tool is “pumped” back and forth, with new torque being applied for each cycle. This is precisely how a lock is impressioned. Pins will only bind when “set” at shear line. At all other times, they will be free to move, just as in the conventional pin tumbler lock.

The major problem in bypassing axial locks is that once picked, the plug will only rotate 1/7 or 1/8 of a revolution. This is why it is important to be able to decode the combination after impressioning/decoding one time. In case of difficulty, the tool can be removed and inspected for all feelers that have been moved to the #6 or #7 positions (far in), then reset to “0.” The tool is then reinserted, and the process repeated.

29_7.6.5.1 Preliminary Considerations for Picking Tubular Locks

Prior to picking any axial pin tumbler lock, the following items must be accomplished:

- **Identification of the type of lock and the corresponding tool to use for bypass. There are four different types of axial locks:**
  - **7-pin center (first pin is at 1 O'clock);**
  - **7-pin center; use HPC TLP-PEANUT or MIDGET;**
  - **7-pin offset;**
  - **7-pin left or right offset:**
    - **RIGHT = just right of keyway;**
  - **LEFT = just left of keyway;**
  - **8-pin center;**

- **Assessment of the best method to bypass;**
- **Selection of the proper pick tool;**
- **Be certain the plug is free to rotate. It can be tested with the insertion and turning of a blank key;**
- **Determine if there is external pressure on the shackle (in a padlock) that may cause the shear line to be inoperable. In this case, reverse shackle pressure may be applied;**
- **Inspect the keyway for dead pins;**
- **Be certain that the plug has some play: at least 1-2º is required;**
- **All pins must be able to move freely and easily. A key can be inserted and removed to move each pin or a regular pick is used to depress each pin;**
- **The O-ring on most tools is used to maintain constant tension of the shims or feelers. Be certain it is intact;**
- **Determine that each tumbler is working by testing with a conventional pick.**

All springs must be operational and not compressed, especially if the lock is exposed to elements (such as corrosion from temperature extremes, humidity, salt air, acid rain, or snow). Be certain that all active components move freely. If the lock is inoperable, it can be rapped with a mallet, sprayed with silicon, oil, or graphite to loosen stuck pins, or heated if

cold. Be careful not to apply too much heat as this may destroy the springs and melt components. If oil is used to clear or clean the lock, insure that it is completely removed from any external surfaces, as it will destroy the "O" ring in a pick tool.

29_7.6.5.2 General Rules Applicable to all Axial Lock Picks

All axial pin tumbler lock picks follow the same design and contain the same components. The following rules apply generally to their use. Special tools and procedures are detailed elsewhere in this section.

- **Practice is required prior to becoming proficient;**
- **Do not use force;**
- **Do not apply too much torque to the tool; it is not designed for heavy rotational pressure. Improper tension is the greatest problem in manipulating axial locks;**
- **All feelers should be placed in the extended position, then zeroed until flush with the end of the shaft;**
- **Insert the tool straight into the keyway and apply slight tension. Angles will cause extreme problems;**
- **Picking is done with an in/out motion, no more than 1/16" change. Practice a smooth in/out motion, with no angle of attack;**
- **Pick the lock until open;**
- **Carefully remove the tool so that decoding of the key is possible;**
- **The application of inward pressure without torque will accomplish nothing;**
- **Collar pressure on the feelers must be fairly high in order to retain their position and simulate proper impressioning of the pin tumblers;**
- **A pick may be inserted into the lock to depress each pin for a determination of spring tension. Tension is correlated to pin length: if tension were applied at random, these locks would be quite difficult to pick. In general, short pins are harder to depress because they must be pushed farther into the chamber. Longer pins will generally have less**

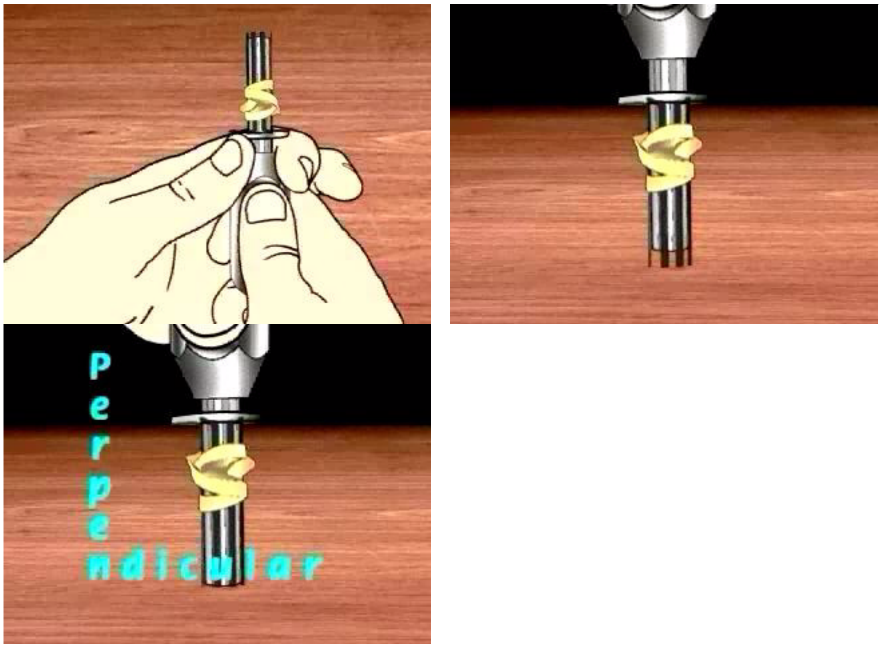
spring bias. With practice, it is easy to determine spring tension and thus the approximate pin length for a given chamber;
- **Try picking in the alternate direction if there is a problem opening the lock.**

29_7.6.5.3 General Procedures for Picking Axial Locks

- **Check all of the feelers on the pick. Their resistance should be about equal to the spring bias on tumblers within the lock. To add tension, add a rubber band rapped around the body of the pick;**
- **Push all feelers downward so that they extend past the tip of the tool. Depress the face of the tool against a flat surface to "zero" all of the feelers;**
- **Hold the tool between the thumb and index finger;**
- **Apply a slight torque;**
- **Withdraw the tool about 1/16," allowing the pins to reach their normal position;**
- **Pump the tool in and out. That is, move the tool back and forth, always maintaining a straight approach; never at an angle. In effect, all tumblers within the lock are being impressioned simultaneously through the action of the feelers;**
- **If the pick slips out of the lock, carefully reinsert so as not to disturb the feelers;**
- **Longer pins will require more movement to set than shorter pins;**
- **If picking a padlock or spring loaded-mechanism, more pressure will be required. The shackle may be depressed to relieve some of the tension;**
- **Once the lock is picked, withdraw the tool, applying a slight rotation of the shaft so it sets between the first and second tumbler position; note the depth for each pin;**
- **After successful bypass and slight rotation of the plug, "zero" all tynes on the pick. Then reinsert the tool with no tension applied so that the exact position of each pin can be determined;**
- **Decode the pick before using it as a key;**

- **Cut the key based upon the code information;**
- **When picking, set the feelers of most tools flush with the edge of the pick, except for mushroom pins. In these cases, the feelers should be set back at the #8 cut position;**
- **Mushroom pins will not cause any more problems to pick if they are properly identified.**

**Figure LSS+2910 The axial pin tumbler key and lock. These diagrams show the key,
and locks in a locked and partially picked position. The pick decoder tools are all
designed to manipulate each of the pin tumblers to shear line in order to rotate the
plug. Through a series of pumping actions, individual shims make contact with the pins
and actually impression each tumbler. Shown is the standard seven pin configuration.
Courtesy of HPC Interactive Learning Series.**



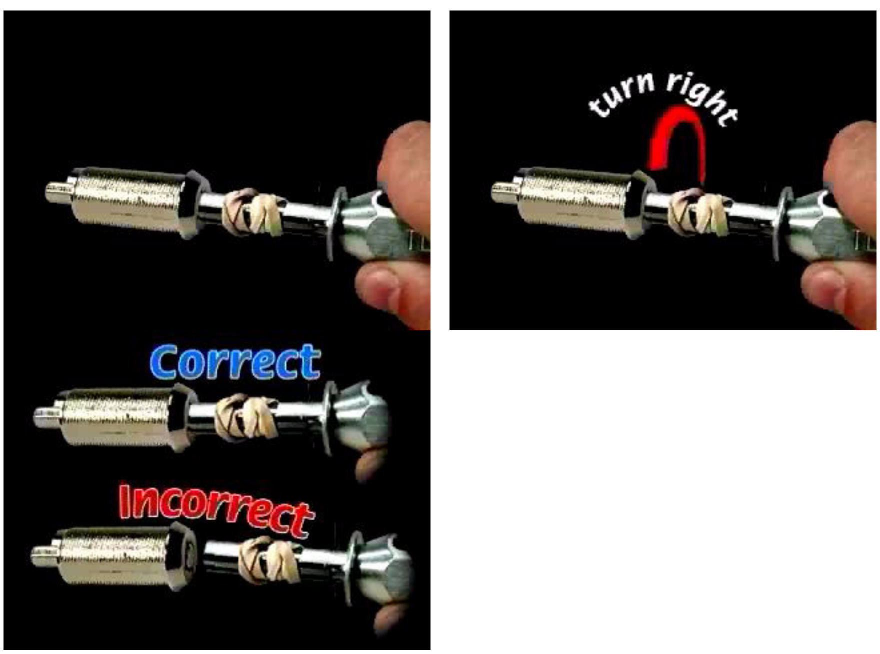


**Figure LSS2911 A rubber band is utilized to provide tension to the tynes and to
retain their position during decoding, while allowing movement as pressure is applied to each pin. The end of the tool is pushed against a flat surface to align
all tynes to the same position. Courtesy of HPC Interactive Learning Series.**

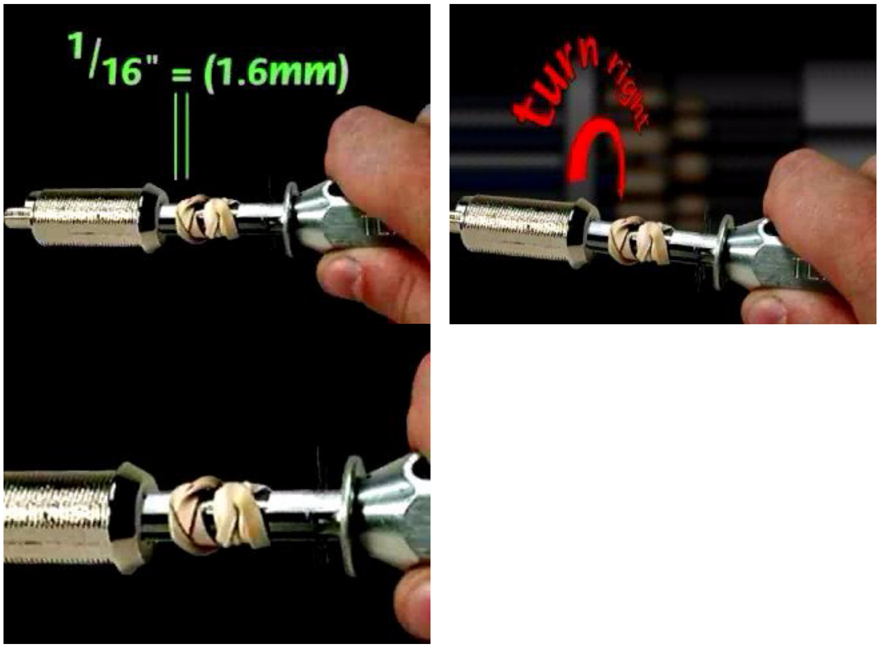

Figure LSS+2912 The pick decode tool is inserted into the lock at a perpendicular angle to a depth of approximately 1/16". A turning and pumping action is applied to, in effect, impression each pin. A series of such actions will cause each pin to move to shear line, with a corresponding movement of the tyne associated with each tumbler. The rubber band will maintain the position of the tyne, while allowing it to move slightly with the pin. Courtesy of HPC Interactive Learning Series.

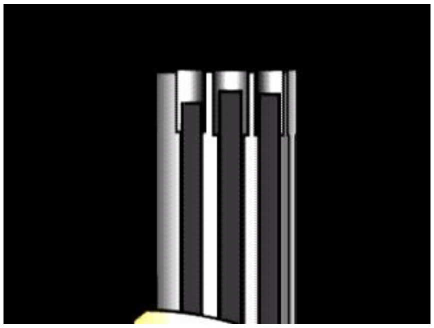

Figure LSS+2913 Once the lock has been picked and decoded, the pick decode tool is pressed against the tumblers to set the tynes to the exact pin depths. This is accomplished by slightly rotating the plug to a position where the pins are not aligned. Pressure may then be applied to the tool fully inserted into the lock, so that to the bottom set of tumblers are firmly forced against the shell. The tension on the tynes is increased to insure that their position is maintained. Courtesy of HPC Interactive Learning Series.

29_7.6.5.4 Picking UL Listed High-Security Axial Locks

High-security axial locks generally have ten or eleven pins, with three or four of those utilizing a telescoping design. The primary difference between these locks and conventional tubular mechanisms is tolerance, added pins, and the use of the telescoping design. The locks pick in conventional fashion: each tumbler must be individually manipulated. Often, the telescoping pins must be picked last.

29_7.6.5.5 Picking Axial Locks with Security Tumblers and Other Features

High-security axial locks will contain security pins resembling traditional mushroom, spool, and serrated designs. These will not cause any more difficulty when incorporated in axial locks than in traditional pin tumbler mechanisms if they are identified and picked properly. The procedure for picking tubular and standard pin locks is the same. It is quite difficult to determine which name-brand cylinders contain security pins, especially because locksmiths may replace standard pins in the field. The procedure for bypassing locks with mushroom and spool security pins generally requires the following procedure:

- **Determine which are security pins. There will never be more than two or three within any axial lock. Mushroom and spool pins are only used in driver**

position; serrated may be used for both bottom and top pins;

- **When utilizing a bypass tool, insert and withdraw in very shallow steps, only about 1/32". This procedure will prevent mushroom tumblers from catching. Pumping too far will cause the pins to catch at shear line;**
- **Pick the standard pins in the conventional fashion. When the lock is partially picked, the plug will shift approximately 5° toward the open position. Continue picking, depressing each feeler individually;**
- **Feelers located adjacent to mushroom or spool tumblers will indicate some movement as they are pushed toward shallower depths;**
- **Reset the pick and set all pins to "0" (at the edge of the tool), except the security tumblers, which are set to a depth of "8".**

In locks containing serrated pins, picking requires:

- **Locating which chambers contain the special pins;**
- **Decreasing the amount of torque;**
- **Picking each pin individually.**

29_7.6.6 Decoding Axial Pin Tumbler Locks

LSS204: Harry Sher on picking axial pin tumbler locks

Figure LSS+2940 Two examples of axial pin tumbler lock picks and decoders, produced by A-1 (left) and Peterson Manufacturing.

When these locks are picked with impressioning and decoding tools, the pin depths must be determined in order to produce a key after the bypass process has been successfully completed. Decoding occurs while the lock is in a picked status; generally, the core is rotated so that it sets **between** pin chamber positions. Pin depths can be derived either from the decoder tool or from a key that operates the lock intermittently (if it is damaged or chipped). Depths are approximately 1/64" per cut.

The **HPC TKPD-1** tubular key and pick gauge is a stainless steel device, having eight depths; number eight is a pin within a pin. This tool may be used for all standard small, large, left and right-hand UL tubular keys. Keys are read clockwise from the front. Remember to keep the corners sharp, do not use a wire brush, and read the key at the corners.

29_7.7 Picking Magnetic Locks

Magnetic mechanical and card locks can be categorized in five primary configurations as detailed in **Chapter 19.** Some configurations can be decoded, others, such as employed by Evva and Chubb, cannot. The basic principle of all magnetic locks rests upon the law of physics regarding magnetic energy: that like poles repel and opposites attract. All magnetic mechanisms rely upon this theory to communicate information and motion between a key and internal parts.

It appears that the first commercial magnetic lock may have been developed in Japan, about 1959, by K. Wak. It was based upon the

traditional pin tumbler design, but the pins were magnetic rather than spring-biased. They were raised by repulsion of the magnets embedded within the key. For many years, magnetic locks did not gain industry acceptance until the development of rare-earth materials and the integration of sophisticated sidebar locking systems.

There are a number of potential security problems and bypass techniques for these types of mechanisms:

- **Magnets jammed in the lock;**
- **Demagnetize all pins;**
- **Remagnetize all pins;**
- **Decode and read the signature;**
- **Copy a key and simulate it;**
- **Read each tumbler, then construct a key.**

The security of all magnetic locks ultimately rests upon the determination of the polarity and location of each magnet. In certain high-security designs, magnetism is used as a medium to cause the movement or rotation of secondary locking devices, such as the Evva, Ikon, and Chubb sidebars. They actually rotate discs, much the same as in the mechanical Abloy disc lock.

Several techniques have been developed for bypassing magnetic locks, although most require decoding the location and polarity of each magnet first. In certain locks, keys can then be simulated with matching magnets to either attract or repel all pins. The following traditional methods are well known:

- **Remagnetize all pins using an extremely strong field introduced into the lock;**
- **Read the magnetic signature and then simulate the location and polarity of each magnet;**
- **Read the signature on the key card and duplicate;**
- **Demagnetize all pins, then rap the lock open;**
- **Sense each magnet's position and polarity by listening and feeling; then simulate with a key or through the use of a Hall-effect probe;**
- **Electronically bypass, by introducing rapidly pulsating fields, to fool the magnets or Hall-effect sensors. This technique requires the construction of a strong electromagnet. This is done by using at**

least 1500 feet of #34 gauge insulated magnet wire wound around a soft steel core, minimum 3/4″ wide and 1/32″ thick, and approximately 8″ in length, folded in half.

A potential of 110 VAC is passed through a rectifier and coil, creating a very strong field. The tip is moved back and forth through the lock to neutralize all magnetic pins. A solenoid coil with the core removed and a rod inserted through the center can be effective. A multivibrator circuit can be employed to drive the field.

Some magnetic locks can be picked by utilizing a very small magnet on the end of a wire to sense the polarity and position of other magnets by listening and feeling their movement. Clark invented a magnetic lock pick (**4073166(289)**) in 1978.

The author has developed a sophisticated procedure for decoding and opening many mechanical and electronic magnetic locks. This technique will provide immediate placement and decoding information for all magnets, allows for the decoding of master keys in card-based systems, and will make possible the generation of a key. See **LSS+/**[x] for a complete description.

29_7.8 Picking Dimple Locks

29_7.8.1 Introduction

Dimple locks contain one or more rows of pin tumblers in either a horizontal, vertical, or combined orientation. They may utilize solid pins, or a pin within a pin (telescoping), for high-security applications. Generally, the locks can be picked and easily impressioned. The locks are so named because the keys have bitting that resembles a series of dimples or indents on one or more surfaces. These dimples perform the same function as the bitting on a traditional key. Unlike conventional pin tumbler locks, however, the pins are all aligned in one or more straight rows, generally at the 12, 3, and 9 O’clock positions, or radially, at 4 or 5 positions.

Dimple locks can be picked, raked, impressioned, or vibrated open. In the photograph below, a Lips dimple lock was the subject of attack at the Antwerp diamond exchange in Belgium during a $100,000,000 burglary in 2003. The tool is a modified Allen wrench that is used to rake the tumblers. Using this tool,

investigators were able to open these locks with no lock picking skills.

Figure LSS+2942 A rake pick, fashioned from an Allen wrench, can easily open dimple locks.

Depending upon design of the keyway, orientation and placement of

the tumblers, and special security features, these locks can be simple to extremely difficult to bypass. They generally have very limited tumbler depths as compared to a conventional lock but will contain many more pins. The locks are provided in cylinder and profile configurations.

It is important to note that the pins and springs may not be at the top of the keyway as might be expected, especially in the profile design. Often the drivers are attached to the springs. Several manufacturers produce machines capable of duplicating dimple keys. For laboratory or field work, the author recommends the Silca SLX for its versatility and reliability.

29_7.8.2 Conventional Bypass Technique

The proper method to pick a “conventional” dimple lock requires the use of a small tension wrench and a half or full-ball pick. Tumblers can be picked individually or raked, depending upon the factors noted above. If dealing with a profile lock, it must not be picked more than 20° in either direction, or there is a risk of losing pins. In fact, in some locks it may be possible to actually remove pins from the lock during bypass.

Picking requires very little movement of the pick tip to simulate the shallowest cut on the key and to move between tumblers. The main obstacle in bypassing dimple locks is to manipulate individual tumblers without disturbing or raising adjacent ones. An “in and out” and rotational motion is generally employed in a modified raking action to open dimple locks with solid pins. Telescoping tumblers can present much more difficulty. There are, however, tools available to bypass certain of the high-security dimple locks. See **LSS+/^{x}** for a full description.

29_7.8.3 Forensic Examination

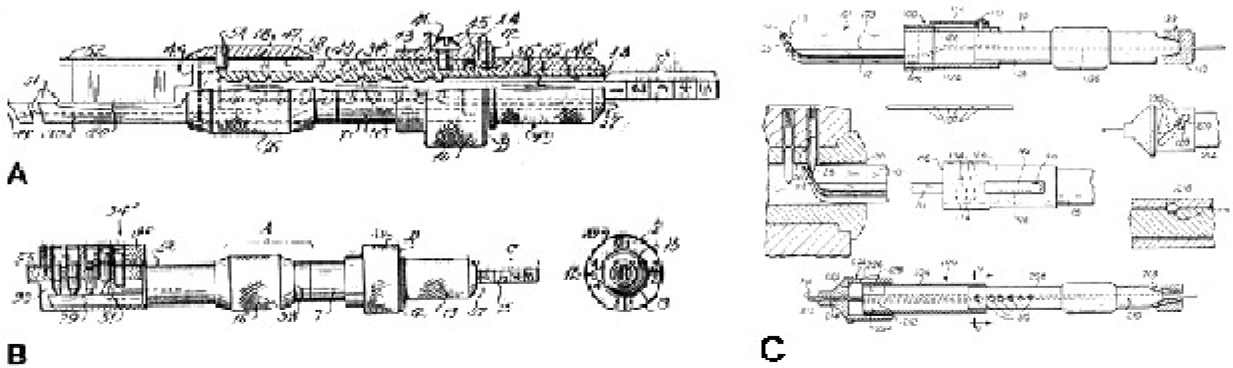
Care must be exercised in disassembly. Some of these locks contain uneven space sliders. Each must be replaced in the proper place and order or the lock will not work. If conducting an examination for evidence of bypass, look for elongated or distorted chambers or deformed or crushed pins. This is highly indicative of impressioning. So also, there may be wax, tape, or other residue within the keyway. See **Chapter 26** regarding forensic analysis.

Residue may be present when a dimple lock has been bypassed. Courtesy of

Hans Mejlshede.

29_7.9 Picking Best Removable Core

Best Lock Company was perhaps the first to introduce removable-core cylinders. Although many other vendors now produce similar and often interchangeable products, Best still is one of the leaders in the industry. The concept is simple: a sealed module, containing the plug, control ring, control pins, drivers, and springs, is housed within the shell. In effect, the removable core is a self- contained lock with a cam and special locking tab to prevent removal of this assembly without the use of a control key.



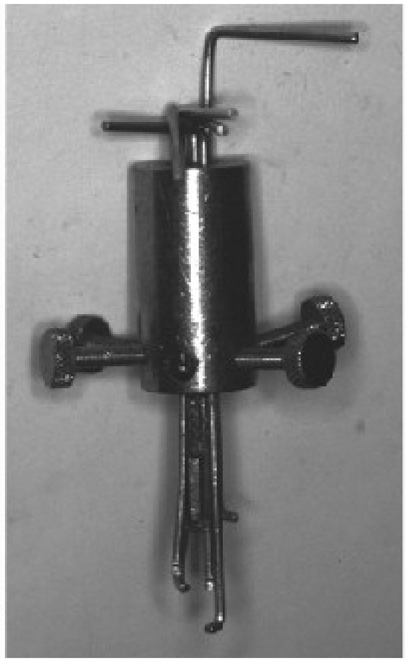
The core can be withdrawn from the lock by inserting the control key, which raises tumblers to a second shear line created by a control ring. The control ring in turn will allow the rotation of a locking tab that ordinarily prevents the core from being removed. In regular use, the change key or master key is inserted. This raises a set of tumblers to the shear line associated with the plug. It is impossible to remove the core by picking the pins to this shear line. The control key raises the tumblers to a second, higher shear line created by the addition of a ring surrounding the plug. This resembles the Corbin Split Ring design used for master keying which is discussed elsewhere in this text. The control shear line splits the pins between the control ring and shell.

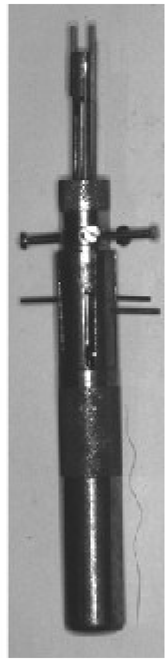
The difficulty in bypassing removable core locks is twofold. Providing the proper torque can be a problem, because there is a tendency to rotate both the plug and control ring. Physically, there can also be a problem with the proper seating of the tension wrench. In the case of Best, the chamber holes at the bottom of the keyway are open. A special tension wrench has been designed that penetrates these holes in order to allow picking of the control ring.

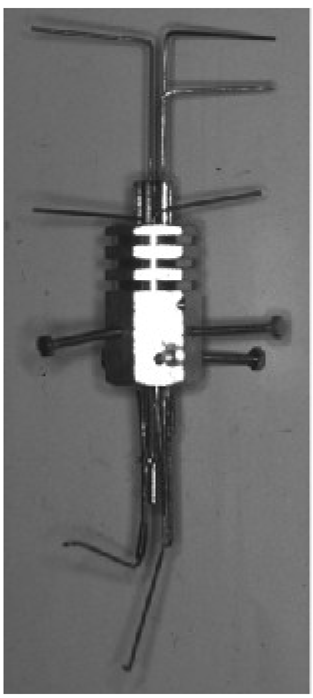
Care must also be exercised to utilize picks with small tips. Pins are spaced quite closely between the regular and control shear lines; thus there is a tendency to over-raise them. Within the Best lock, it is possible to decode the control key by removing all of the top pins and measuring them. Their length will directly correlate with the control pins.

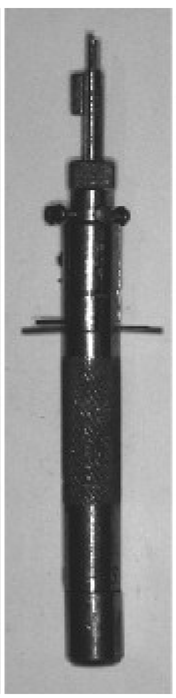
29_8.0 Specialty Pick Tools

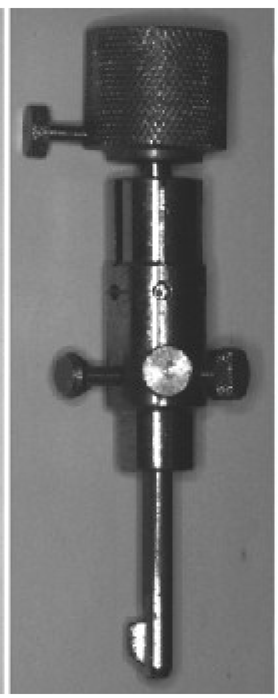
Many specially designed picking tools are produced by John Falle, HPC, Lock Defeat Technology Corporation, MSC and other vendors for high-security locks. Some implements incorporate extremely sophisticated mechanical designs to bypass equally sophisticated locking mechanisms.

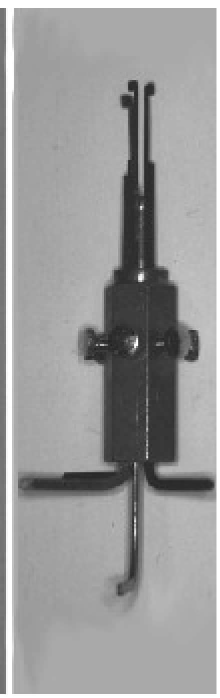












A montage of some of the most clever and innovative tools for picking locks is shown at the end of this chapter. Development of such implements began more than two centuries ago. The ingenuity of locksmiths and government operatives is evidenced by the fact that very few locks are immune to bypass with such tools.

Exploded views 1, 2, 3, 4.

Other devices for decoding and picking locks are examined in **Chapter 31.**

29_8.1 Sputnik Picking and Decoding Tool

LSS201: MSC "Sputnik" bypass tool, courtesy of MSC.

MSC and Oliver Diederichson have developed a specialized picking and decoding tool dubbed the "Sputnik" for pin tumbler locks. This device utilizes fine wires that are manipulated by the operator to move each pin tumbler, through the action of telescoping members. The name of the tool was derived from the first Russian satellite because of the antenna protrusions from the spacecraft which closely resembled the tool design. The tool closely resembles one that was described in a patent issued to Bitzios in 1992 (**5172578(290)**).

Special blanks are produced by MSC for each keyway, and will function with five or six pin locks. The tool has the advantage of allowing the manipulation of all tumblers without disturbing the relative position of any one pin. In conventional picking, the length and position of one tumbler can cause the resetting of all other tumblers as the operator attempts to lift a particular pin. The Sputnik provides a way around this problem. Picking is accomplished by sensing the position of each tumbler as the wire associated with it is moved, causing the pin to reach shear line. Use of the tool is fairly straightforward, and is shown in the video demonstration.

Once the lock is picked, the position of each telescoping section can be locked in position and decoded.

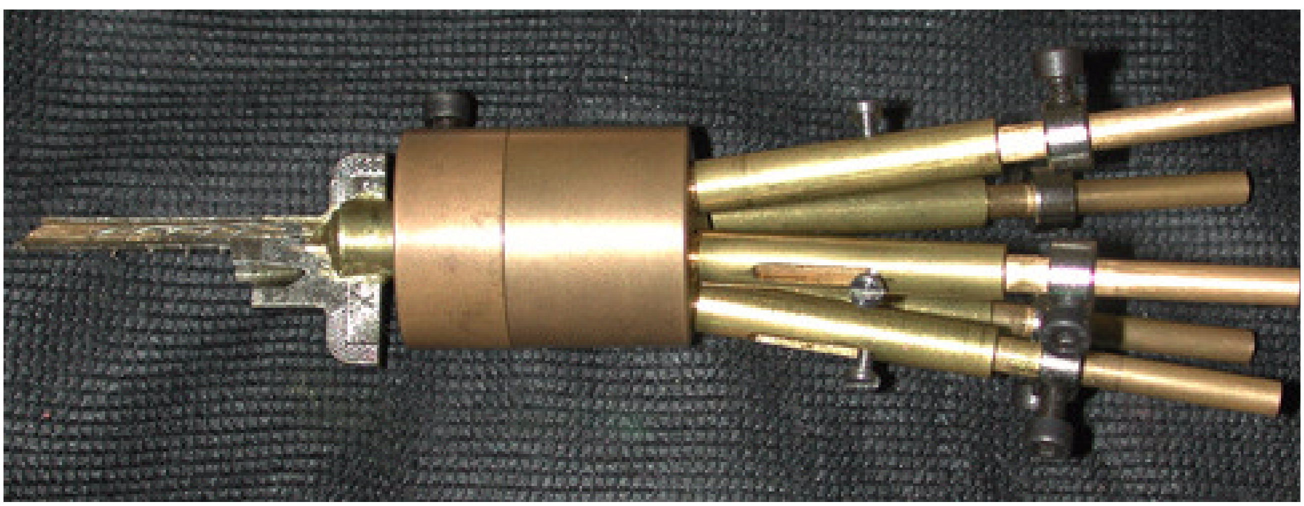


Figure LSS+2914 The MSC Sputnik tool can manipulate all pin tumblers simultaneously.
Each telescoping tube controls an individual wire. The setscrews determine the relative
position of each wire, and can be locked in place to decode the lock after picking.

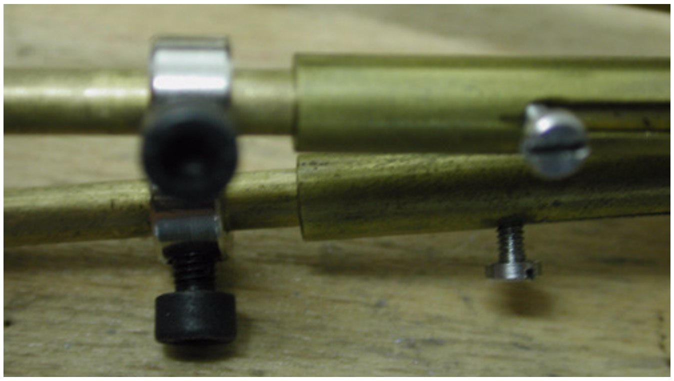

Figure LSS+2915 Each member of the Sputnik controls an individual wire shim. The moveable ring is secured by an Allen screw to lock the member into position for later decoding. A locking screw retains each shim wire in position.

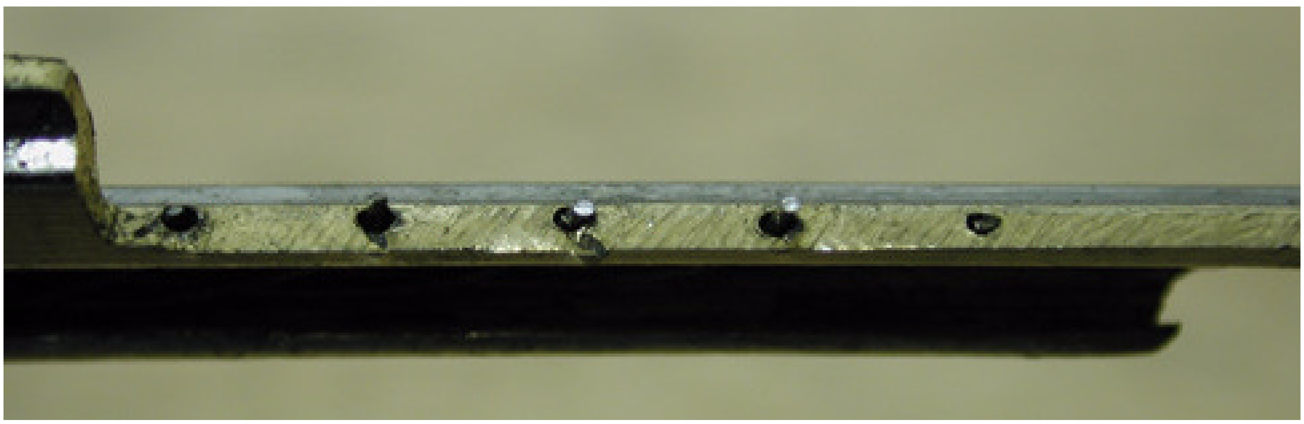

Figure LSS+2916 A blank key with the correct keyway profile must be produced by MSC
for a specific lock. A hole is drilled to correspond with each pin chamber.

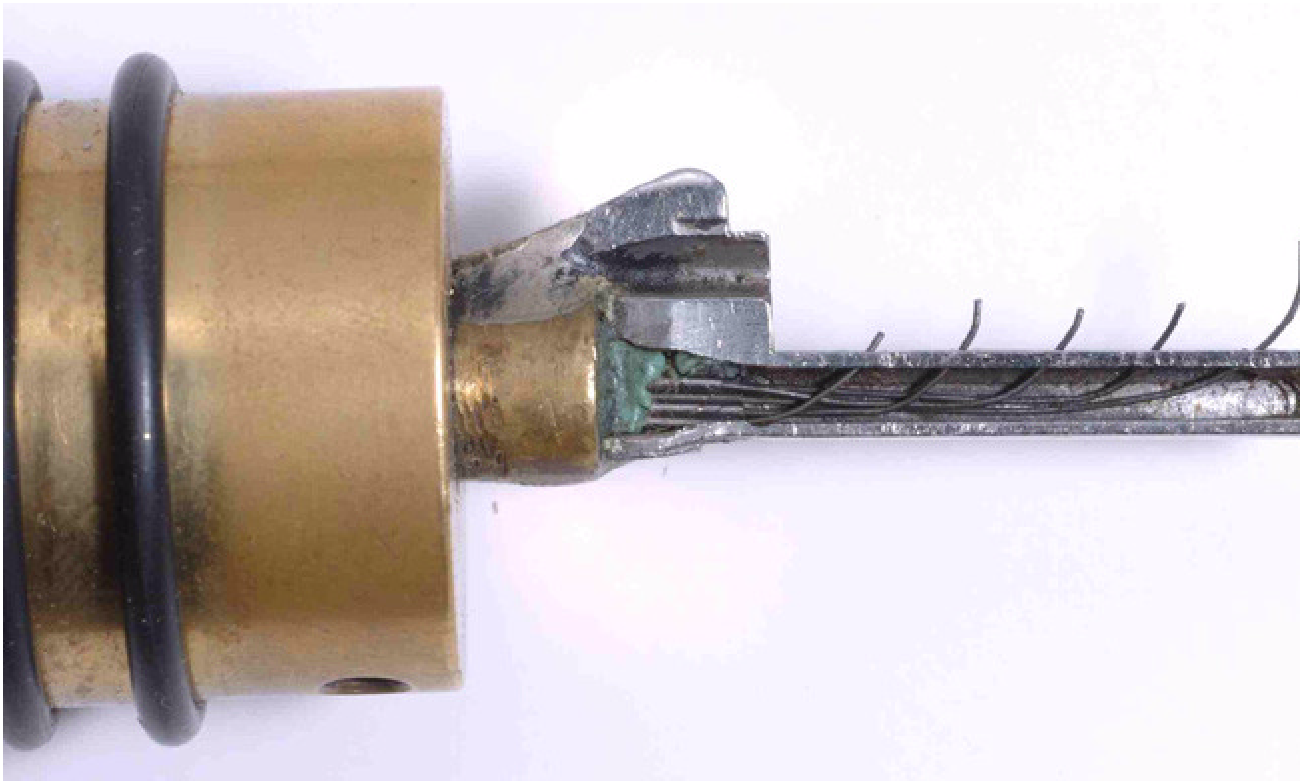

Figure LSS+2917 This photographs shows how each shim wire is associated with a chamber.
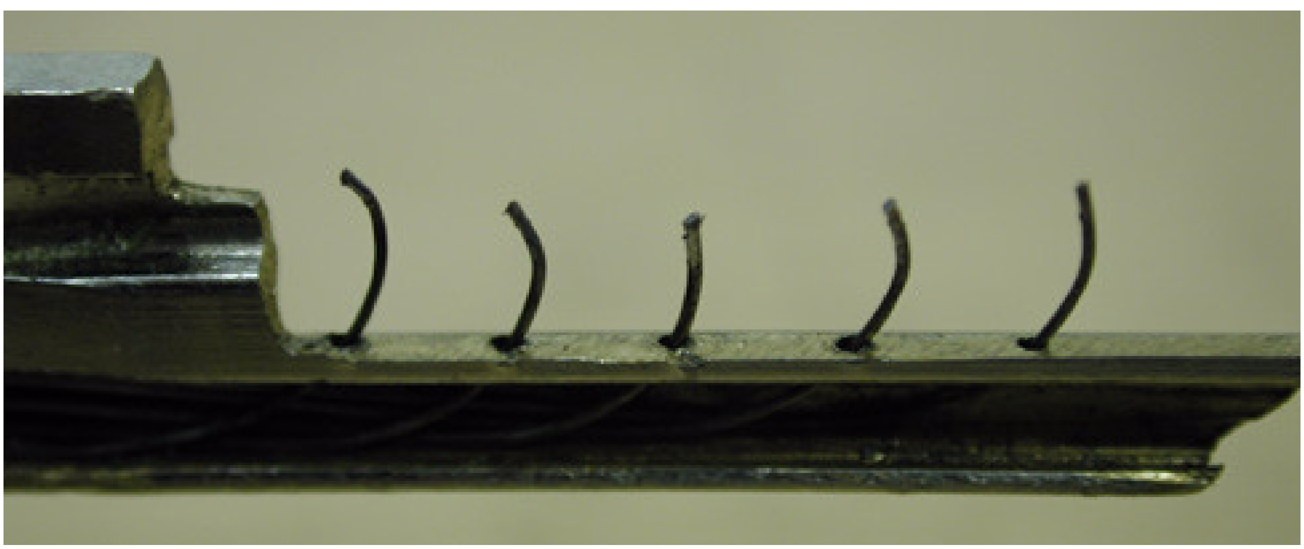
The wires are utilized to force each pin to shear line.



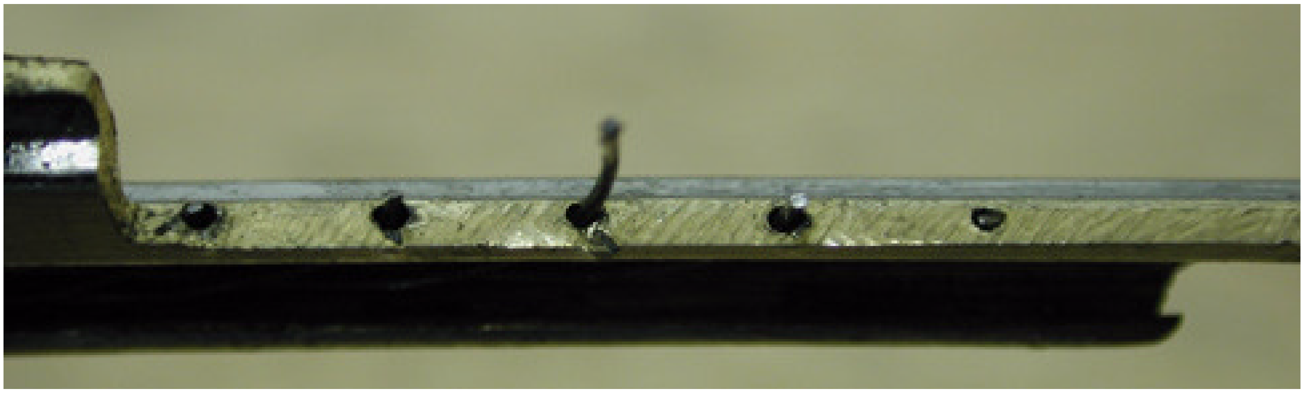


Figure LSS+2918 This photograph shows all shim wires fully extended.

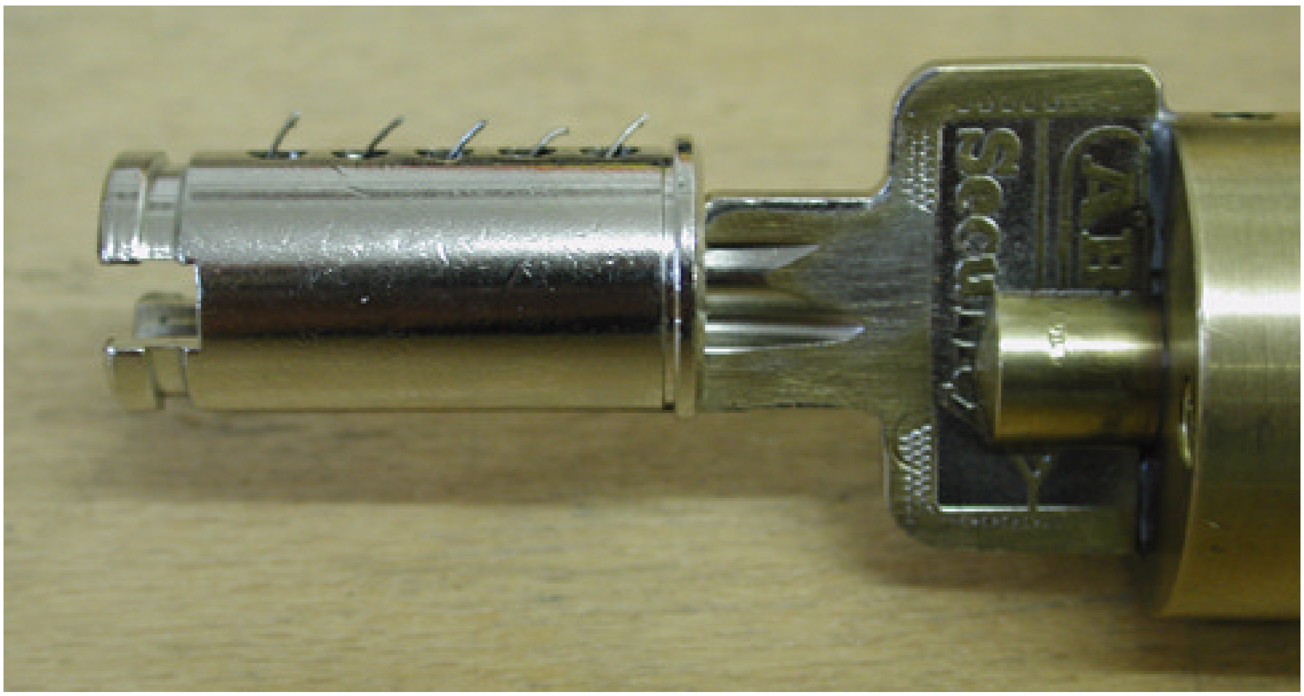

Figure LSS+2919 Any one or more shim wires can be manipulated individually while picking a lock.

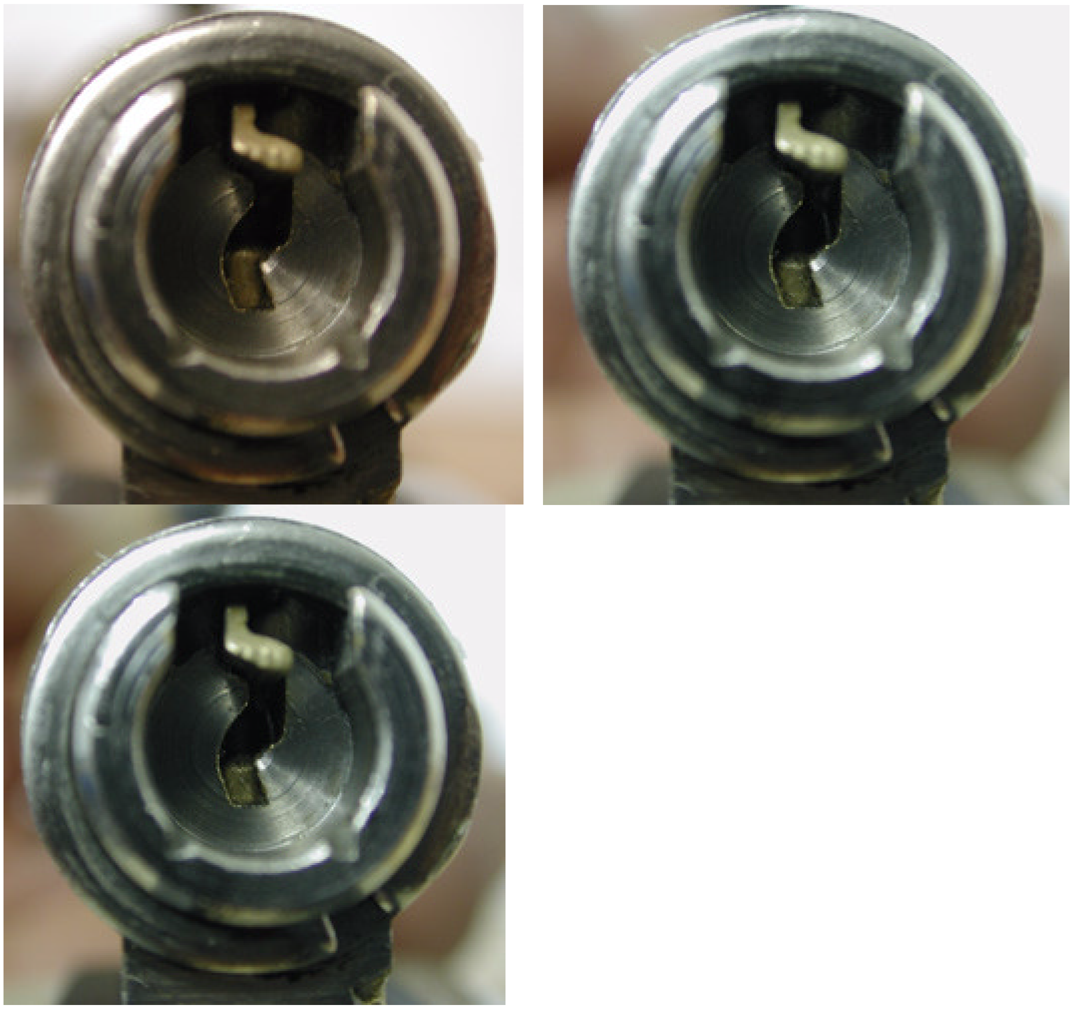

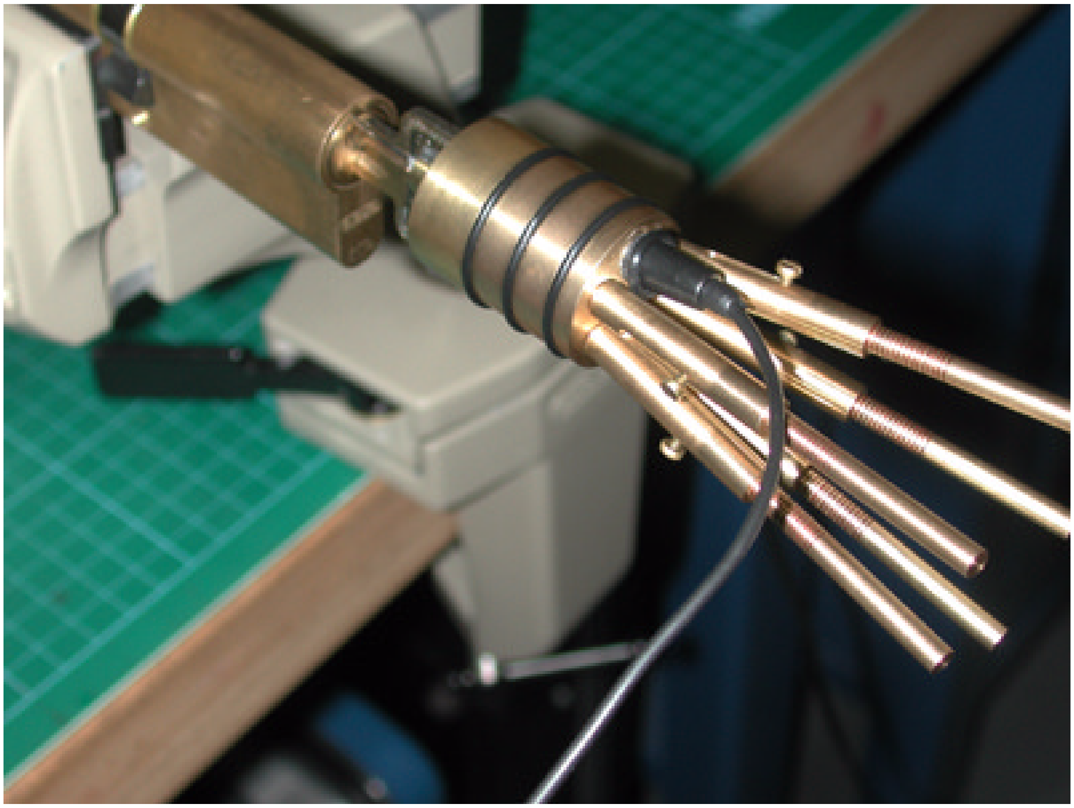

Figure LSS+2920 The Sputnik tool can manipulate each tumbler to any position within its chamber.
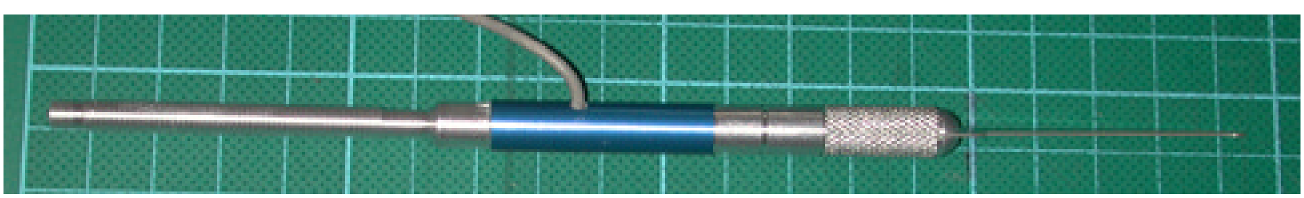
In the photographs above, three different positions of the last pin in the keyway are shown,
as the shim wire is moved up and down.

A modified version of the Sputnik was released in 2003 that incorporates a microphone into the system. This provides excellent feedback on the status of set pins at shear line.

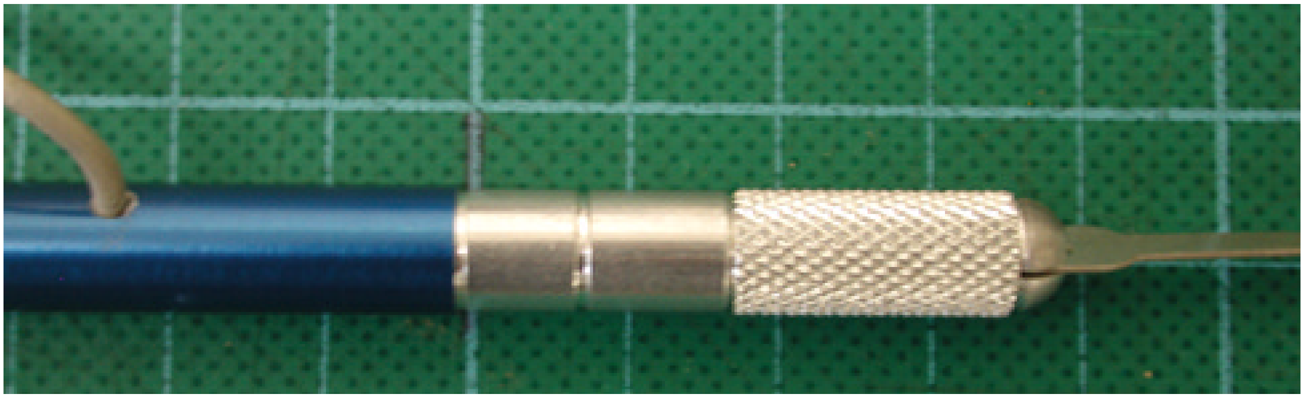


LSS204: MSC Sputnik II with audio probe

29_8.1.1 Acoustic Feedback Incorporated Into Picking Tools

MSC has incorporated a microphone into a traditional pick to provide a better indication of the status of setting pins. The audio feedback can make the picking process easier.

LSS203: MSC Acoustic picking tool demonstration



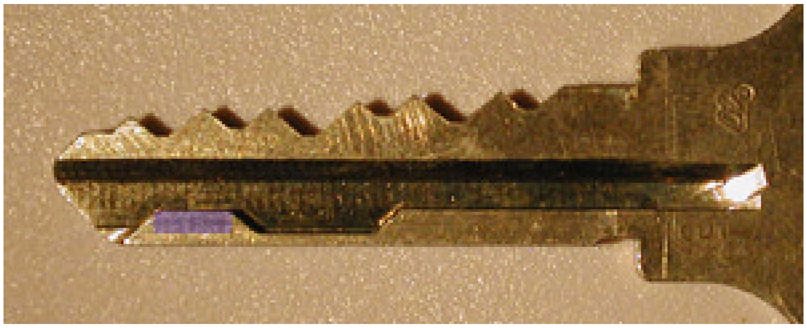


Figure LSS+2933 MSC acoustic picking tool.

29_8.2 Schlage Everest Cylinders

See section **6_4.4.3.1** for a description of the Schlage Everest mechanism. These patented cylinders can be picked in the same manner as other conventional locks, with the exception that the spring biased check-pin must be raised to allow the plug to rotate. **Peterson Manufacturing** has developed two unique tools to make bypass of this lock quite simple and straightforward. The ET-2 provides tension and also raises the check-pin. The ET-1 is a single formed piece of spring steel that enters the keyway within the undercut area and raises the pin to allow tension to be applied to the plug. Its use does not interfere with picking or the application of torque.

In the view of the author, these cylinders should not be utilized in any high security application. Other than the increased difficulty in replicating the blanks, the only distinguishing feature is the requirement that the check-pin must be raised to allow the plug to rotate. All Everest cylinders appear to have the check-pin located in the same position; thus, the blanks are all identical with regard to the side channel. Even if the manufacturer were to change the position of the check-pin, its operation would be the same with regard to bypass. The shaded portion of the undercut channel in the photograph below shows where contact with the check-pin occurs. See **Chapter 8** for a description of the use of the Easy entrie profile milling machine for replication of a blank that will allow rapid bypass of these cylinders.

A Schlage Everest blank can also be utilized as a tension wrench by removing the bitting portion of the key and utilizing the bow to apply torque. Lock shops that routinely service these cylinders have reported this practice.

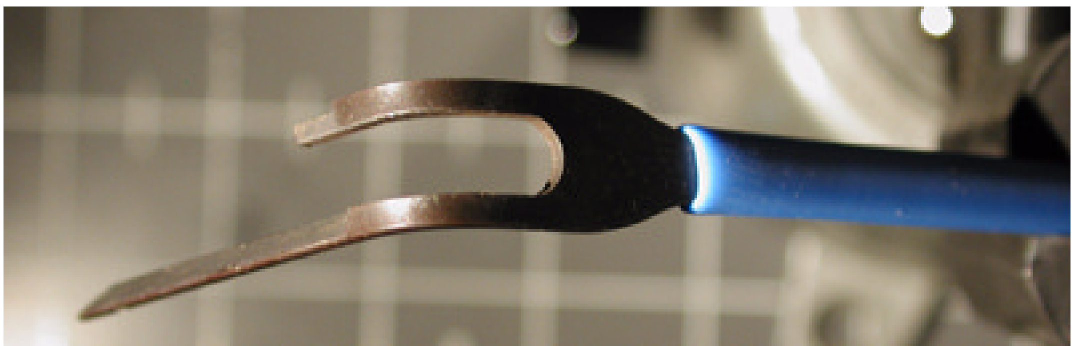

Figure LSS+2941 The Peterson pick tools for the Schlage Everest cylinder. The ET-2 is a combination tension wrench and second prong to raise the check-pin, while allowing ample room to insert a pick into the keyway. The ET-1 is an individual insert that enters within the undercut portion of the keyway to raise the pin. A separate tension wrench is inserted to apply torque.

29_8.3 Immobilizing Pin Tumblers

A process was developed by Israeli covert entry specialists that locks the top pins in position within each chamber, while at the same time allowing the bottom pins to drop below shear line. As described to the author, this procedure requires the injection of a spray material into the plug so that it permeates the upper and lower portion of each chamber. The chemical is like a glue that retains the pins, once they are forced upward by the insertion of a special blank key. Then, a special element is inserted into the keyway which allows the bottom pins to be very rapidly heated. This will break the glue bond and allow the pins below shear line to drop, thus allowing the plug to be turned. A solvent can be

used to release the top pins.

CHAPTER THIRTY: KEYS FROM IMPRESSION

Impressioning

Master Exhibit Summary

Section 1: Theory of Impressioning

Theory

30_1.0 Introduction

How does impressioning work? A discussion by Harry Sher.

Impressioning is a process that encompasses various techniques for deriving a specific key for a given lock, without the requirement of drilling, picking, or disassembly. In certain instances, it may be impossible to remove the lock to produce a key; thus, impressioning becomes a necessity.

Outwardly, it is difficult to know if a lock has been impressioned; a forensic analysis described in earlier chapters must be conducted to make such a determination.

The usefulness of the impressioning technique. Courtesy of Hans Mejlshede.

There is evidence that the original Egyptian pin tumbler lock was first impressioned using wax. The art was improved upon when warded mechanisms became popular and was perfected with the introduction of the lever lock.

Early in the nineteenth century, there were two large gold bullion thefts in England. Twelve thousand pounds sterling was stolen on a railroad shipment between Britain and France using a key that had been copied by impression. A second major theft followed; this time from a bank vault in England. These popularized the technique of **copying** keys through impressions in wax.

This chapter is primarily concerned with making keys from impressioning of the internal components of a lock, not copying them. See **Chapter 8** for detailed information about impression copying techniques. Although the principles of impressioning have not changed, the techniques have been modernized. Now, there are special tools for handling blanks during insertion into the lock. There are also keys made of composite materials that can make

impressioning a great deal easier. Systems based on the use of pressure-responsive materials have also become quite popular.

Impressioning is perhaps the most valuable skill of the covert entry specialist and the locksmith. Once the technique is acquired, it will provide a working key. Whereas many locks cannot be picked for a variety of reasons, impressioning is a method to bypass almost every locking mechanism, even if certain security enhancements are present. While most locks can be impressioned, certain mechanisms such as sidebar can be extremely difficult and require a combination of procedures to produce results. UL (in Standard 437) and most other testing laboratories rate locks for their resistance to impressioning as well as picking, drilling, and other entry methods. Locks that are capable of impressioning include:

- **Warded locks;**
- **Wafer locks;**
- **Abloy disc locks;**
- **Ava wafer locks;**
- **Chicago double-bitted eleven-wafer locks;**
- **Double-sided wafer locks;**
- **Lever locks;**
- **Tubular locks;**
- **Pin tumbler locks;**
- **Dimple pin tumbler locks;**
- **Medeco and other sidebar locks.**

Many techniques and systems have been developed to impression locks. They all, however, rely upon the same principle: **except when they are at shear line, properly bound active locking components (tumblers, levers, or wafers) will be immovable.** This chapter will describe the proven methods for impressioning and underlying theories. Procedures, problems, practices, and techniques for each primary kind of locking mechanism are presented.

As in lock-picking, a great deal of skill is required to successfully produce keys. Patience, practice, and persistence will yield large dividends and allow the bypass of most of the mechanical locks described in this book. Whenever the term "pin" or "pin tumbler" is used, it should be considered synonymous with "active locking component." The material in this book primarily relates to pin tumbler locks, except when otherwise noted. **Active**

locking component refers to wafers, levers, wards, discs, or other mechanical parts that block rotation of a bolt or other mechanism by its movement, and which is controlled by a key.

30_1.1 Overview of Impressioning

A discussion about impressioning, by Harry Sher.

A blank key, often specially prepared, is used to provide an indication as to which pins are binding and which are set at shear line during the impressioning process. The proper selection, preparation, and filing of the bitting surface are critical to a successful opening. In practice, a key is prepared, then inserted into the lock using a special holding tool to control and apply proper torque and rotation. The key is turned in order to bind the pins with specified controlled vertical and horizontal movement. If the procedure is carried out properly, tumblers that are binding will produce markings on the key; there will be a corresponding **absence** of marking for pins that are **set** at shear line.

The process of impressioning simply requires that sufficient **samples** be taken of bitting depths (through insertion of the key and binding of the pins to cause marking) to assure that each pin (or other component) has had an opportunity to reach shear line. Thus, the craftsman files the key in small increments, taking continuous readings for each pin that is marking by repeating the insertion-binding process. Often, keys will be cut or filed to known code depths for a given lock during the procedure. This will be explained later in the chapter. As long as marks continue to be produced, the key blade surface is filed. Theoretically, when all pins stop causing marks, the lock will open. Of course, there are many variables in this equation.

30_1.2 Marks: How and Why They are Produced

In order to impression a lock, a key blank is systematically and methodically filed at each tumbler position until the correct bitting depth is determined. How much metal to remove and at what position on the key is a function of marks produced by active locking components. So, how exactly are these marks produced? An understanding of the concept of marking is critical to successful impressioning; it is often not communicated by the instructor and is misunderstood by student.

Impressioning provides a direct indication of the position of active locking components at shear line, or in another position. As has been noted, there is a positive correlation between pins, wafers, discs, or levers that are precisely at shear line and the **absence** of any marking on the surface of the key. Conversely, marking at any tumbler position **must** indicate that a locking component is located other than at shear line. **These two absolutes make impressioning a science, in contrast to picking, which is considered an art.**

So, why are marks produced upon the surface of the key. The answer relies upon the following mechanical characteristics of the lock, key, and their interaction during impressioning:

- **The tolerance between the keyway wards and the mating pattern of the key;**
- **The amount of vertical tolerance in the keyway;**
- **The amount of longitudinal tolerance or "play" along the entire surface of the key;**
- **The precise indexing of the key during impressioning;**
- **Alignment of locking components with reference to centerline of the chambers, gates, slots, or shear line. In picking, this would be referred to as "order of picking." It relates to the deviation from perfect alignment from an imaginary centerline;**
- **The amount of torque applied to the plug;**
- **The hardness of the key;**
- **The dimensions and angle of the contact surface of the active locking component in relation to the bitting surface of the key;**
- **The position of the tumbler with reference to shear line.**

Marks are produced because the bitting surface of the key and the active locking component cannot occupy the same space at the same time. That is, if the impressioning process is executed correctly, the bitting surface of the key is actually forced into the position occupied by one or more tumblers. In this circumstance, one of two things must occur: either the active locking component will **move** when the key is lifted, or material upon the surface of the key will be **depressed** or **displaced**.

30_2.1 Tolerance Errors and Impressioning

The following tolerance errors are significant to the impressioning process.

30_2.1.1 Plug-Shell Tolerance

The gap between the plug and shell will determine the possible vertical travel, or float, of a **set** pin or disc. Likewise, the tolerance between racking stump and gate will determine how the key marks in the lever lock. High-security cylinders can be more difficult to impression because:

- **The plug-shell tolerance is extremely close, minimizing the possible vertical travel of locking components when at shear line for a correct reading;**
- **Indexing of the key to the keyway is more precise, thereby minimizing vertical travel of the key;**
- **The complex paracentric design of the keyway further limits vertical movement of the key.**

30_2.1.2 Movement of the Key During Impressioning

There must be sufficient tolerance error to allow a key blank to move vertically, albeit very slightly, within the keyway. During the impressioning process, the key is used as a wedge, attempting to raise pins, discs, wafers, or levers while they are frozen in position by virtue of applied torque. If the indexing of the key is so precise that it cannot move, then impressioning will not be possible. Note, however, that there must not be excessive vertical movement of the blank, either, or false marking will occur. This is because the vertical travel will exceed the clearance between the plug and shell.

A properly designed keyway is difficult to pick and impression. Angled rather than square wards are employed for closer indexing between key and keyway. This forces the key to the bottom of the keyway to create closer tolerance. Very close indexing can cause serious problems during impressioning and may require milling of the longitudinal grooves in the key to provide some vertical play.

30_2.1.3 Alignment of Locking Components

The misalignment of active locking components determines which of those components will mark the key and in what sequence. It is the same theory as "order of picking" covered in **Chapter 29.** Those pins or other devices that are most out of alignment will bind first. **Only pins that can bind cause marks on a key.**

30_2.1.4 The Amount of Applied Torque

The amount of torque will determine which pins are bound. If slight torque is applied, then fewer pins will be trapped between plug and shell. In theory at least, it is impossible to apply too much torque during impressioning. The primary purpose of this action is to securely bind pins and prevent their vertical movement. In contrast, picking seeks to marginally bind pins in order to retain them at shear line while **allowing** vertical movement.

30_2.1.5 Metal Content of the Key

The hardness of a bitting surface is critical to the production of marks. Soft metals such as brass and lead are preferred to harder materials, such as nickel silver. Special composite blanks have been produced specifically for impressioning using brass and lead. See the Martin patent (**4400956(291)**, **4817406(292)**).

30_2.1.6 Contact Juncture of Active Locking Components

The dimensions of the contact point of the active locking component will determine how the marks appear on the bitting surface. Thus, marks may appear as pinpoints, flat spots, or other shapes, depending upon the design of the pin or surface. Pins having pointed or sharp tips will produce excellent marks and indicate how much material to remove. This is especially true for newer locks.

Chamfered surfaces will be less exact and more forgiving. Flat tops will require more precise filing and often produce marks that are harder to read. If the tip of the pin is rounded, marks will be broader and more difficult to discern. Generally, the flatter the tip of the pin, the poorer the mark. Remember that the bottom of the locking component actually makes an "impression" or depression upon the bitting surface. It is that impression which is being interpreted to indicate the position of

the component with respect to shear line.

30_2.1.7 Active Locking Component Position

The vertical position of the active locking component, with respect to shear line, will determine if a mark is produced. Marks will only appear from those pins that are not at shear line.

30_3.1 Basic Impressioning Theory

The fundamental theory for all impressioning techniques is quite simple and often eludes both instructor and student. A lock can be impressioned when two mechanical conditions occur: **active locking components (wafers, levers, discs, and pins) must be immovable when they are <u>not</u> at shear line with binding force applied; these same components must be capable of slight movement when they <u>are</u> at shear line.**

Theoretically, all impressioning techniques rely upon the fact that the bitting surface of the key and the active locking component cannot occupy the same space at the same time. Thus, when the components are properly bound after the application of torque and the key is lifted, an extremely slight amount of metal must be displaced from the key, equal to its vertical travel.

Impressioning relies upon binding of active locking components. In the case of pin tumbler locks, imperfections in manufacturing allow both top and bottom pins to bind. When the key is lifted and the pin, disc, or lever remains in a fixed position, only two options are possible: a depression is created on the bitting surface of the key, or the locking component is moved upward, thereby diminishing the produced mark.

This is the reason why new, sharply pointed pin tumblers will so effectively mark a key during impressioning. An actual **depression** is produced in the bitting surface that exactly corresponds to the vertical travel of the key. The plug must be strong enough to allow sufficient torque to be applied in order to bind active components and permit marking. In order to impression a lock, then, the following must occur with respect to its mechanical characteristics and the key that is used during the procedure:

- **Pins, wafers, discs, levers, or other active locking**

components must move to a "shear line" through normal operation;
- **These active components must block rotation or movement of the bolt-actuating device (plug, cam) until properly aligned;**
- **There must be a tolerance between moving components;**
- **When sufficient torque is applied to the plug or its equivalent, the active locking components must be capable of being "frozen" in position, preventing any movement whatsoever;**
- **When the active locking components are precisely at shear line (or its equivalent), there must be sufficient tolerance to allow very slight travel of these pins, levers, discs, or wafers; the only time that any movement is allowable for active components is when they are at shear line;**
- **The key blank must fit properly into the keyway;**
- **The key must be made of metal that is soft enough to allow marking by binding pins, and yet strong enough not to break or fracture.**

30_3.1.1 Active Components must be Immovable when not at Shear Line

The first mechanical condition that must be met requires that when a binding force is applied to wafers, discs, levers, or pins, they must be capable of being "frozen" in all positions **except at shear line.** If sufficient torque is applied to the plug when one or more moveable locking components is not precisely at shear line, those components will be incapable of any vertical or rotational travel. That is because they will be bound between a fixed (shell) and moveable (plug) surface.

As described in **Chapter 29**, the design of mechanical locks is based upon active components preventing movement or rotation of a plug, cam, or other device until all are "set" at shear line. This is the fundamental principle of all modern locks: **pins, discs, levers, or wafers must all be properly aligned in order to create a shear line or break-point that corresponds with the contours of the moveable part (key) that controls the bolt or other locking device.**

30_3.1.2 Movement of Active Components at Shear

Line

Pins, wafers, discs, or levers **must be capable of slight travel or movement when at shear line.** This critical design characteristic makes impressioning possible. Pins at shear line must **not** bind; they must be able to move a few thousandths of an inch (at least .015") or more.

30_3.1.3 Time Required to Impression a Lock

There is no accurate means to gauge how long it will take to impression a lock. Sometimes, a completed key can be produced in as little as five minutes. In part, it depends upon preparation of the blank, the type of lock, the design of active locking components, and other variables detailed below.

30_3.2 Definitions

30_3.2.1 Active Locking Components

See **Chapter 29**. Active locking components such as pins, wafers, discs, or levers, block rotation or movement of the plug or bolt until aligned at shear line.

30_3.2.2 Components of the Key

There are five critical components of a key that are considered as suitable for impressioning.

30_3.2.2.1 Blank

This is an uncut key with no portion of the bitting surface removed.

30_3.2.2.2 Bitting Surface or Blade

This is the portion of the key that comes directly into contact with the active locking components and from which material is removed in order to produce a working key.

30_3.2.2.3 Depth of Cut

The depth of cut can be measured from the top or bottom of the blade to the base of the valley. Generally, code depths are

computed from the bottom of the blank.

30_3.2.2.4 Keyway

The keyway is formed by protruding wards within the plug and is the opening through which the key enters the lock. Corresponding grooves milled into the sides of the blank will index with the wards to provide for proper alignment.

30_3.2.2.5 Tip of the Key

The tip of the key is at the end of a blank, opposite the shoulder. It is the first part of the key to make contact with the keyway.

30_3.2.3 Detainer Lever

A detainer lever has an open-ended gate.

30_3.2.4 Impressioning

Impressioning is a combination of techniques whereby a key is derived through a sampling process that produces definable marks upon the bitting surface of a key blank. These marks directly correlate to the position of active locking components and their physical relationship to shear line. Impressioning does not require disassembly of the lock in order to produce a working key.

30_3.2.5 Marking of Key

The key blade surface is marked by the base of the bottom tumblers or other active locking component during the impressioning process. Marks are produced as a result of the intentional binding and lifting of pins.

30_3.2.6 Shear Line

See **Chapter 29**. The shear line is that point between fixed and rotating materials where all active locking components must be aligned before the lock can be opened.

30_3.2.7 Tang (File)

The tang of a file is the tapered end to which a handle is

attached.

30_3.3 Tools Required for Impressioning

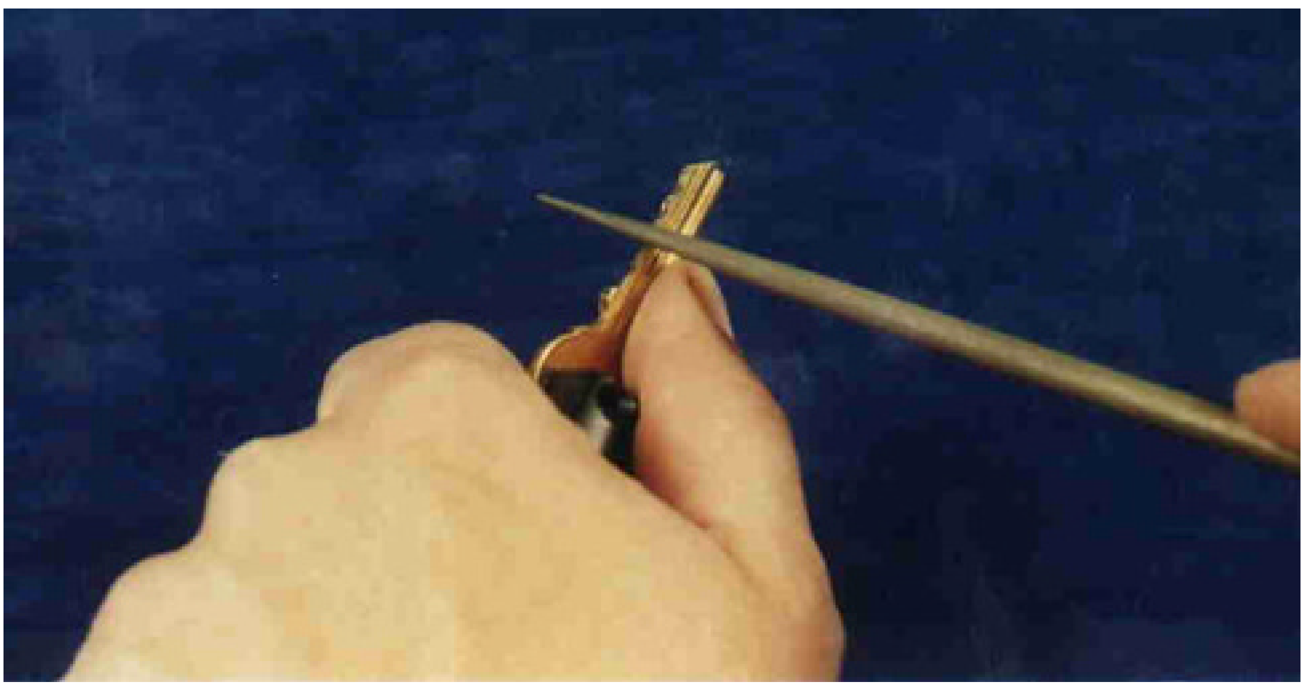
In any instance where a key is to be created by physically removing material from the bitting surface, there are two primary tools required to properly impression the lock: **files** and an instrument to **hold** the blank key. Other tools discussed below can aid and speed the process.

30_3.3.1 Files

The file must perform three critical functions: removal of bitting material, shaping of the cut, and polishing the bitting surface. Files are defined by their shape, length, tang, cut, and coarseness.

30_3.3.1.1 Shape

Files come in many shapes, including round, half-round, Pippin, flat, square, three-square, and warding. The **Pippin** teardrop shaped, #4 Swiss pattern fine slim taper (Nicholson 40524 8" 2-XF) and **round file** are probably the most popular to use for impressioning.



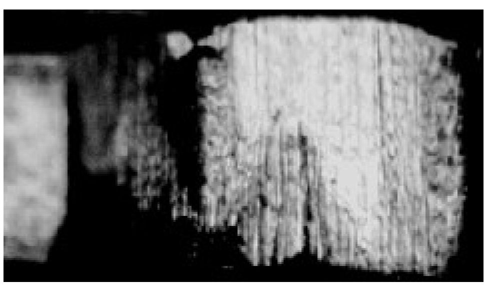


Figure LSS+3002 Use of a pippin file for impressioning.

These files taper down to a smaller cross-sectional size towards the tip. Although some craftsmen utilize the #2 Swiss pattern, the coarseness of the cut makes reading marks more difficult and is not recommended by the author.

The Pippin file resembles a teardrop cross section, rounded on one side, with two flat surfaces meeting at a knife-edge on the opposite face. The flat surfaces are similar to the flat file and are used to shape the sides of the cut. This file is ideally suited for impressioning because it creates a very fine dull finish and slightly ridged surface on the blade, thereby allowing observation of marks made by the pins. Proper filing technique continually renews the dull finish.

If a round file is employed, it must generally be used in conjunction with a small flat or triangular file for shaping the ramps of the cuts. In addition, both 4” and 6” warding files (.045"-.050" thick) can be used. Files suitable for impressioning may be obtained from locksmith, jewelry and machine shop supply houses.

30_3.3.1.2 Length

The length of a file will generally vary from 4" - 8". Sometimes, a file 8" in length actually measures 6" but has a tang extending the remainder. Files may also be tapered so that their dimensions change over the entire length.

30_3.3.1.3 Tang

The tang is the uncut portion of the file and is used to enhance control and to attach to a handle.

30_3.3.1.4 Cuts

There are two worldwide rating systems for cuts and measurement

of coarseness: Swiss and American. The number of teeth per inch determines the ability of a file to remove metal. The Swiss utilize a numeric rating system of #00 - #6, (00, 0, 1, 2, 3, 4, 5, 6), denoting the number of teeth-per-inch in relative terms. In the Swiss system, a 00 cut is the coarsest; the #6 is a fine cutting file.

The American system utilizes three primary cuts to define how much metal will be removed: bastard (equivalent to Swiss 00), second cut (Swiss 0), and smooth (Swiss #2). Files can have more than one set of teeth, meaning that there are two or more separate sets and angles of cuts on the surface. The number of teeth-per-inch will vary, based upon the length of the file and coarseness, and can range from 30 to 295.

30_3.3.1.5 Removal of Bitting Material

How a file removes metal from the key depends upon many factors, including: design, shape, coarseness (teeth per inch), applied pressure, movement, and bitting material. If the file is too smooth, it will not cut or will require too much time to remove metal. In addition, the teeth can clog. If too coarse, it will not polish a surface properly, which is particularly important when impressioning. A coarse file will remove too much metal and cut faster, and will create more dramatic striations on the surface of a key. This will diminish the clarity of impressioning marks.

30_3.3.1.6 Required Files

Depending upon the lock, the following files are most often required for impressioning:

- **6″ Pippin #4 file;**
- **6″ Round file;**
- **100 mm warding file;**
- **150 mm warding file;**
- **200 mm warding file.**

30_3.3.2 Instrument to Hold the Blank Key During Impressioning

Many tools have been developed or modified by locksmiths to hold a key for impressioning (**5058465(293)**, 855280, 1427668, 1933748,

4384499, 4815346). To work properly, these tools must accomplish the following functions:

- **Allow the key to be firmly retained without slippage;**
- **Allow the key to be precisely controlled during movement within the lock;**
- **Extend the centerline of the plug to avoid excessive stress on the key, and enhance sensitivity;**
- **Allow the key to be horizontally and vertically rotated during impressioning;**
- **Avoid creating discomfort to the operator during repeated use of the tool.**

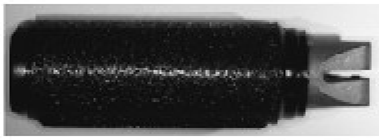
Three tools have achieved popularity in the trade: modified vice grips, pull grips, and specially designed round holding tools.

30_3.3.2.1 Vice Grips

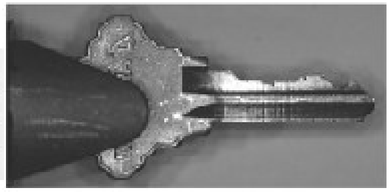
Four or six-inch vice grips marketed by HPC (KIP-1) have been modified so that the grip portion is completely smooth and perfectly parallel. The design allows for great holding strength. In the author's view, this is an acceptable compromise but not optimum for impressioning.

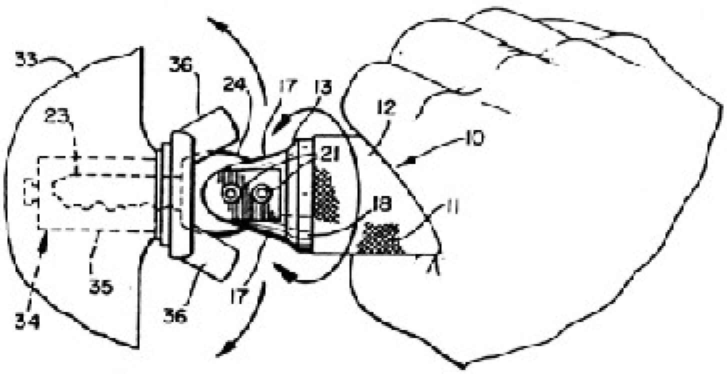
30_3.3.2.2 Pull Tool

The old "pull tool" was a specially designed gripping plier that would allow locking of the key into position during impressioning. Squeezing the handle would cause a pin to be ejected at the base of the blank key into the face of the plug. It forced the key to retract slightly from the cylinder (about 1/16"). This tool was the standard for many years in the locksmithing industry and has been available since the Second



World War.





Although awkward, a vice grips can be used in conjunction with a screwdriver to accomplish the same result by wedging the screwdriver between the key and plug in order to slightly retract the blank.

30_3.3.2.3 Round Holding Tool

The author prefers the round plastic or metal holding device. It allows the clamping of the key by setscrew or automatically. The tool, which measures several inches in diameter, provides a firm grip and precise control during movement of the key. The drawback to some of these devices is the coarseness of the exterior knurl pattern, especially when made of metal. The pattern tends to cut or irritate the hands during repeated use and can become extremely uncomfortable.

30_3.3.3 Other Tools

A number of other tools and implements can make impressioning a great deal easier. It is recommended that the following be obtained:

- **File handles: Files are generally fitted with handles for greater control and comfort;**
- **File card: A special brush (file card) is used to clean the teeth of a file, because they have a tendency to become clogged during impressioning. This can affect the appearance of the blade surface and thus the ability to properly interpret marking;**

- **60-100x handheld magnifier: This is an extremely valuable aid to viewing marks, especially for the older craftsman;**
- **UV light and pen for marking the blank;**
- **Special composite material blanks (if available);**
- **Calipers;**
- **Spacing gauge.**

The following tools are recommended to impression lever locks:

- **100 mm warding file;**
- **150 mm warding file;**

- **200 mm warding file;**
- **Hacksaw;**
- **Combination pliers;**
- **Side cutters;**
- **Penlight flashlight;**
- **300 mm lengths of 1.5 mm music or spring wire for applying tension to the lock bolt;**
- **An assortment of key blanks;**
- **Portable vice.**

30_4.0 Impressioning Procedure: Seven Steps

There are seven theoretical steps required to impression a lock, regardless of the particular technique employed. Both the theoretical procedure and practical application is presented for the different impressioning methods. Note that this discussion does not precisely apply either to dimple locks or to the Martin or Falle-Safe specially prepared blanks for use in conventional locks.

- **Select and prepare the blank key;**
- **Bind active locking components;**
- **Move the blank key within the lock to produce marks;**
- **Interpret marks;**
- **Remove bitting material from the blank key;**
- **Stop removing bitting material from the blank key;**
- **Produce a working key.**

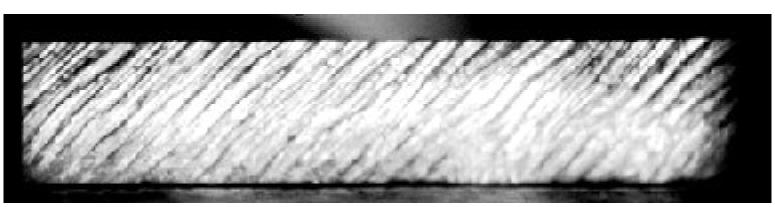
30_4.1 Theory: Select and Prepare the Blank Key

Select the proper blank. If special blanks have been designed for impressioning a specific lock, those may be utilized. Prepare the surface of the key to enhance the ability to read marks, removing any aberrations or artifacts.

Practice: Select and Prepare the Blank Key

Key blanks for impressioning should be made of soft metal such as brass, avoiding nickel silver, steel, or Avional. Blanks must be

strong enough to withstand the application of torque, but soft enough to mark from the pressure of the active locking components. It is suggested that inexpensive blanks be selected because tolerances are not as closely maintained.



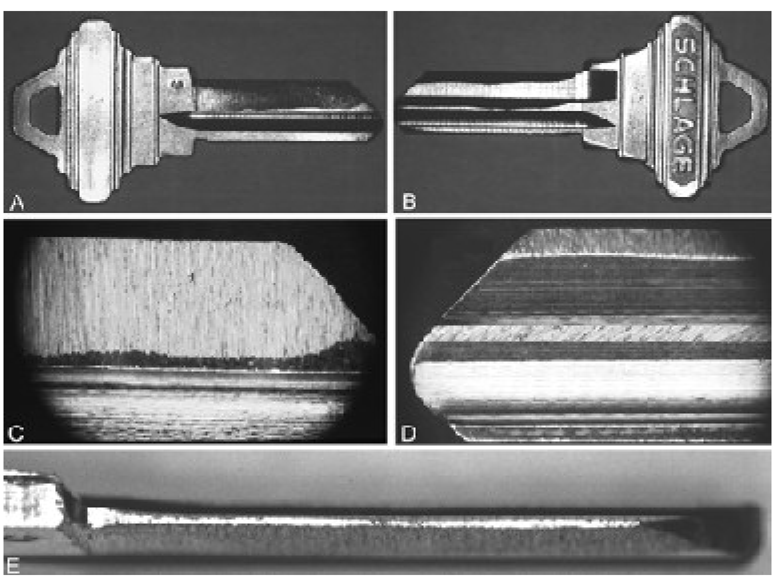
A few patents have been granted for key blanks designed for impressioning. Martin received two U.S. patents (**4400956(294)** and **4817406(295)**) for special keys suitable for impressioning. One utilized metal foil; the other, a soft metal bitting insert, set within brass. Other patents have been issued for impressioning tools and decoders (**5058465(296)**, **4300416(297)**, and **2763027(298)**). In 1996, Falle introduced a series of blanks utilizing metal foil, that were patterned after his dimple lock impressioning system.

30_4.1.1 Indexing

Be certain that the key properly indexes to the keyway. If necessary, slight side-milling may be required to provide for vertical play. Also, verify that the blank is long enough for the keyway. A five-pin blank cannot be used to impression a six-pin lock. Forward pressure must be applied during movement. This is to insure that the key is indexed properly to the active locking components and that, for every sampling, the marking will appear in precisely the same position on the surface of the bitting.

30_4.1.2 Surface Appearance

A slick surface will not easily show impressioning marks. During the manufacturing process, keys are made smooth as the punch forces the brass stock through the die. Key blanks are burnished and deburred in a tumbling process after being milled. The surface is polished to a smooth finish by this procedure.



If brass blanks have been plated, remove the surface cover by filing in long, angled, even strokes from the shoulder to the tip, thus providing a uniform texture for the brass. Be careful not to remove any excess material, as some lock manufacturers

utilize the full height of the bitting for a zero-cut. It is required that a uniform texture be created with sharp microridges. A few light file strokes are all that is necessary.

The area that makes contact with the active locking components must be perfectly smooth in order to show marks. Very lightly buff the bitting with a file; just enough to create a smooth appearance without removing any significant material. It is desirable that minute striations be visible upon the bitting surface. Gently file the top surface to read tumbler spacing after the first sample is taken. Remove less material than the depth of the shallowest cut to establish proper spacing.

30_4.1.3 Surface Preparation

There are two primary methods for the preparation of the bitting surface of a blank key for impressioning: reduce the blade width or knife-edge the material. In either case, the premise is based upon the notion that it is easier to deform a thin piece of metal than a thicker one. It also follows that it is easier to view the marks produced on such metal.

30_4.1.3.1 Surface Preparation: Narrowing the Bitting Surface

One method to prepare blanks for impressioning requires that the width of the blade be reduced. Thinning weakens the key but makes it easier to move in the keyway. Thinning requires that

the lateral surfaces of the blade be reduced. This does not extend to that area immediately adjacent to the shoulder that remains at the entry point of the keyway. A great deal of stress is placed on this point, and it is where fractures are most likely to result.

30_4.1.3.2 Surface Preparation: Knife-Edging

Knife-edging or blading is quite popular, especially where an older "pullout" tool is utilized. The technique has the advantage of producing clearly defined tumbler spacing, and accentuates marking. The key is prepared with either a single or a double knife-edge as described below. New locks will generally produce marks without blading a key due to the relatively sharp points at the base of the tumblers. However, once pins show some use, the key should be bladed to improve marking. Ultraviolet ink may also be employed to enhance visibility.

The procedure requires that the top portion of the blade be thinned almost to a point or knife-edge in order to make marking more visible and pronounced. Thinner material will bend easier under the pressure of pins. Depending upon preference and technique, file the surface on one or both sides of the top of the blade at about a 45° angle. When the key is placed in the lock as described below, the marks will be much deeper and easier to produce. Care should be taken to maintain the sharp angle on the blade sides throughout the process, because eventually the key will always mark there.

30_4.1.4 Problems Encountered with Blanks

The most prevalent problem encountered with blank keys is fracture. During impressioning, there is a great deal of stress, especially at the juncture of the shoulder and bitting surface. Should a fracture begin, it is imperative that the key be removed and duplicated prior to severance. Fracture can be caused by the application of too much torque or turning a blank hard in one direction and then the opposite way. In addition, it can occur if a cut is made too deeply, especially toward the bow.

If the bitting is cut too deep, the material can be formed with a small hammer or pin punch just below the cut. Solder may also be employed but it is not particularly effective. A key machine, key micrometer, or carbon blackening can also be used to make a copy. With practice, fracturing will become rare. In the beginning, it is inevitable.

30_4.2 Theory: Bind Active Locking Components

The blank key is inserted into the lock and then a horizontal rotational force is applied in order to bind active locking components.

Practice: Bind Active Locking Components

The essence of impressioning theory requires that active locking components be bound between moveable and non-moveable parts of the lock (i.e., the plug and shell). It is therefore of critical importance that the internal mechanism of the target lock be understood so that the craftsman is aware of which components must be bound in order to create markings on the key.

Sufficient torque must be applied against active locking components in order that they are frozen in a fixed position. They must be immobilized while the key is manipulated. The amount of tension to be applied is generally more than required for picking but not enough to fracture the blank. Movement of the key must cause the active locking components to bind in order to induce marking. This requires sufficient torque to trap the pins, levers, wafers, or discs against the fixed portion of the lock so that they cannot move vertically.

The precise amount of applied torque is difficult to specify. It must be sufficient to immobilize the active locking components but not so severe as to inhibit vertical movement of the key. With practice, the correct force can be easily determined. The characteristic of the binding process will change, depending upon the position of the tumbler or other locking component during the impressioning process.

When active locking components are in a position other than at shear line, they will be bound against the walls of the shell or plug chamber. Such binding will present a solid, immovable object against which the bitting surface of the key will interact. This circumstance causes discernible and often deep impressions on the key. As the plug is able to turn to a greater degree when more components reach shear line, there is a corresponding increase in the resistance to vertical movement of the key. This will create marks that are even more readable.

As moveable components reach shear line, an entirely different interaction occurs between the key and such component. When the

tumbler, lever, or wafer is precisely at shear line, it is bound neither by the shell nor by the plug chamber; it is free floating within a very narrowly defined space. So long as the distance of vertical travel of the key (when it is lifted) does not exceed the "free space" between plug and shell, there will be no resistance to movement of the pin, lever, or wafer. Only when the locking component is **stopped** from moving will a mark occur.

The difference in impression marks between a pin that is at shear line and one in any other position is quite pronounced. The pin at shear line will create a very slight mark, whereas the pin presenting an obstruction to movement will actually displace a very slight amount of metal. This is particularly evident when impressioning with the Martin patented key using a lead-bitting insert.

30_4.3 Theory: Move the Blank Key Within the Lock to Produce Marks

There are three recognized methods to create marks: **bind and lift** (often called wiggling), **bind and pull**, and **bind and tap**. Each one of these techniques will produce marking on the blank key. **Bind and lift** requires that the key be turned to apply torque, then moved in an up and down motion.

Bind and pull is a modification of the bind and lift technique. It requires a specially designed gripping tool that physically withdraws the key a very short distance from the plug. This causes marks on the ramps of the cut.

The **bind and tap technique** generally involves the use of a cylindrical rod, such as a file, screwdriver, or long Allen wrench placed through the bow of the key. It is then twisted to apply torque. The top and bottom of the key shoulder is then tapped with a mallet or similar object to cause up and down motion of the bitting surface. Whichever of the above techniques is employed, the proper blank key must be inserted into the lock, rotated, and then moved to cause marking on the surface of the key blade.

Practice: Move the Blank Key Within the Lock to Produce Marks

Successful impressioning is based upon the proper insertion and movement of the key blank within the lock. This action is based upon three critical stages: **indexing** of the proper blank in the

keyway, **binding** of all active locking components, and proper **movement** of the blank to produce marks.

30_4.3.1 Physical Control of the Key During Movement

Control must be maintained over the key while it is inserted in the lock in order to obtain the best marks on the bitting surface. Holding the blank close to the shoulder is preferred both for sensitivity and to reduce stress to the key. Wrist control, rather than use of the elbow, is more effective when moving the blank. A snapping action during up-and-down movement is preferable to simply lifting and lowering the key.

30_4.3.2 Movement of the Key

Perhaps the most critical action is the movement of the key within the lock. Often misunderstood, this process must be correctly repeated for every sample reading. It requires that a **key holding tool** be utilized that will in effect extend the centerline of the lock through the axis of the key. This must occur so that rotation and movement becomes an extension of the plug.

Movement must be accomplished in such a manner as to insure contact between each bound active locking component and the bitting of the key. In addition, the **sequence** of movement in relation to binding of components must be correct to insure marking. There are four distinct planes or positions to insure reliable contact and marking. This is especially true in the pin tumbler lock. Because of difference in tolerance, alignment, and concentricity of pins and chambers, only one or more of these positions is sure to cause marking for any pin. Thus, it is imperative that all four points of contact are accomplished, or the key will not mark properly or consistently.

To insure that both the front and back portion of the key is contacted by pins, the key must be placed in the following positions during each sample:

- **Right rotation;**
  - **tip raised;**
  - **shoulder**

raised;

- **Left rotation;**
  - **tip raised;**
  - **shoulder raised.**

Not only must the key be lifted in the proper planes or orientation, the sequence of binding and lifting must be correct. This requires that for each of the four positions, the torque be **released**, then reapplied prior to lifting. This function is often misunderstood by beginning students and leads to erratic marking. The proper procedure is:

- **Briefly release torque on the key;**
- **Place rotational torque on the key, either left or right, to bind active locking components;**
- **Move the key to attain one of the four positions as described above;**
- **Briefly release torque on the key;**
- **Place rotational torque on the key, either left or right;**
- **Move the key to attain the next one of the four positions;**
- **Repeat the above procedure until all four positions have been attained.**

Depending upon the lock, it is often desirable to lift the key more than once in each plane during the above-described sequence in order to enhance marking. Active locking components must be "reset" each time they are bound and lifted or they may not mark correctly. This is because there may be a very slight gap between moving component and the surface of the key, occurring from the last sample.

Be certain to continually examine the key near the shoulder for fracture. This problem requires constant attention. If the blank begins to split, duplicate the cuts onto a new key and continue the process. Actual physical movement of the key is usually accomplished in one of three ways: **oscillating** (wiggling), **tapping**, and **pulling**.

30_4.3.2.1 Oscillating or Wiggling

Oscillating or wiggling requires the application of torque, then movement of the blank up and down. This causes the bitting surface to make contact against the active locking components.

30_4.3.2.2 Tapping

Tapping is slightly different than wiggling. This procedure requires that the blank be inserted into the keyway while placing a steel rod through the bow of the key to provide torque. A small mallet is used to tap on the top and bottom of the bow to mark the bitting surface. Tapping on the top raises the tip of the key; tapping on the bottom lifts the shoulder. This technique is particularly effective and is preferred by the author to the use of special key-holding tools, especially when the lead bitting composite key is used.

30_4.3.2.3 Pullout Method

The **pullout** method is only effective when the bitting surface has been cut to at least the first depth for all pin positions. This technique works well in pin tumbler locks by applying rotational torque, then slightly withdrawing the blank. Likewise, a C-clamp may be used to hold the blank, then a screwdriver employed as a wedge to slightly extract the key.

Remember, however, that the marks will not precisely correspond with the center-point of the pins but will be related to how far the blank is withdrawn. In addition, marking may not be constant because the blank may be pulled to a slightly different position for each sample. The method should not be used for wafer and disc locks because of the potential for distortion of components.

30_4.4 Theory: Interpret Marks

Read the marking for each sample taken. Repeat the process until no more marks appear and the key opens the lock.

Practice: Interpret Marks

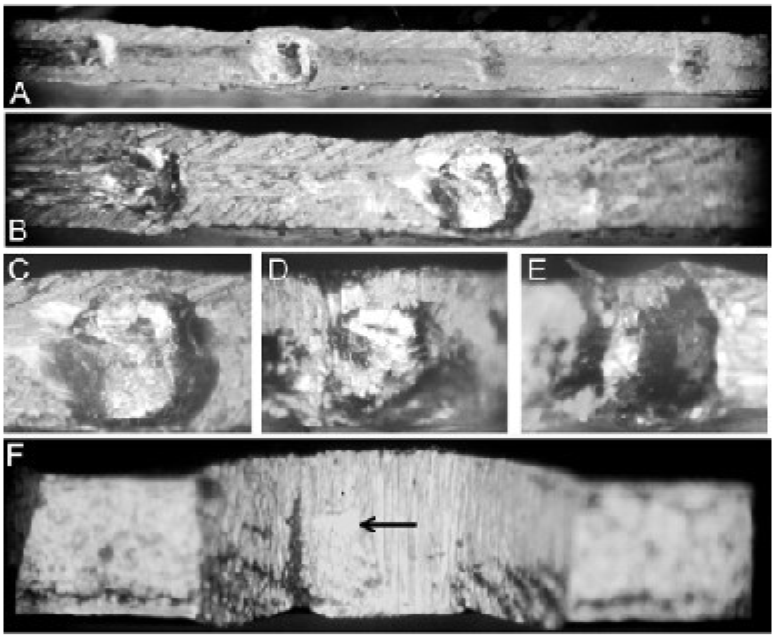
Marks will indicate the position of active locking components,

whether they have reached shear line, and, in some cases, how close they are to shear line. Theoretically, all active locking components that are not at shear line will cause marks to be made upon the surface of the key. However, there are several practical problems involving the interpretation of marks, order of marking, location of the marks, readability, and visibility.

30_4.4.1 Interpretation of Marks and Artifacts

Many artifacts may be present or imprinted on the surface of the key. They are caused during manufacturing or preparation of the blank for impressioning and from insertion, removal, and filing.

30_4.4.1.1 Artifacts



If the bitting surface is not filed properly at the outset, then uneven areas, ridges, marks, scratches, pits, or other irregularities may be present. Streaks may also be visible, caused by pins running across the specially prepared surface. The craftsman must be familiar with the appearance of all artifacts so as not to be confused with actual marking by active locking components. There should be no preconceived idea as to how the impression marks will appear.

30_4.4.1.2 What Marks Look Like

The question as to what "actual" marks look like is difficult to answer because marking will differ depending upon the design of the pin, wafer, lever, or disc. The answer becomes even less clear when the metal content of the key, the method of filing, binding pressures, and rotational forces are considered. Further complicating the issue is the consideration of **when** during the impressioning procedure the marks were made.

Generally, marks will be less pronounced at the beginning of the impressioning cycle and much more visible when several tumblers are at shear line. An evaluation must constantly be made to determine if marks are significant, strong, or not important. If the marks are slight, then less material should be removed than in the case of heavy or pronounced marking.

Marks may appear anywhere in a predefined area for each cut under the active locking component. There is no clear definition or rule as to how the marks will appear, although they are generally evenly spaced.

They can look like pinpoints, flat depressions, indentations, or burnished marks. Although impression marks cannot be defined as scratches, nicks, scrapes, or gouges, they are in fact an indication of metal binding against metal.

If impressioning is done properly, marks will be left from tumblers binding against the blade and will only appear under active locking components. Marks that are on the side of the key or near the edge of the chambers are not relevant. An effort should be made to keep marks directly below the active locking component, as they will have a tendency to drift depending upon filing technique.

Generally, marks are very subtle depressions in the bitting surface, although actual concave points will be present in some locks. If the material has been prepared and filed properly, the marks may simply cause a change in the reflectivity of the surface. Filing should leave a slightly dull finish. This characteristic may change during impressioning and is caused by burnishing of the metal by the contact or rubbing of the locking component.

The appearance of marks will differ, based upon the type of locking mechanism (pin tumbler, lever, wafer, disc) and are often more pronounced as locking components come closer to shear line. As noted earlier, the shape of the moving component will affect the appearance of the mark; pin tumblers will generally mark as

points, whereas wafers appear linear in shape. When interpreting marks, do not be confused by long dark bands across the surface of the blade. They are caused by insertion and removal of the key as the pins track against the blade.

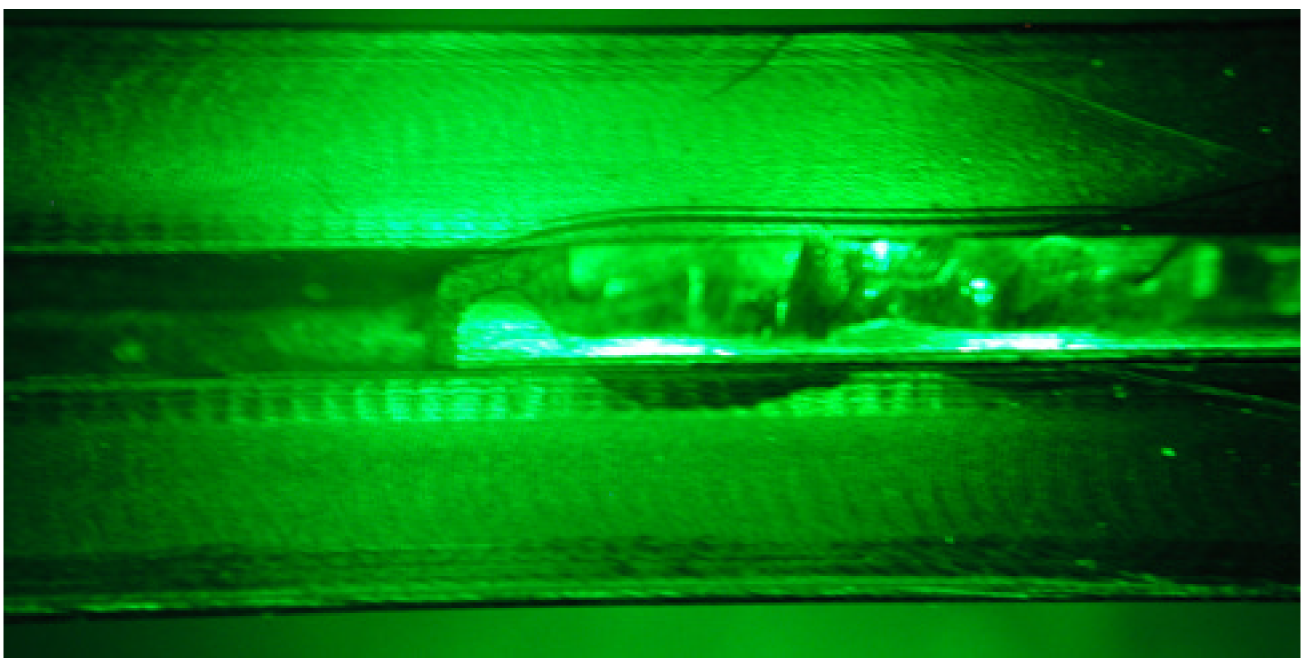
30_4.4.2 Order of Marking

Depending upon alignment and tolerance, some active locking components may not immediately produce marks. The rule of practice states: **file only those positions where marks appear**. As pins reach shear line, new marks may appear.

30_4.4.3 Visibility of Marking and Enhancement of Marks

Depressions are often quite subtle and difficult to see. The author sometimes uses a high-intensity light or UV source with a magnifying visor to view marks. In other cases, a low light level is preferred. Sometimes, a 60-100x hand-held magnifier is also helpful. The orientation or angle of the blank may also be changed to alter its reflective characteristics. The lighting must be direct and not diffused. Unfrosted incandescent bulbs or halogen is recommended.

A rough blade surface will diffuse light, whereas a polished spot on brass can reflect the light and make a mark visible. Ideally, marks will appear bright against a dark or dull background. Remember that marks may be extremely small and very subtle. There is always a temptation to attempt to interpret artifacts and metal imperfections as tumbler markings. If the blank is prepared properly, the marks actually caused by binding will be most visible. Various techniques have been utilized to enhance marking and facilitate reading of impressions. These include:



- **Magnifying loops;**
- **Smoking" the blank as described earlier;**
- **Application of nail polish;**
- **Use of inks to cover the surface of the key and application of ultraviolet light to see disturbance of the ink;**
- **Use of plasticine, lead, plastic tape, or foil.**

The employment of such aids is a matter of personal preference; some work and some are not effective.

It may be necessary to buff cuts with a file to insure that the surface will permit proper marking. Remember, when removing material from the key, be certain only to file at tumbler positions and not the entire surface.

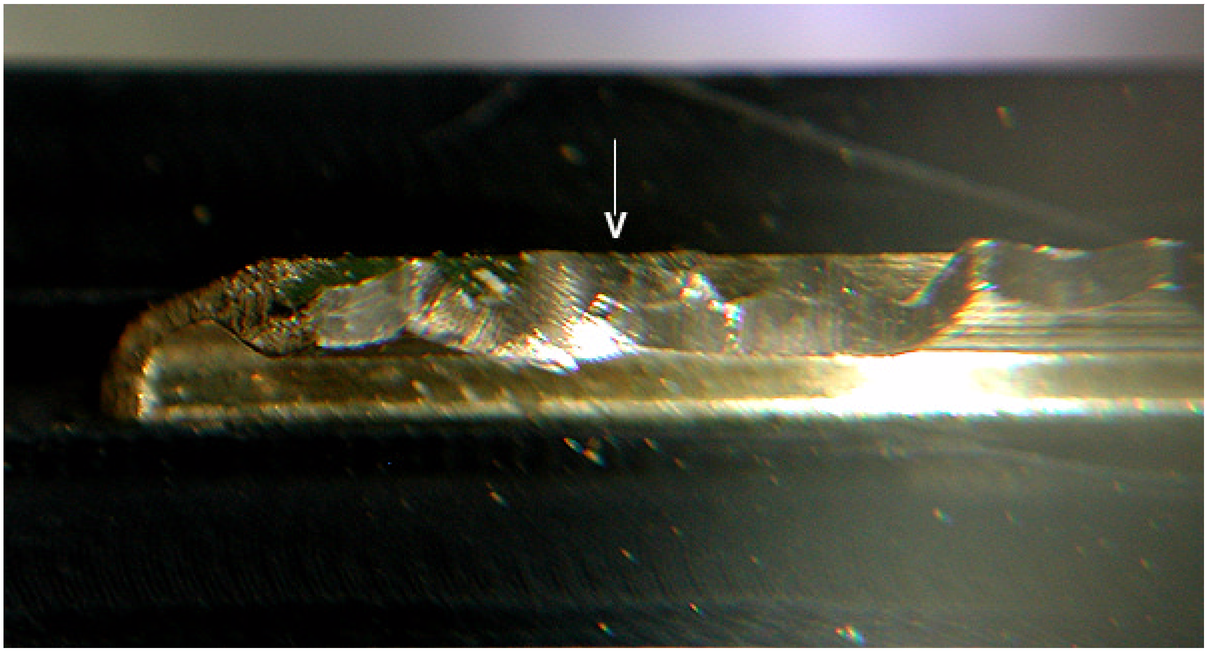


Figure LSS+3001. The impressioning light box, available through John Falle, makes impression marks more visible, especially in covert entry operations. This device allows viewing of a key in any orientation under white, green, and blue light. Shown is a key during the impressioning process with a mark clearly visible.

30_4.5 Theory: Remove Bitting Material from the Blank Key

Bitting material must be removed from the surface of the blank, corresponding to active component marking. If standard depth coding is followed by the manufacturer, then metal should be removed to the next depth for each mark.

Practice: Remove Bitting Material from the Blank Key

How much material to remove and where and when to remove it is the essence of impressioning. This discussion actually relates to the use of files, the interpretation of markings, and the shaping of the cut for each active component. As will be noted, the selection of the proper file is critical. Conventional practice has suggested that the Pippin #2 or #4 file be utilized for impressioning. The author and other craftsman have also utilized a square-cut file, slightly narrower than the width of one depth-cut, to create perfectly flat valleys. This technique has the advantage of enhancing the ability to distinguish active component marking, especially where special composite keys are

utilized. Soft lead composite blanks can be used to produce easily read marks.

30_4.5.1 Standard Depth Coding

A lock that is keyed pursuant to standard depth and spacing specifications is easier to impression than one that has been randomly pinned, because the craftsman knows exactly how far to file for a given depth position. So long as the disc, wafer, lever, or tumbler continues to mark, material can confidently be removed to the next depth without concern regarding those regions in between. The author recommends code cutting the key to the first depth prior to impressioning. This will provide the proper spacing and indicate where to look for marks. Use a code punch machine, file, HPC 1200, or equivalent cutter. It is also useful to draw vertical lines on the side of the key with a felt marker, corresponding with each pin. This practice will help maintain the lateral position of each cut in a straight vertical line.

If a depth and spacing reference guide is not available for a specific lock, such information can be determined from other keys for the same lock. Optimally, a key micrometer, caliper, key punch, or key machine can be used to make cuts during impressioning. After the first sample is taken, it is especially critical that each tumbler position be filed only to the first standard depth. If a cut is made too deep at this point for any tumbler, then the lock can never be successfully impressioned. The time required for impressioning can be reduced if material is removed to specific factory depth coding, rather than simply removing material without correlating such filing to precise depths.

30_4.5.2 Principles and Guidelines for the Use of Files

Selection of the proper file is required in order that:

- **The proper amount of material can be removed to insure that bitting is not improperly reduced beyond the correct depth;**
- **More than one pin position can be filed for each sampling. Every position that marks can be filed;**
- **The cut can be shaped properly so as not to overlap to adjacent areas. This is especially critical in cases where there is a long pin next to a short one.**

Too wide a cut will affect the next position;

- **The cut is smooth, with a dull, flat, and constant finish to allow reliable viewing of subsequent marking. Some craftsmen prefer a mirror finish to enhance visibility;**
- **The cuts follow standard specifications in terms of ramp and valley angles for smooth insertion and removal of the key.**

The true craftsman understands the proper and efficient use of a file. The following principles and guidelines apply when removing materials from key blanks:

30_4.5.2.1 Use of the File

- **The work piece must be properly supported at the correct working height;**
- **The file must be held correctly with the cutting stroke properly guided;**
- **When the work is small and delicate and the filing is done by the motion of the hand or the hand and arm alone, the work should be held at a level that allows close scrutiny and control;**
- **Lift the file during the return stroke;**
- **Filing with a seesaw motion should be avoided, as it produces a convex rather than flat level surface;**
- **Keep files mounted on a rack or with their tangs placed in a row of holes drilled into a block of wood;**
- **Keep files in a dry atmosphere to avoid rusting;**
- **Files should be used with handles to facilitate control, although some craftsmen prefer to impression without them. In such cases, a protective cover such as electrical tape is advisable so that excessive force is not utilized when filing. This permits more control;**
- **Never hammer or pound the point of a file to seat the tang in a handle;**
- **It is desirable that the file produce a smooth surface that will allow contrast for easy viewing of marks;**
- **Do not saw or drag the file as it is brought back**

for the next stroke;
- **Learn proper filing technique and how much material to remove per stroke.**

30_4.5.2.2 The Type of File

- **Select the proper file for the job according to the type of metal to be filed, the amount of material to be removed, and the size and contour of the piece to be worked;**
- **Use a rat-tail with a #2 or #4 Swiss cut pattern to produce smooth surfaces when impressioning;**
- **A round file should not be used as a reamer to screw into a hole to enlarge it, nor as a pry bar;**
- **Do not place files on top of each other in a tool box; they will become dull;**
- **Only use Pippin files on brass;**
- **A Pippin file, preferred for impressioning, will allow the creation of both flat and curved cuts;**
- **Use a round rat-tail file with a #2 or #4 Swiss cut pattern for disc and wafer locks.**

30_4.5.2.3 Exerting Pressure While Filing

- **The proper pressure must be applied during the cutting stroke;**
- **Too much or too little pressure can cause damage to the teeth of the Swiss file. Only use enough pressure during the forward motion to maintain cutting during the entire stroke;**
- **Too little pressure on the cutting stroke can quickly dull the teeth of the file;**
- **Too much pressure will result in excess metal removal and will cause the teeth of the file to become pinned;**
- **The key may be filed horizontally to change the angle of cut without affecting the depth;**
- **A file cuts only during the forward stroke;**
- **Push the file forward slowly and evenly with gentle cutting pressure, and draw back the file without any cutting force;**

- **Do not apply pressure when drawing back the file, as it tends to polish the surface of the blank (a dull surface is needed when impressioning);**
- **Hold the file with an extended index finger pushing down on the top edge to control cutting pressure;**
- **Light cutting pressure will produce the finest finish for producing visible marks;**
- **Use heavier pressure to remove material rapidly, followed by lighter strokes to finish the surface for marking;**
- **Do not attempt to remove too much material during each stroke. A lighter, more even pressure on the file is desirable.**

30_4.5.2.4 Removal of Material

- **If the file is too coarse, more material than desired will be removed, and dramatic striations will be created on the surface of the key that can diminish the clarity of markings;**
- **If the file is too fine, it will require a greater amount of time to remove material and the teeth will tend to clog; however, the result will be easy to read in terms of marking visibility;**
- **Be careful that cuts are not made too deep so as to create a back-cut key that can be extremely difficult to remove;**
- **Be certain not to remove too much material on keys for high-tolerance locks;**
- **A code machine with a milling cutter may be effectively used in place of a file.**

30_4.5.2.5 Cleaning of the File

- **The file must be clean;**
- **Proper cleaning of files with both a file card and chalk will help maintain the finish of the work and reduce scratching;**
- **Chalk will reduce chip build-up in the teeth of the file;**
- **Use chalk and an oil brush to remove oil and grease**

from the file.

30_4.5.3 Filing the Marks

The removal of bitting material is straightforward. Whenever a mark is observed, file to the next depth. Do not guess as to marking; **if not sure, do not file.** If movement of the key is accomplished by the pullout method, remember to file where the actual pin centers are located and not where the mark appears. File so as to remove a minimum amount of material, taking care not to go below the next standard depth. Two or three strokes should be sufficient before looking for marks. Consult the depth-coding chart for the particular lock to determine the distance between positions.

Pay attention to the shape of the cut; as each position is filed deeper the ramp angles will increase until tumblers become trapped. Use the side of the Pippin or a flat file to create an angle of about 45° for smooth operation of the key. Remember that the width of the cut need only be slightly wider than the pins.

Often, a pin will stop marking prior to reaching shear line. If this occurs, stop filing and move on to other pins. At some point, the pin will begin marking, wherein filing may be again commenced. In an emergency, bitting material can be replaced using solder. This may be particularly helpful in covert operations where the supply of blanks has been exhausted.

30_4.6 Theory: Stop Removing Bitting Material from the Blank Key

If no mark is visible after binding the key, **do not file any further** for that particular tumbler position.

Practice: Stop Removing Bitting Material from the Blank Key

Impressioning theory is quite simple: any active locking component that is at shear line will **not** cause a mark to be made on the surface of the key. Thus, if there is no marking, assume that the component is at shear line.

Remember that impressioning, like picking, is based upon an alignment order of active locking components. Thus, certain pins may not bind until others have reached shear line. Therefore, do

not assume that because a pin has not thus far marked the key that it will not do so subsequently. Until the key opens the lock, nothing is final.

30_4.7 Theory: Produce a Working Key

When all active locking components are brought simultaneously to shear line, the lock will open.

Practice: Produce a Working Key

When the key has been filed so that each active locking component is resting at shear line or its equivalent, the lock should open. However, remember that each component may not be precisely **centered** at shear line during the impressioning process. Cumulative tolerance error may require the key to be jiggled and adjusted in order to open the lock.

The key may be measured against a known standard to produce a proper working key, based upon manufacturer's depth and spacing. Remember that during impressioning, the key was moved within the lock to cause marking. If there was a variance in interpretation of those marks, the bitting may be slightly high or low, or cuts not centered with reference to shear line.

30_5.1 Difficulties Encountered During the Impressioning Process

Many variables can be encountered prior to and during impressioning, especially involving pin tumbler locks. This can cause erroneous readings, resulting in improperly cut keys that will fail to open the lock. The following summary details the difficulties inherent in the process.

30_5.1.1 Improper Use of File

Improper use of a file or the use of the wrong file can make impressioning difficult or impossible. The selection of the proper file is critical; a Pippin #4 is recommended, although the author also suggests a small warding file to flatten the cuts prior to taking samples.

Use of an improper file in terms of shape, coarseness, or cut can result in the removal of too little or too much material. It can also cause the obliteration of marks through a failure to create

a smooth surface and thereby reduces contrast. If the file is too coarse, then excess material will be removed and dramatic striations will be created on the bitting surface. This will diminish the clarity of markings. Conversely, too fine a file will remove too little material, require excessive time, and will clog the teeth.

30_5.1.2 Good Lighting: Illumination is Essential

Movement of the key in different orientations is generally required to interpret and view the contrast between actual markings and artifacts.

30_5.1.3 Verify that the Lock is Mechanically Functional

All active locking components must be working properly in order to successfully impression a lock. Preliminary to taking any samples, the integrity of the mechanism should be determined.

30_5.1.4 Bore Centering

If the bores that form pin chambers (pin tumbler lock) are not in perfect center-to-center alignment, pins will bind based upon the relative location of each bore, from an imaginary centerline running the length of the plug. This is the equivalent to "order of picking." Thus, some pins may not mark until other pin positions are filed to the proper depth. The problem of bore centering then becomes a complex issue. Pins whose bores are most out-of- alignment will bind before those that are closer to centerline. Those pins closest to perfect alignment cannot bind until other tumblers whose bores are misaligned are correctly brought to shear line by filing the key.

If pins that are not actually binding are incorrectly believed to be producing marks, then the key is cut improperly. The entire process is then corrupted, resulting in wasted time and the necessity to start over with a new blank. Conversely, if binding pin positions are filed to the wrong depth, then other improperly aligned pins will never mark the key.

30_5.1.5 Point Contact Definition and Surface

The wear, dimension, and shape of the active locking component and the hardness of the key blank will affect the position,

depth, size, and shape of the marks. Severely worn tumblers can be difficult to impression because of their inability to properly mark the blade. This results from the imprecise surface contact and interaction.

30_5.1.6 Applied Torque

The amount of applied torque will determine which pins bind, how many pins or active locking components bind at the same time, and how the marks are created. The characteristics of the impression markings are directly related to the amount of torque placed on the pins. Not only must the proper torque be utilized, but also it must be applied equally in all four directions (upward left, downward left, upward right, and downward right). It is preferable to get as many pins to bind at one time as possible.

While impressioning pin tumbler locks, the plug may turn with hard torque as the key is close to being cut correctly. Do not continue to rotate the plug when this occurs, but continue the impressioning process. Failure to adhere to this rule can result in breaking the key or plug and scoring of the cylinder walls.

30_5.1.7 Security Tumblers

The size, shape, and design of the security tumblers determine how they bind and the marks that they create. Security pins shaped in the form of a spool that are positioned in upper chambers present little problem during impressioning. That is because the head of the pin should never travel below shear line. However, a few locks contain spool pins in the lower chambers. A probe can determine if such pins are present.

If there are spools in lower pin positions, remove bitting material for those specific cuts until the pin stops marking. Then, impression all other pins normally, ignoring the spool tumblers momentarily. When only the spool tumblers remain, the plug will slightly turn, catching the heads of the spools. Then, file down the cuts until they start to mark again. Continue filing slightly until shear line alignment is proper.

30_5.1.8 Preparation of the Bitting Surface of the Key Blade

The key must be prepared properly in order to optimize creation and viewing of the marks. Any distortions, irregularities, or imperfections on the surface caused by scratches, gouges, filing

marks, or artifacts can make impressioning more difficult.

30_5.1.9 Plug-Shell Tolerance

The tolerance between plug and shell or equivalent will determine how marks appear, the amount of binding force required, and the exactness required when removing bitting material. A theoretical problem with markings can arise in a situation with the following factors:

- **The plug-shell tolerance is extremely close;**
- **The indexing of the key to the keyway is relatively loose (thereby allowing greater than normal vertical movement of the key);**
- **The center-to-center chamber alignment is almost perfect.**

In this scenario, pins may actually be lifted **through shear line. This can occur because the vertical movement of the blank is greater than the gap between plug and shell.**

30_5.1.10 Device Used to Hold Blank Key

There are many devices for holding keys during impressioning. In the view of the author, most of these suffer certain defects that may make the process more difficult. Pliers, vice grips, special impressioning holders with forward moving pins to automatically withdraw blanks, round gripping tools, and similar implements are all designed to allow for the precise vertical, horizontal, and rotational movement of the key. Some work quite well, others are marginal.

30_5.1.11 Blank Milling and Indexing

The milling and indexing of grooves of a blank can be critical, because the key must be free to move in the keyway during impressioning. As noted previously, the key must not move so much as to lift tumblers **through** shear line, although it must be capable of lifting pins sufficiently to cause marks to be produced. Too much movement that allows excessive motion can allow a blank to mark after the pin has reached shear line. If no vertical movement is possible, then no useable marks can be produced. The design of the keyway will be a serious factor in the ability of a key to move both vertically and horizontally.

It is axiomatic that the correct key blank must be used if possible. The number of pins, wafers, discs, or levers must be determined in order to assure that the blank is long enough. A common problem is to find that too short of a blank was employed, thereby making impressioning impossible.

30_5.1.12 Movement of Key During Impressioning

The key must be moved uniformly and properly during the impressioning process in order to make consistent marks.

30_5.1.13 Failure to Release Torque

Failure to release rotational pressure between samples will result in erratic or invalid markings. Torque must be released and reapplied prior to lifting the key.

30_5.1.14 Impressioning Technique

As will be subsequently explained, there are a number of different methods of impressioning. All are valid and, in large measure depend upon training and personal preference. Whichever method is chosen, it must be capable of consistently producing readable marks in direct correlation to the position of active locking components.

30_5.1.15 Removal of Bitting Surface During Impressioning:

The amount of material that is removed during each sampling is critical. It directly relates to the time required to produce a key, the accuracy of the key, and the success of the procedure. Not only must the proper amount of material be removed in terms of depth of bitting surface but the angle and width of the cut must be correct. If the cut is either too narrow or wide, off-center, filed at an angle, or there are depth and spacing errors, the locking component will not seat properly.

Assuming the lock was pinned by factory coding, the craftsman should strive to make cuts correspond with established bitting depths. This will eliminate the problem of over or under cutting during sampling. Ideally, a stamp or code-cutting machine should be utilized to remove bitting from the key. The use of non-standard depth coding can cause too much bitting material to be removed during each sample.

30_5.1.16 Broken, Warped, Angled, Worn, or Crushed Locking Components

Damaged locking components can seriously affect the ability to mark reliably. If the top of the bottom pin tumbler has been filed by hand and is angled, then marking may occur erratically and unreliably. Tumblers that are severely worn can likewise cause marking problems because of poor contact between pin and key.

30_5.1.17 Pin-Stack Orientation

Orientation of the pin-stack, and long pins next to short ones, can cause errors in the impressioning process due to excess removal of bitting material.

30_5.1.18 Key Blank Material

In order to mark properly, keys must be softer than the active locking components but strong enough to resist breakage or fracture. Nickel silver blanks are generally too hard; aluminum too brittle. Brass is generally preferred.

30_5.1.19 Dirt, Residue, or Contaminants

The presence of dirt, residue, other environmental contaminants, or broken or weak springs can create difficulty in reliably marking the key. Small specks of debris or the introduction of oil can also make reading of marks more difficult.

It is not desirable that the lock work smoothly during impressioning. The use of either wet or dry lubricant is not recommended because they can leave a residue on the key that must be removed to see markings. The blade surface should be wiped clean to insure that what is viewed as a mark was actually produced by impressioning. Covered elsewhere in this text are proper methods and materials for cleaning locks.

30_5.1.20 Obliteration of Markings

There is a temptation to insert and remove the key during impressioning more often than is necessary. This practice can destroy or obstruct fragile marking. When applying torque and lifting the key, only insert once per sample. It is not necessary to insert and remove each time this operation is

accomplished.

30_5.1.21 Short Pins

Sometimes extremely short pins are used in the pin-stack. These can often be viewed if in the first tumbler position, and the "split" can be seen and decoded. If this information is available, it speeds up the impressioning process. An otoscope, flashlight, and pick can be used to identify short pins. Simply lift all pins and then release each in sequence from the back of the keyway and look for a visible split. The depth and position can be estimated. Conversely, if no splits are visible, then all cuts can be initially filed to a position that would exclude short pins.

A straight pick-probe filed to a sharp point may also be employed to locate splits in pin stacks. This type of instrument is calibrated so an accurate determination can be made with regard to the active tumbler. The point is scraped across the face of each pin after all are lifted, then individually released. A forensic examination of the lock will reveal the use of such a probe. Minute scratches will appear on the sides of the tumblers.

30_5.1.22 Master Key Systems

Impressioning of master key systems is no different than making keys for standard configurations. The produced key may actually be a cross-key combination, or master key rather than the actual change key. Unless the mechanism utilizes a master ring or similar scheme for preventing cross-keying, there is no way to determine the relationship between the impressioned key and the actual change key. Impressioning more than one lock in a master keyed system can yield the actual master key combination.

30_5.1.23 Precautions Relating to Common Errors

The following precautions should be observed:

- **Be certain that the plug is being turned in the proper direction to open;**
- **Do not impression plastic locks;**
- **Examine the plug to be certain that it is strong enough to withstand the torque of impressioning; some keyways may split. Be especially careful in**

the case of wafer locks. If discs are bent, the lock will not open;

- **A pin may ride on the ridge of the key, making the mark difficult to observe;**
- **Do not rotate the plug to the unlocked position until the key fits properly;**
- **When the plug finally turns, do not rotate to an open position prior to insuring that the key is working properly and not binding;**
- **Manufacturing tolerances will cause certain pins to bind first, then others later. This is normal, and should not be cause for concern.**

Section 2: Opening Specific Locks

Impressioning Specific Locking Mechanisms

In order to properly impression a lock, a thorough knowledge of its mechanical design characteristics is required in order to understand how marks are produced. See Chapters 13-16. The following discussion provides information regarding the production of keys for basic types of locking mechanisms, and certain unique ones.

30_6.1 Impressioning Warded Locks

The very first locks to be impressioned were warded. Today, they are the easiest to open due to the simplicity of their construction. Rim and mortise warded locks can be found in older homes and hotels, especially in Europe. Inexpensive warded padlocks are still very popular.

In order to impression these locks, the wards, their position and shape, and the position of the throat cut must be determined. Originally, wax was used to find the position of the wards. Today, the accepted technique is to “smoke” a clean blank with the tip of a flame, thereby depositing a thin carbon coating evenly along all bitting surfaces.

30_6.1.1 Bit and Barrel Keys

Certain warded and lever locks use bit or barrel keys. These are

easy to impression because the manufacturing controls are not precise. A bit key has a solid flag; the barrel key fits over a post. A summary of the procedure for producing keys for these locks is presented:

- **Trim the length of the key to allow rotation in the lock;**
- **File smooth the bitting surface of the flag;**
- **Insert the key into the lock and rotate until contact is made with the wards and the key is stopped. This will mark the blank at every contact point, indicating the position of the wards. Simply file the key at each of these points, on both sides, to form deep square cuts;**
- **Use a warding file to make each cut in the shape of a square;**
- **Insert the key and rotate, causing new markings to be made;**
- **Repeat the process;**
- **Do not apply excessive torque on the key;**
- **Do not file if a mark is not present.**

When bitting material has been removed to clear all wards, the key will turn. Generally, square cuts must be made in symmetrical form on both sides of the flag. Be certain to file straight down into the blank and not at an angle. Care must be exercised because the file will tend to drift.

30_6.2 Warded Padlocks

Internal wards block the rotation of the key. Therefore, corresponding square cuts on both sides must be present in order to clear all wards and release the shackle. Remember that keys for warded padlocks only have "cuts" and "no cuts." Remove material only where marks are visible, and use the proper warding file. It must be equal to the dimension of one ward.

Be certain that the cuts are wide and deep enough to clear the wards. Do not weaken the key by making the cuts too deep or wide; they must also be perfectly symmetrical. It is important to insure that the key blank is long enough to bypass all wards and reach the locking bands, and wide enough to spread the bands to release the shackle.

30_6.2.1 Procedure for Impressioning Warded Padlocks

The procedure to produce a key for a warded padlock is straightforward and requires the following steps:

- **Always make the throat cut first;**
- **Place the key completely into the lock and turn sharply without warping or twisting the metal;**
- **Small spots will be observed to indicate throat and wards contacting the side of the key;**
- **Use a warding file to remove material on both sides of the key;**
- **All cuts will be the same depth;**
- **The width of a cut will correspond with the dimensions of a ward;**
- **A skeleton key for warded padlocks will have all ward positions removed. It will be comprised of raised areas only in those positions that are required to spread locking bands.**

30_7.0 Impressioning Lever Locks

Lever locks are extremely popular for use in safe-deposit boxes, safes, vaults, coin telephones, and mailboxes. In other than the United States, they are the primary lock for residence and business access control. They can be impressioned using hard keys, special brass blanks, or plasticine. If metal blanks are utilized, they are produced in much the same fashion for pin tumbler and wafer mechanisms.

The difficulty of the task will in part depend upon the number of levers and their design. Keys can be produced for locks having levers that have both a standard “H” gate, referred to as closed or secure levers, and open gates. Soft impressioning using plasticine is also popular, where the lever bellies are non-uniform. Several decoding techniques are also available for producing keys. These rely in part upon traditional impressioning theories, covered in **Chapter 31**. Decoding allows keys to be quickly produced for most locks, even those having up to nine levers used in safes and vaults.

Other sophisticated techniques have been developed by John Falle,

Martin Newton, and others.

A clever device for impressioning lever locks has been developed in Bulgaria. Courtesy of Hans Mejlshede.

30_7.1 Identification and Definition of Lever Lock Components

The following definitions describe components within a conventional lever lock. See **Chapter 14** for detailed explanations. They are repeated as a matter of convenience to assist in understanding the material.

Belly

The belly of the lever is one of the most critical components. It is essential to understand its function and design in order to successfully impression these locks. The bottom portion is formed in the shape of a concave arc. It allows the key to control and lift the lever and hold it at a constant height as the bolt is moved horizontally. Because the angle of contact changes as the key is turned, the arc of the belly must track this change simultaneously. Thus, the angles, shape, and size of the belly will vary according to the height to which the lever is to be lifted. A long belly is required for **high-lift levers**; a short belly for a **low-lift lever**. The parameters will range between these two extremes, based upon the precise placement of the gates.

The straight edge or end near the lever pivot may also vary in length to compensate for the difference in swing. Differs are created by the variance of the distance from the belly to the gate. The key bitting determines how far the levers are raised and thus the position of the gate. In a six-lever lock, there are approximately 10,000 useable permutations.

Bitting

The material on the part of the key that comes into direct contact with the levers. Bitting is removed from the **flag** in order that each lever is lifted to the precise alignment point.

Bolt

The bolt is the locking component that is blocked from lateral

movement when the levers are out of alignment. It forms the fastening method between the lock and the container to which it is affixed.

Bolt Stump

It is often described as a projection that is formed as part of the bolt. It acts as a fence to which the lever gates must be indexed and aligned prior to movement of the bolt.

Bolt Tail

The area at the base of the bolt where material has been removed in order to allow the introduction of the key, and thereby transmitting energy to move the bolt. The actual cutout portion is called the **talon**.

Flag (Bit)

The portion of the key that is equivalent to the blade of a pin tumbler blank key is referred to as a flag or bit. It is the projection on the lever key upon which the various cuts are made.

Gate

The precise space within a lever tumbler through which the bolt stump travels.

Post (Lever)

The point upon which the lever pivots vertically.

Monitor Lever

A lever that monitors the operation of the bolt. This is accomplished by moving a projection over the keyhole when the bolt is not fully thrown.

Shank

The shaft of the key upon which the Bow and Flag are connected.

Talon

The cutout in the bolt tail wherein the key transmits motion in

order to move the bolt.

30_7.2 Impressioning Theory for Lever Locks

In much the same way that pins must be positioned at shear line in the pin tumbler lock, all of the gates must be aligned so that the bolt stump can pass. Based upon the same principle as the pin tumbler mechanism, levers will mark the key whenever their gate is not aligned with the stump as torque is applied. Conversely, any lever that is positioned so that the gate is in line with the stump will not mark the key. Serrated or sawtooth levers will not affect the ability to impression.

In some locks, it is possible to examine the belly of each lever to determine the approximate combination of the lock.

Impressioning requires that the **position** of the gates be ascertained, rather than where the blank key makes contact with the levers. The height to which the levers must be lifted will determine when to stop filing the blank key. Any blank that has been filed to the proper dimensions with the correct throat cut can be inserted and made to revolve inside the lock. In this manner, it will engage the levers and stop upon touching the inside of the talon. This, however, will provide no relevant information as to the position of the gates. If the key were to be filed when it first touches the belly, then the flag or bit would soon disappear. This is perhaps the most common error made by the craftsman when impressioning lever locks.

30_7.3 Procedural Summary for Impressioning Lever Locks

The following provides a summary of the actions and procedures required to impression a lever lock:

- **Select the proper key blank, or produce one that will fully enter the lock without binding;**
- **Reduce the width of the key and its tip to freely enter the lock and talon, if required;**
- **Mark and cut the throat first in order to allow the key to rotate;**
- **Cut the bitting portion to bypass any ward plate;**
- **Determine where there are levers and any wards. Rotate the key several times to the point where it**

is blocked from movement. Wards will appear on the edge of the key as heavy or large impressions. They must be bypassed prior to impressioning the levers;

- **Ignore marks on the tip of the key;**
- **Impression marks must be discriminated from burnishing caused from rubbing;**
- **Be certain that the width of all cuts is equal to and never greater than the thickness of the levers. Use a warding file to make cuts;**
- **Rotate and lift the key to mark, using sharp pressure;**
- **Do not apply too much torque. Consider the weakness of throat and tip;**
- **Find the depth of each cut;**
- **The key will not stop marking, but significant marking will cease when the levers are aligned;**
- **When the key operates the lock, open it immediately.**

30_7.4 Impressioning Standard Lever Locks

Two different procedures will allow the production of keys for drawer, till, cupboard, antique, and other low-security lever locks. Such locks may be impressioned and then require disassembly in order to produce a precisely accurate key. The lock may also be **picked and then decoded.** This technique requires that the levers be properly aligned with the stump entering the gates so that they are locked in position. The height of each lever may be determined by viewing with a borescope or otoscope, causing marks to be produced on a blank key or with plasticine.

If a blank key is to be utilized, it must first be cut to the internal dimensions of the lock in order to be able to rotate against the levers. Determine the thickness of the bolt tail and then turn the key into the levers to mark each one. Blackening with a flame will assist in reading the key.

The levers should be considered as wards for this procedure: the key must be pulled against the lock case so as not to move the bolt while causing the levers to mark. Continue filing the key until it turns smoothly. Remember to remove only enough material from the flag to allow clearance for each lever. Once the key is turning smoothly, produce a duplicate onto another blank, leaving enough material to fit in the talon. A slight adjustment may be required to make the new key work properly.

30_7.4.1 Impressioning Bit and Barrel Lever Locks

Bit and barrel key locks may incorporate wards or levers. They may be impressioned or visually decoded through a viewing hole. To decode, insert the key and file the bitting corresponding with the lever closest to the sighting hole. Once aligned, the next lever is read and its gate brought to the fence. This procedure is continued until all levers are aligned with the stump.

30_7.5 Impressioning Medium and High-Security Lever Locks

Medium and high-security lever locks are impressioned differently than antique, cupboard, and cabinet locks. In part, this is because the number, configuration, tolerance, and placement of levers is altered, especially in safe and vault locks. In theory, there is no difference in impressioning detainer levers (open-ended gates) and H or closed gates. Forcing the racking stump against the lever will cause one or more of them to come into contact with the stump sooner than the others. That lever will be the one that is held at shear line. There is also no difference, in theory, between serrated and standard levers or in locks with uniform and different bellies.

A number of factors affect the difficulty and ability to impression a given lock:

- **Insure that the key gets past the talon as the first cut;**
- **Rotating the key toward the locking direction will accomplish nothing;**
- **Presence of serrations or false gates;**
- **Design of the fence or stump;**
- **Type of levers (brass or steel);**
- **Type of blank (brass or steel);**
- **Method of preparation of the blank (flat top or knife-edge);**
- **Reaction of specific mechanism to impressioning;**
- **Complexity of the mechanism;**
- **Tolerances and method of construction. Stumps are often soldered or riveted and, therefore, they never fit perfectly. Levers are never exactly the same**

size;

- **The relationship of the size of the bolt stump to the size of the gate. If the stump is very close to the dimensions of the gate, the lock will be extremely difficult to impression;**
- **How well the bolt stump is fixed into the bolt. With sufficient pressure it can break, especially if soldered in position;**
- **Product knowledge, including:**
  - **Height of the levers: for example, if it is known that the lock is a Chubb 3G114, with 5 levers, then there are 1,000 differs (5 positions for each lever). Each lever would have 7 or 8 steps, depending upon age;**
  - **Number of differs;**
  - **Measurement of each step;**
- **Condition of lock and levers;**
- **Whether the door is badly fitted. This can place pressure on the bolt, causing difficulty in obtaining correct readings;**
- **Force of the door upon the bolt;**
- **Presence of grease and other contaminants.**

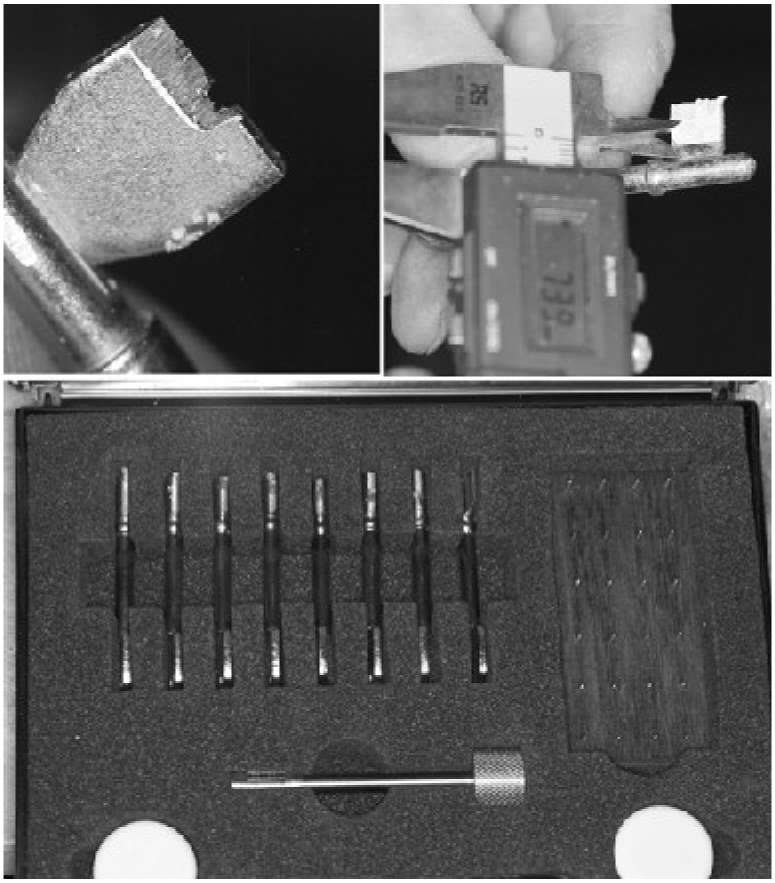
A cursory examination of the lock should first be made in order to gain an insight into the number and gating of the levers. This will provide an estimate of the design of the key and can reduce the time needed to impression.

Be certain that the correct key blank is selected. If this is not possible, then it should be modified to fit. Be sure that the width and height of the flag is correct and allows proper clearance into the keyway and free rotation. The bit should be square-cut, making sure the key fits properly into the talon.

30_7.5.1 Preparation of the Key

Marks generally appear as small nicks on the edge of the bitting surface. As in other locks, the key can be prepared to enhance marking using knife-edge or flattopping. The flattop technique requires that the blade of the key be thinned. However, care must be exercised that too much material not be removed, causing weakening. Knife-edging is done in the same manner as with pin tumbler locks: the top of the blade is brought to a thin edge by

removing material at a 45° angle. The key can be blackened using a flame or marking pen to enhance visibility of marks. Carbon deposits can be created on the blade by holding a flame below the surface of the bit.



In order to obtain the best impression of the thickness of the bolt tail, the key is turned **counterclockwise** until it makes contact with the bolt. It is then filed to the shank so that it will pass over the bolt tail, thereby touching the levers. Next, insert the key again fully into the lock, taking care not to create any scratches on the surface. Then turn the key in the direction that the bolt will withdraw. It should be pulled fully against the wall of the outer lock case, thereby causing the bellies of the levers to become engaged. Some of the levers will resist lift due to the angle of contact. Thus, more torque than normal is required.

Remove the key and examine it for marks that should reveal the number and approximate height of the levers. Note that most levers are stamped from a metal sheet and are thus slightly angled on one edge. This may provide an opportunity for inaccurate spacing indication. The key is then inserted and turned against the levers. Any resistance to rotation will cause marking, indicated by a polished area on the bit. Where such marks occur, material should be removed in small increments. This process should be continued until the key turns smoothly and without resistance (other than the normal spring bias of the levers).

Although the key produced by impressioning may open the lock, it may not in fact be cut precisely to the correct depths. This phenomenon occurs because gates can be aligned at several points along the bellies due to their design and manufacture. Thus, after an initial key has been generated, the lock should be disassembled and a proper key produced based upon standard readings. In fact, the actual cuts for the key may be one to four millimeters deeper than the impressioned cuts. High-lift levers will mark closer to the real depth than with low-lift levers.

30_7.6 Impressioning Using Plasticine

Levers with bellies that correspond to the position of their gating may be impressioned with plasticine. This material resembles clay. It can be overlaid on a milled blank key to provide a soft surface to receive impressions.

Exploded view of photographs 1, 2, 3.

When a plasticine-coated key is inserted into a lever lock having non-linear bellies, the material will mark in direct correlation, as a reverse image, to the dimension between the belly and gate. From this information, a key can be decoded and produced because the amount of lift required for each lever is displayed. Plasticine allows decoding in both rotation directions. Falle has produced a combination impressioning and decoding system that utilizes plasticine (see Section **12.2.3.4)**.

30_7.6.1 Techniques for Using Plasticine

There are two methods to use Plasticine to impression and decode a lever lock. A coated key may receive an impression of the levers at the initial point of contact (at rest), or the levers are lifted to their maximum height to take the impression. Plasticine will create a reverse image of what the key looks like. Depending upon the lock, the type of levers, and whether

impressioned in the locked or unlocked position, two different readings may be taken. Because the portion of the key that controls bolt throw has already been removed, only the bitting that contacts the levers is present. Thus, the key can be turned to its maximum height.

In order to use plasticine effectively, each mechanism must be studied and a determination made as to which technique provides the most information. Some lever packs will always contain one particular lever that might have a special characteristic. For example, a lever may be thicker than all others, or it might not mark at all. Careful research will result in a lock being impressioned using a single blank. In other cases, data will indicate that a certain lock cannot be impressioned.

30_7.7 Self-Impressioning Key System for Lever Locks

Falle has developed a self-impressioning system for lever locks that employs a specially designed key with a moveable pin for each lever. Each of the pins is set in a nylon busing that provides sufficient resistance so as to allow movement only when forced against an immovable lever that is not aligned with a gate. The system, in theory, resembles a shim pick-impressioning tool for axial pin tumbler locks, wherein the moveable pins replace the tynes.

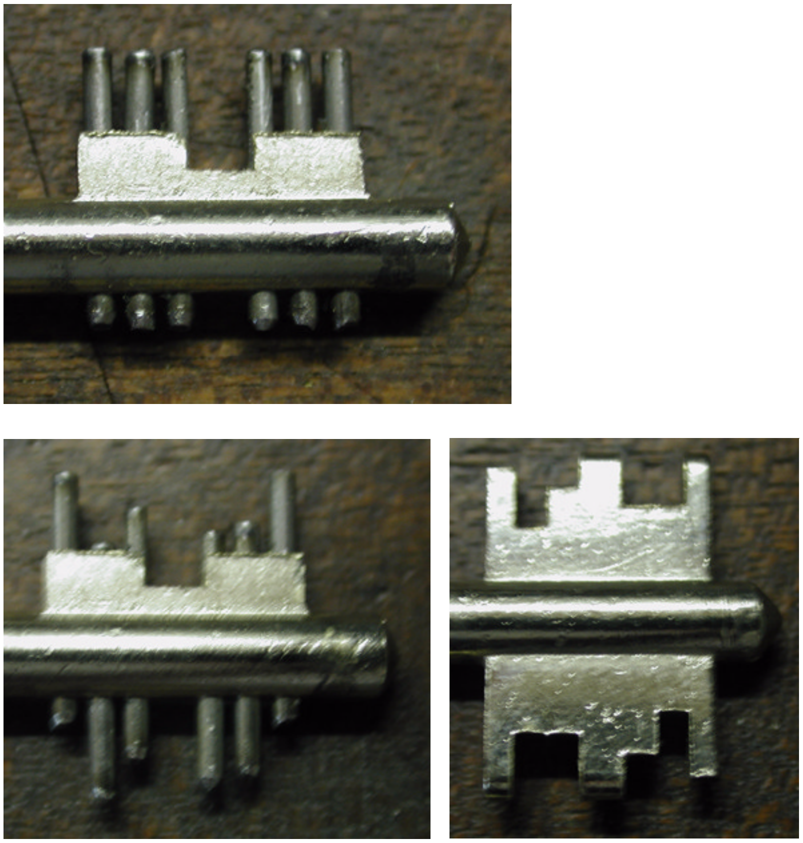


Figure LSS+3003 John Falle has developed an extremely simple impressioning system that works with virtually every European lever lock. The system is silent and leaves no trace, and can allow a lock to be opened in less than a minute. Shown is a "blank" key, having all moveable pegs set to a level position. Upon impressioning, the individual pins are moved to the proper depth based upon the depth of each belly.

30_8.0 Impressioning Disc Tumbler Locks

Disc tumbler or wafer locks are impressioned based upon similar principles for pin tumbler locks. As discussed in **Chapter 31**, these locks may also be decoded and include special high-security mechanisms such as AVA (Chubb) and Abloy. Steel keys are utilized, allowing extremely heavy torque to be applied.

30_8.1 Summary of Procedural Steps for Disc and Wafer Impressioning

- **Consider decoding in conjunction with impressioning;**
- **Be certain that the blank fits and indexes properly**

within the lock;

- **Prepare the blank using standard techniques, such as blading;**
- **Mark the blank for each wafer position in order to eliminate false readings;**
- **Insert the key and apply rotational torque;**
- **While applying torque and vertical pressure, lift the front, then the rear of the key to cause marking. Several cycles of this movement may be required;**
- **Do not apply too much torque once the key is inserted. Excessive force can damage the wafers, key, and die-casting.**

Locks are impressioned in the same fashion as the pin tumbler, although the method of applying torque must be slightly modified due to the cast metal construction. It is recommended that the pullout holding tool and techniques described in an earlier section **not be used** because of the potential deformation and damage that may be caused to the discs. Due to their construction, less torque is applied during the impressioning process.

- **Care must be exercised in the interpretation of marks because of their fragility. Generally, a high intensity light must be used to create a glare in order to enhance their readability;**
- **Marks will generally appear as straight lines, based upon the outline of the wafers;**
- **Make cuts with a Pippin file, using a forward motion;**
- **Do not rotate the plug to an unlocked position until the key fits properly. When the plug does turn, mark the key to insure a proper fit if there is any binding. If the plug is rotated to an open state, it will lock again, requiring disassembly or a repetition of the process;**
- **Forcing the plug to rotate before the key fits correctly can distort the corners of wafers. If the plug is then turned in the opposite direction, the key may not work properly;**
- **Be very careful not to bend the discs through the application of excessive torque.**

30_8.2 Differences in Marking

The marks produced from discs or wafers may appear slightly different than those made by pin tumblers or levers and are in part dependent upon the juncture point discussed above. Marks can look like small dots on the edge of the blade, or a straight line or band across the width of the bitting surface.

30_9.0 Impressioning Pin Tumbler Locks

Impressioning pin tumbler locks is covered extensively in Sections **1-5**, of this chapter. Only a brief overview of the procedure is provided here.

- **Prepare the blank key in order to make the bitting surface more conducive to impressioning;**
- **Modify the key to allow for vertical movement, if necessary, by milling. Take care not to weaken the key;**
- **Insert the key into the lock;**
- **Be certain that the key is indexed properly in the keyway;**
- **Apply sufficient torque to bind the pins;**
- **Move the key vertically in both a downward and upward motion, causing marking of the entire length of the blade;**
- **Repeat the bind-lift cycle several times before each removal of the key, to interpret marks;**
- **Once a working key is produced, duplicate it. Do not give a bladed key to a third party unless part of a covert entry team.**

30_10.0 Impressioning Sidebar Locks

Sidebar locks can utilize both traditional and secondary locking mechanisms that can make impressioning difficult or impossible. Sidebar technology is employed in pin tumbler, wafer, disc, and magnetic devices. The most popular of these are the original Briggs and Stratton automotive lock and the Medeco series of cam and pin tumbler devices.

The difficulty in impressioning any sidebar mechanism results from the inability to bind the active locking components in order to generate markings relative to their position at shear line. In the traditional sidebar lock, the shear line is secondary. There is no **direct** mechanical correlation between the position of the pins and the ability to turn the plug. In the Briggs and Stratton lock, for example, the application of torque to the plug will have no effect. The sidebar is designed to catch on the lock body unless all wafers are fully aligned. Thus, no significant markings can be obtained through traditional binding techniques.

30_10.1 Impressioning Briggs and Stratton Sidebar Locks

The sidebar lock used in all General Motors automobiles can be easily decoded as described in **Chapter 31**. Although some locksmiths claim to be able to impression them within ten minutes, the task is by no means simple or assured of success. Some of these locks can be impressioned by obtaining marks indirectly from the contact of the sidebar to the individual wafer. Pressure is exerted on the side of each wafer that then makes contact with the sidebar.

Theoretically, it requires almost the same procedure that is involved in impressioning lever locks. The “gate” or V cut that appears in one of five vertical positions on the wafer must be aligned to allow the “fence” or protruding portion of the sidebar to enter. If pressure is exerted on the wafer in the direction of the sidebar, a slight indication of the contact resistance may be registered on the key as it tries to force the wafer into the sidebar. The process is aided because these cylinders are cast and thus do not maintain close tolerances.

General Motors has a 0.5 depth-cut tolerance; thus a “1.5” cut will operate for both a “1”(.248”) and “2” (.223”) depth; a “3.5” for a “2”,”3”(.198”) and “4” (.173”) cut; and a “4.5” for a “4” and “5”(.148”) cut. These tolerances allow keys to work in the same fashion as the old tryout keys, described elsewhere in this text. To impression these locks, test depths of .235”, .185”, and .160” will work for all depth cuts. All cuts should initially be filed to a 1.5 depth. Turn the blank in the lock about 20 times to cause contact between the sidebar and the wafers. If a mark is visible, file to a depth of 3.5. If there is still a mark after repeating the insertion process, file to a 4.5 depth.

Generally, marks will appear on the top or on the corner edge of the key blade. If the mark is on either side of the wafer position or does not run all the way across the bitting surface, more material should be removed. The marks may appear as a shiny spot or dot. These locks can also be drilled with a #60 bit immediately above the protruding surface of the sidebar. A wire is inserted to place pressure against the bar. The tumblers are then individually picked until each gate locks into the protruding V cut of the sidebar. To read the tumblers after picking, use the R&D tool described in **Chapter 31**.

30_10.2 Impressioning Medeco Locks

Medeco pin tumbler locks can be impressioned in the same fashion as other pin tumbler mechanisms insofar as the **length** of the pin-stack and determination of shear line. Impressioning will not provide information as to the rotational position of the pin. This problem can often be overcome after a key has been produced with the proper depth cuts through the following procedure:

- **Fully insert the key;**
- **Apply light torque in a clockwise direction;**
- **With a small rubber mallet, repeatedly and lightly strike the face of the lock, causing vibration;**
- **Continue this process of releasing and reapplying tension until all of the pins find their proper orientation. The process may take up to twenty minutes.**

Be certain that the valleys are wide enough to allow the chisel point of the pin to rest in a flat spot rather than on a ramp. This is called butterflying and creates a left, right, and central angle for each cut.

Once the lock is opened and the plug rotated, a decoder must be utilized to determine the proper angle of rotation for each pin. See **Chapter 31** for a detailed discussion of decoding these locks.

30_10.3 Impressioning Axial Pin Tumbler Locks

Impressioning tubular locks take two basic forms: use of picking/decoding tools and the more traditional physical marking of a key. The decoding tools that are discussed in **Chapter 29**

actually impression **and** decode the lock. The picking/decoding tools can be likened to a reuseable foil system: the shims will move to the depth where no further resistance is encountered from the pin. Although no marking occurs when using these devices, the shim indicates tumbler contact through its movement.

To properly utilize these tools, torque is applied to the plug and then the pick tool is pumped. Torque is then released and the process repeated until all tumblers are aligned and no more movement of the shims is noted. At this point, the lock will open; the tool may then be decoded and a key cut by code.

30_11.1 Conventional Impressioning of Tubular Locks

Because of the orientation of the pins in comparison to standard pin locks, impressioning axial pin tumbler locks is accomplished in a slightly different fashion. The total number of pins is not relevant, although their age, condition, and quality should be considered. Some axial locks will not impression. Impressioning is preferred over picking primarily when:

- **Dead pins and security tumblers are employed;**
- **The lock is affixed so tightly that the application of sufficient tension would be impossible;**
- **The proper pick and tension tools are not available;**
- **Ball bearings or security shrouds prevent the entry of a pick;**
- **The production of a key is required.**

30_11.1.1 Tools

Required tools for impressioning include **brass blanks, holding tool**, and a **file** with a handle. A tool for firmly grasping the key must be utilized. One can be fashioned using an 8" pair of vice grips, combined with a small dent puller and slam hammer. The tool must clamp onto the body of the key, not just the head. The linkage between the head and key is not strong enough to withstand the torque that must be applied to the center of the plug in order to affect all pins. Commercial tools are available for this purpose, such as the MT-1, manufactured by Pro-Lock. A mallet and rod may also be utilized to apply torque to the key. In such case, a thin rod is inserted through the bow as described earlier in this chapter.

30_11.2 Twelve Steps to Impressioning Axial Locks

The following steps are required to successfully impression most axial pin tumbler locks:

- **Remove the protruding key guide slot from the top of the barrel. This will allow the withdrawal of the key at any position of rotation;**

- **Test each tumbler position for spring tension, the presence of security tumblers, and heavy springs. These devices will mark differently and can give false readings;**

- **Examine the keyway for dead pins and note their location. A slot must be cut into the tip of the key using a narrow warding file. These pins are simple to identify; they produce a perfect impression mark;**

- **Chamfer or file, at a 45º angle, the front of the key completely around its circumference. Do not make the bitting surface a knife-edge. There must be some flat portion remaining. The reason for creating a 45º angle is to catch the edge of each tumbler during the impressioning process. Without such an angle, the marking can be very obscure and difficult to read;**

- **Insert the prepared blank fully into the lock, then withdraw it less than 1 mm. If the key is extracted too far, top pins may bind. This makes valid readings impossible to obtain. Some craftsman make cuts to the first depth for each tumbler position prior to starting the process;**

- **Apply torque and exert forward pressure on the key;**

- **Initiate a series of rocking or bumping movements with torque applied. Tap the key with the head of a plastic screwdriver, or if using a modified dent**

puller, slam the blank into the lock. Aggressive movement is not required and in fact may damage the head of the key;

- **Release the torque for each reading (sample) taken and repeat the above process;**

- **Stop filing when there are no significant marks;**

- **Rotate the plug 20° and tap the key with a hammer to positively seat the pins in case they were cut too shallow. If too deep, file the entire tip of the key. This will then raise all of the cuts;**

- **Marks will appear as digs or moon-shaped nicks. They are caused by contact with the sharp edges of flat-topped pins. Use a warding or Pippin file, taking care not to remove too much material. Widen each cut slightly. Keep the file perpendicular to the key when filing;**

Throughout the impressioning process, the key will never stop marking. Real impressioning marks will appear as solid and quite different from marginal or false marks. The major problem encountered during impressioning is the determination of whether marks resulted from a strong spring or from the position of dead pins. In order to avoid this difficulty always use brass blanks, never steel.

30_12.0 Pressure-Responsive Material Impressioning Systems

Conventional impressioning techniques rely upon the production of extremely minute and subtle depressions or displacement of material on the bitting surface of a key blank, obtained through a series of samples of the position of active locking components. Material is removed from the key in small increments for each pin, wafer, or lever until all depth positions correspond to shear line.

There are several drawbacks to conventional impressioning techniques. These include:

- **Difficulty in seeing marks;**
- **Creation of artifacts and false marking;**
- **False interpretation of marks;**
- **Requirement to have specific blanks for a keyway;**
- **Time required producing a key.**

More sophisticated techniques for impressioning and decoding have been developed by Martin, Falle, Bates, Gruber and others. These can make the process faster and simpler and often eliminate the requirement of blanks for specific keyways. Once the theory of conventional impressioning is thoroughly understood, these advanced techniques can easily be mastered and appreciated.

Although there are many similar systems, the most popular utilize **pressure-responsive materials** whose consistency or density is altered during impressioning, based upon the relative position of the active locking component. All of these techniques eliminate the necessity of manually removing material from the key; it is inherent in the process.

In one system developed by Martin, soft lead replaces the bitting surface of the key, enhancing visibility of the marks. As discussed below, material must be physically removed when using this system. Other systems use metal foil, plastic or cellophane tape, plasticine, wax, or wood.

Axial pin tumbler locks rely upon a similar theory, discussed earlier in this chapter. Gruber developed and patented a tool that used moveable shims that were the forerunner to foil. Their position would be displaced or moved precisely correlating to the depth of the pin in relation to shear line. The only significant difference between the Gruber and Falle or Martin system is the ability to reset or reuse the pressure-responsive material. Depending upon the technique, special blanks, dies, or keys are required to hold or retain the impressioning materials.

30_12.1 Theory: Impressioning with Pressure-Responsive Materials

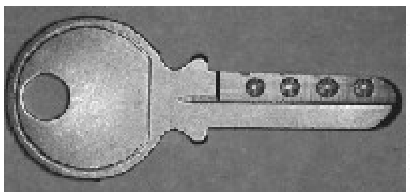
To understand advanced techniques, we must consider what happens during conventional impressioning: **a key is moved vertically inside the lock after the active locking components are bound.** Assuming the pins, levers, or discs are not at shear line, a depression is created upon the bitting surface corresponding to

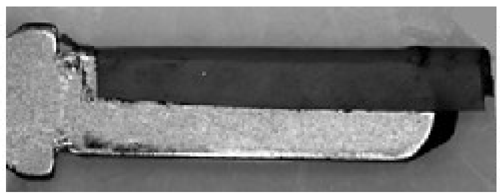
the distance of vertical movement of the key and the theoretical corresponding displacement of bitting material. The key is filed, removing material equal to one or more depth cuts at that point where such minute depressions occur. Filing continues until there are no more depressions, at which point the lock will open.

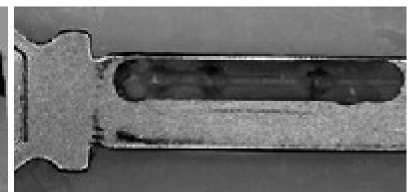
Now consider a system that **automatically** displaces bitting material whenever a depression occurs. In fact, that is exactly what happens whenever foil and other pressure- responsive materials are employed. Special keys or dies are covered or treated with such materials. The treated key is inserted into the lock and torque is applied, generally with a separate tool. As the key is moved vertically, the displacement of material (which causes marks in conventional procedures) permanently depresses the foil or other mechanism. The material will retain the depressions throughout the process.

Repetition of the bind-lift-displace cycle is continued until a key having depressions corresponding to the position of each active locking component is achieved. At this point, the lock will open. This process can take less than thirty seconds in some dimple locks. It is silent, will not damage the lock, and has the advantage of yielding a key that can be decoded and duplicated.

The bitting surface of a key that is forced against an immovable pin cannot occupy the same space at the same time; the foil or other pressure-responsive material must yield. To produce a key, the process simply requires that the correct amount of material be displaced for each tumbler position. Once a pin reaches shear line, it does not present an obstruction to the foil, and thus, no further displacement will occur.

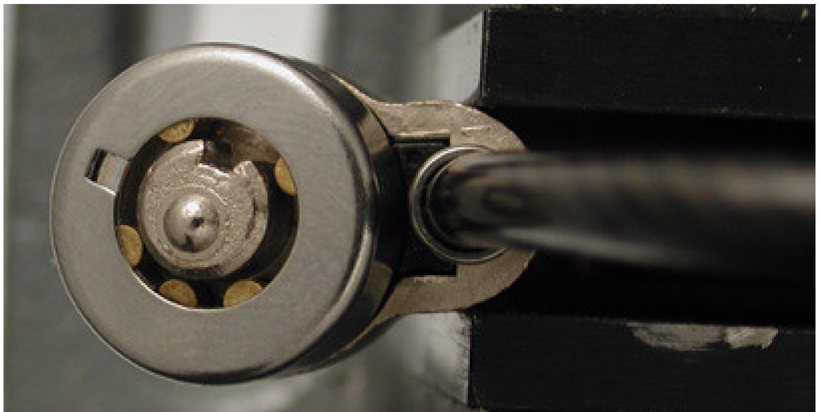






Many pressure-responsive materials have been successfully utilized. Falle uses .3 mm adhesive-backed foil; Mark Bates utilizes either wax or plastic tape. Others have even used wooden popsicle sticks soaked in alcohol until softened to accomplish the same result. The selected material must:

- **Be capable of depression or displacement with slight force while maintaining its altered shape;**
- **Fit into the keyway;**
- **Not leave a residue that would adversely affect the operation of the lock;**

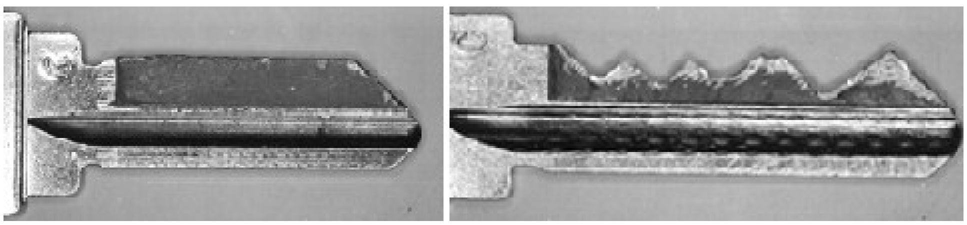


- **Provide good resolution, meaning that the material must be displaced in close correlation to the size and shape of the pin, lever, or wafer.**

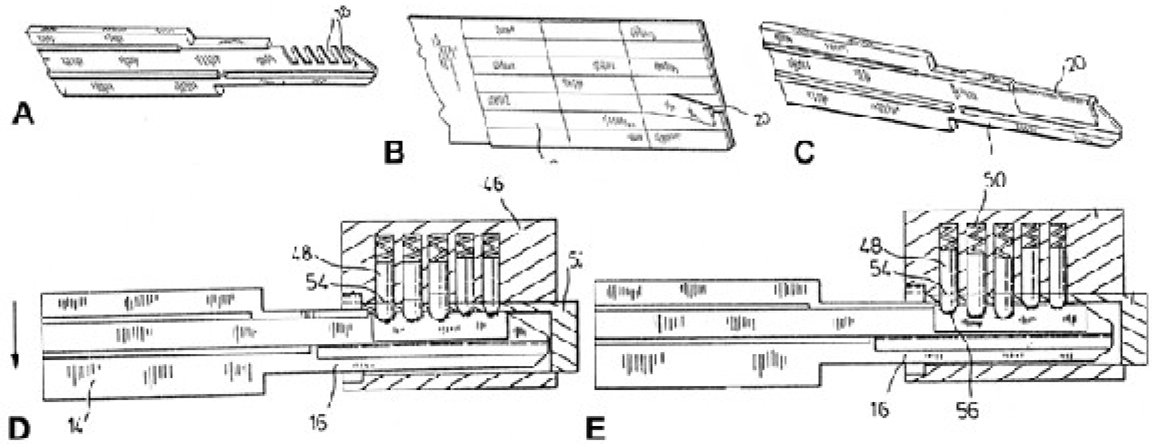
30_12.2 Description and Use of Different Systems

The Martin composite blank, the Bates plastic tape system, and the Falle foil systems are described here. See **Chapter 31** for a discussion of the patented electronic pressure- sensitive system for decoding pin tumbler locks developed by the author.

A variation of this system utilizes the end of a plastic pen, such as produced by Papermate, to impression small format axial pin tumbler locks, such as used on computer locks. The inner diameter of the keyway, as shown, is almost exactly the outside diameter of the pen. To open this the lock, the end of the pen is inserted as shown, and pressed against the tumblers. Torque is applied, then forward pressure, causing deformation of the plastic to occur in relation to the length of each pin below shear line. The process is repeated, similar to that found in conventional impressioning technique, until each pin is resting at shear line, and compression of the plastic, equivalent to the length of each pin, has occurred. The reader is directed to the sections on the Falle foil impressioning systems for further insight into how this process works. The lock that is shown is produced by Kensington, and is perhaps the most popular in the industry for securing laptops. The lock can be opened within a few seconds, with essentially no skill level, using a ball point pen costing less than one dollar. In the photograph, the pins are shown in a picked state. In the opinion of the author, these locks are not secure and should not be relied upon for any level of security against theft.



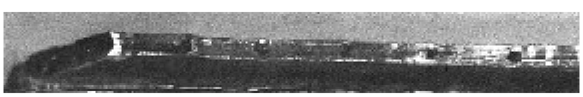
30_12.2.1 Martin Composite Blank Impressioning System



30_12.2.1.1 Introduction

Martin received two patents for his impressioning systems that were described earlier. In one system, a composite key was produced with the bitting surface replaced with soft lead. This

material makes impressioning extremely simple to accomplish by enhancing the marks produced by wafers and tumblers. Composite keys can be easily constructed by soldering a lead insert onto the blank key that has first been filed down to the wards. No special tools are required for impressioning other than a file, a plastic mallet, screwdriver, or other object to tap the top and bottom of the key.



This system was never a commercial success although it works well, requires little skill, and is easily learned. It has the advantage of producing extremely readable impression marks. Standard impressioning procedure can be followed; however, a special holding tool for the key is **not** recommended or necessary, especially for insertion and removal. The use of such tools may in fact damage the blank.

To impression a wafer or pin tumbler lock using the lead composite key, the following procedure is recommended:

- **Insert the composite blank gently into the lock using light finger pressure. Reduce the pressure if tumbler resistance to the lead portion of the key is detected. Move the key from left to right and in some cases up and down until it enters easily. The lock can be cleaned with WD-40 to lessen friction;**

- **Great care must be taken when inserting the blank for the first time. Tumblers will tend to gouge or plough their own particular pathway along the top of the lead insert. To avoid dents in the metal, proceed slowly. Subsequent insertions will be faster and smoother because the tumblers will follow the original path;**
- **The tang of a file may be utilized to apply tension by inserting it through the hole in the head of the key;**
- **Move or rock the key up and down at least twice for each of four separate orientations (up right, down right, up left, and down left). The author prefers tapping both the top and bottom of the bow in each of the four orientations once tension is applied;**
- **Release the tension for each of the four samples;**
- **Wiggle the key to the left and right to loosen the tumblers from the lead and then gently withdraw from the lock. If "drag marks" occur along the length of the blank, clean the lock with WD-40. File to the next tumbler depth where marks appear;**
- **Reinsert the key;**
- **Repeat the bind-lift-tap sequence;**
- **The use of vice grips or other holding tool to control tension and lift can produce much deeper marks than the file or metal rod and will sometimes be necessary. However, such tools must not be clamped onto the key while it is being inserted or withdrawn, as it will be overbalanced. This can greatly reduce the feel of insertion resistance, potentially damaging or distorting the lead.**

30_12.2.1.2 Impressioning Wafer Tumbler and Flat-Bottomed Pin Tumbler Locks

Wafer tumbler “dig” marks appear as channels across the lead blade of the key. Wafers and flat-bottomed pins do not leave false marks, because their total spring and tumbler pressure is distributed over a relatively large area of lead. All marks may safely be filed until they disappear; never file any deeper.

Remember, a tumbler will "dig" to its proper depth and then stop. The real job of the craftsman is to interpret marks, remove lead from around the mark, and shape the valleys.

30_12.2.1.3 Impressioning Round and Pointed Pin Tumbler Locks

Round and pointed pin tumblers concentrate their total pressure onto a relatively small area of lead. This can cause light (false) marks even when the tumblers are not digging. To impression round and pointed pin tumbler locks, follow the same procedure as for wafer and flat-bottomed pin tumblers, with the below noted exception:

- **File only the deep (deepest) tumbler marks;**
- **Never file a light (false) mark until after the lock has opened;**
- **If there are only two or three equally light marks on a blank, do not cut;**
- **Obtain added samples until one tumbler produces a deeper cut. Occasionally it will be necessary to take several samples in this manner to produce reliable readings. When this occurs, use vice grips to apply tension and move the key vertically in all four planes.**

The recommended sequence is to:

- **Insert impressioning blank;**
- **Clamp vice grips to the blank;**
- **Complete the vertical movement of the key;**
- **Remove vice grips or holding tool from the blank;**
- **Withdraw the blank to remove bitting material;**
- **Repeat the process until all depths are determined.**

30_12.2.1.4 General Precautions and Comments

- **Although in most instances more than one tumbler will mark, this is not always true. File only those tumblers that produce a marking;**
- **It is normal for a tumbler to stop digging (will create false marks for a few samples) and then start**

digging again;
- **Learn to distinguish true and false marks. The distinction is quite simple: a true mark is deep; a false mark is not;**
- **Take enough samples to obtain good marking.**

30_12.2.1.5 Filing and Shaping the Key

The following guidelines apply to the removal of bitting material from the key:

- **The area under each tumbler must be wide, centered, and level;**
- **Do not allow unnecessary ramps to form on the bitting surface;**
- **Use a 1/8″ wide warding file for large pin tumbler locks and a 3/32″ file for wafer and small pin mechanisms;**
- **Do not use a round file to make cuts. Because of the softness of the material, it is important to create as few ramps as possible when shaping the key. Since concave ramps present more of an obstacle to pins than do straight angled ramps, a round file should not be used;**
- **A flat file will create fewer, lower, straighter and more gradual ramps than a round file. It is easier to observe dig marks on a flat surface than one that is rounded;**
- **Use the thickness of the file to make the starting cuts on all but the last tumbler position on the key;**
- **Slope the ramps to provide for smooth operation while taking care not to cut into adjacent depths;**
- **Prevent unnecessary or extra cuts from forming.**

30_12.2.1.6 Inserting the Impressioning Blank

Although a brass key can be forcibly inserted or removed without damage, such action will distort the soft composite blank because of the inherent resistance of the lead. Any tension on a tumbler during insertion will create resistance to movement, causing the tumblers to dig into the lead, with potential distortions as the result. In this event, the blank must be withdrawn and the dent

or distortion removed and smoothed before proceeding further. To insert the blank without causing this problem, no torque can be applied to any tumbler.

30_12.2.1.7 Drag Marks

Drag marks can occur in three instances:

- **Whenever the blank is carelessly withdrawn from the lock without removing the tension on the tumblers;**
- **Lubrication is required;**
- **Vice grips (which disguise tumbler resistance) are clamped to the blank.**
